60th Annual Meeting

& ToxExpo • March 14–18, 2021

ORLANDO, FLORIDA

Important Dates and Deadlines:

- **May 15, 2020:** Scientific Session/CE Course Proposal Submission Deadline
- **October 9, 2020:** SOT Awards Nomination and Application Deadline
- **October 16, 2020:** 2021 Abstract Submission Deadline
- **October 16, 2020:** Undergraduate Diversity Awards, Perry J. Gehring Diversity Student Travel Award, and Other SOT Undergraduate Awards Deadline

www.toxicology.org/2021

Preface

This issue is devoted to the abstracts of the presentations for the Continuing Education courses and Scientific Sessions of the 59th Annual Meeting of the Society of Toxicology, held at the Anaheim Convention Center, Anaheim, California, March 15–19, 2020.

An alphabetical Author Index, cross-referencing the corresponding abstract number(s), begins on page 542.

The issue also contains a Keyword Index (by subject or chemical) of all the presentations, beginning on page 580.

The abstracts are reproduced as accepted by the Scientific Program Committee of the Society of Toxicology and appear in numerical sequence. If a number is missing in the numerical sequence, the abstract assigned to the missing number was withdrawn by the author(s). Author names that are underlined in the author block indicate that the author is a member of the Society of Toxicology. For example, J. Smith. SOT members may sponsor abstracts that do not include an author with SOT membership. Authors who are members of designated organizations could serve as the sponsor of the abstract if an SOT member was not a co-author; these types of sponsorships are displayed with an organization name after the sponsor name (e.g., Sponsor: A. Smith, EUROTOX).

Scientific Session Types:

- CE Continuing Education Courses
- EC Education-Career Development Sessions
- IS Informational Sessions
- PL Platform Sessions
- PS Poster Sessions
- RI Regional Interest Sessions
- R Roundtable Sessions
- S Symposium Sessions
- W Workshop Sessions

The 2020 SOT Event App and Online Planner

The Event App is available via the SOT Annual Meeting website and app marketplaces. The Event App, alongside the Online Planner available on the SOT Annual Meeting website, enables attendees to engage with organizers, exhibitors, and each other and to manage their time and maximize their experience during the Annual Meeting. ePosters also can be accessed electronically via the Event App until May 15, 2020.

To cite a 2020 SOT Annual Meeting abstract, please format as follows: *The Toxicologist*, Supplement to *Toxicological Sciences*, 174 (1), abstract #__, 2020, Title, First Author.

1001 SR01: Advances in CRISPR-Cas9 Tools and Applications for Toxicologists

C. Rockwell. *Michigan State University, East Lansing, MI.*

CRISPR-Cas-based technologies have revolutionized science by significantly decreasing the time, money, expertise, and labor required to implement gene editing. Thus, this approach is becoming routine in many laboratories as a facile method to alter the genome. And yet, CRISPR-based methodologies continue to evolve. Recent publications demonstrate that CRISPR gene editing can be expanded in new directions to widen the utility and potential applications of this technology. The first presentation in this course will provide an overview of the latest developments in CRISPR-Cas-based techniques, with a focus on new Cas9 variants with new and expanded capabilities. The first presentation also will cover the new field of RNA targeting and the use of pooled CRISPR libraries with single cell transcriptomics to characterize complex phenotypes. The second presentation will focus on the use of CRISPR-Cas9-based screens from a toxicologist's perspective. Specifically, this presentation will discuss how such screens can be used to gain a detailed, mechanistic understanding of a toxicant's effect as well as the role of specific genes. Overall, this course is designed to provide an overview of the most recent advances in CRISPR-based technologies as well to provide some insight into future uses.

1002 SR02: Qualifying Biomarkers and Navigating the US FDA *Predictive Toxicology Roadmap* to Improve Decision-Making in Toxicology and Drug Safety Assessment

R. Young. *MilliporeSigma, Rockville, MD.*

This session will provide an educational opportunity for attendees interested in learning how information from adverse outcome pathways (AOPs) can be leveraged with two recent US Food and Drug Administration (US FDA) initiatives (i.e., the Biomarker Qualification: Evidentiary Framework and the Predictive Toxicology Roadmap) to improve decision-making for toxicology and human safety issues. The biomarker framework is aimed at identifying and qualifying biomarkers that, within a defined context of use, can be used reliably for specific interpretations and applications. The predictive roadmap is a call to action highlighting the need for a comprehensive strategy to assess new methods and technologies that can improve predictive capabilities, minimize the use of animals, and guide decision-making in regulatory reviews. Because firsthand industry knowledge with these regulatory initiatives may be limited, it is important that experience and learnings available to date be broadly communicated. This session will open with a discussion of ongoing efforts to use AOPs as tools to enhance our mechanistic understanding of various toxicities and to use networks of AOPs as the basis for biomarker development. An example of the genesis and application of biomarkers will be discussed in the context of efforts to develop comprehensive predictions of liver cancer in rodents, including their use in de-risking compounds that would cause cancer through rodent-specific mechanisms. From this initial presentation, session attendees will gain an increased appreciation of the importance of exploiting opportunities for mechanistic screens incorporating biomarkers to define the AOP through which a chemical may mediate effects. The session will then ask a crucial question: After identification of a potentially useful biomarker, what are the next steps needed to ensure regulatory acceptance? To address this point, the second presentation will summarize how the Biomarker Qualification: Evidentiary Framework can be used to define the steps needed to validate the linkage of a biomarker with a specific toxicity or mechanism and provide advice—including a list of dos and don'ts—on how to move efficiently through the process needed to ensure regulatory acceptance of the biomarker for its intended purpose(s). The value of this approach when interacting with regulatory agencies will be demonstrated by reviewing how an understanding of the AOP was used to support arguments that a carcinogenic response with a mutagenic test material could be ascribed to nongenotoxic mechanisms. Collectively, material presented in this session will instill a greater awareness of the value that can be realized with the recent US FDA Biomarker Qualification: Evidentiary Framework and Predictive Toxicology Roadmap initiatives. Although these initiatives were formulated by US FDA, their conceptual underpinnings are universal and applicable for focusing and guiding the dialogue on toxicology issues and concerns with other regulatory agencies, such as the US Environmental Protection Agency. Session attendees will recognize that energetic engagement between industry and regulatory scientists will contribute to the success of the vision of these initiatives and improve decision-making for toxicology, safety assessment, and risk management questions that directly affect human health.

1003 AM03: Developing Therapeutics for Ocular Indications: A 20/20 View

K. Krenzer. *Iuvo BioScience, Rush, NY.*

No longer are eye drops the only way to treat the eye; the emergence of novel therapeutic and development approaches for ocular indications has impacted how we design toxicology assessments, select species, and perform toxicity evaluations. Additionally, the structural complexity of the eye as well as the unique aspects of ocular dose-administration routes require continued refinements of ocular evaluation techniques and assessment strategies. The goal of this course is to provide toxicologists with a broad overview of highly specialized ocular anatomy, current ophthalmic diagnostic techniques, evolving histopathological assessment strategies, and thought-provoking ocular drug development strategies, including case studies. The first speaker will open the session with an detailed overview of ocular anatomy complexity, focusing on unique features of the eye and critical anatomical and physiological features that may influence or impede a drug's efficacy and safety in human patients. The speaker also will discuss novel routes of drug administration in ocular drug development. The second presentation will tune in to gold-standard, in-life ophthalmic diagnostic techniques with selected case examples showing how modern ocular diagnostic equipment can be used to prove multifactorial questions. This presentation also will touch upon recent efforts at harmonization of ocular finding nomenclature and clinical record-keeping lexicon in preparation for SEND (Standard for Exchange of Nonclinical Data) requirements dictating reporting of ocular toxicology studies. The third talk will focus on evolving strategies for histopathological assessment of ocular tissues, which will include key points to consider when processing the eye to ensure a thorough examination of key structures of the globe as well as the effect of factors such as the route of administration and the formulation or character of the therapeutic candidate on effective examination of the eye. The last presentation will highlight unique nonclinical safety challenges and considerations during ocular drug development using case studies to push our assumptions of what is the best way to evaluate the safety of ophthalmic therapeutics.

1004 AM04: Introduction to Open-Access Computational Toxicology Tools

A. Karmaus. *Integrated Laboratory Systems Inc., Durham, NC.*

Computational toxicology is rapidly accelerating our ability to develop methods for predicting chemical properties and chemical-mediated effects, both in the environmental chemical space and in the area of drug development. With frequently updated tools and approaches, overwhelming feedback suggests that more training is needed to help all toxicologists understand the fundamental approaches, use available tools and databases, and interpret outputs. This CE course is designed to offer an introductory-level foundation for leveraging some widely accepted approaches and demonstrate how to use open-source tools and resources to make use of these methods. Course participants across all sectors, ranging from students to career toxicologists, should walk away with the confidence to use the resources presented for computationally characterizing and predicting chemical-elicited toxicity. In addition to gaining familiarity with basic computational toxicology concepts, participants will gain insight into what makes an approach useful for research projects versus which are ready for potential regulatory applications. The first speaker will help lay a foundation for how chemicals are "interpreted" computationally, explaining how chemical structures are leveraged for subsequent analyses (i.e., fingerprinting and its use for read-across). Building on these concepts, the second speaker will provide a thorough example of how to use the US Environmental Protection Agency (US EPA) CompTox Chemicals Dashboard, which provides data for nearly 900,000 chemicals and drugs. Attendees will learn how to assess the confidence in available data, as well as learn how to use the tools available in the dashboard for predicting chemical toxicity and download pertinent data, including mechanistic information, exposure data, animal toxicity doses, and much more. The third presentation will provide a demonstration to empower course attendees in using the Integrated Chemical Environment (ICE), an interactive tool that contains *in vitro* to *in vivo* extrapolation workflows that users can leverage to conduct analyses themselves, as well as provides curated *in vivo* and *in vitro* datasets that can be used to evaluate predicted toxicology outcomes. The fourth presentation will steer the course further into the realm of biological interpretation, describing how toxicogenomics data and literature mining underlying the Comparative Toxicogenomics Database (CTD) can be utilized to computationally characterize chemical mode of action and provide insight into toxicity mechanisms. The last speaker will introduce Sysrev, a collaborative computational systematic review tool to extract pertinent data from literature, incorporating approaches such as machine learning and metadata tagging. Overall, course attendees will gain a fundamental understanding of approaches underlying the most widely used computational toxicology methods, as well as learn to use publicly available, open-source tools that apply these methods.

1005 AM05: Lung Function: It's Not Just Breathing

A. J. Gow. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

There are a variety of techniques available for assessment of the effect of toxicants upon the lung. One of the most powerful techniques available is the measurement of lung function. There have been a number of both conceptual and technical advances made in recent years in the assessment of lung function, particularly with respect to airway dynamics. However, for many toxicologists, lung function assessment is unclear and the possibilities for its use remain underutilized. The purpose of this Continuing Education course is to examine the fundamentals that underlie lung function testing and consider in what ways they can be measured and how these data can be related to toxicological outcomes. The first presentation will introduce the concept of lung function and how it has developed with newer technologies, in particular relating structure with function and how modeling can play a part in assessing this relationship. The second presentation will present an overview of lung mechanics. The physiological elements that make up the measurable units of lung function and how pressure and flow data can be used to generate models of lung function to assess toxicological outcomes will be discussed. The third presenter will describe the challenges of measuring lung function and the various approaches that are available to the investigator. The presentation will concentrate on parameters that can be extracted from different measurement techniques and how they can be utilized to gain information about the physiological elements of the lung. This information will be of critical importance to the practicing toxicologist. The fourth presenter will present on feed forward modeling of lung function and how both pathological and physiological data can be combined. He will focus on how animal scale function data can be used to understand the consequences of toxicant exposure to humans. The final presenter will provide a detailed example of how imaging data can be used to predict lung function. The focus of the presentation will be the longitudinal analysis of whole animal *in vivo* imaging data following toxicant exposure and its relationship to outcome. This technique provides a novel paradigm for assessing the continuous effect of toxicological exposure in the lung. Overall, these presentations will provide the audience with a practical understanding of lung functional data within the context of disease models as well as an understanding of how lung functional data can be used to further their own research.

1006 AM06: Modern Modeling Strategies to Address Uncertainty and Variability in Dose-Response Assessment

K. Shao. *Indiana University, Bloomington, IN.*

Quantifying dose-response relationships to evaluate the toxicity of environmental chemicals is a key step in human health risk assessment and has evolved substantially in recent years. In addtion to fundamentally developing a dose-response curve and estimating a dose level that results in a predetermined critical effect, recent advances in toxicology and modeling stategies enable dose-response assessment to more comprehensively and quantitatively address uncertainty and human variability. The purpose of this course, to be delivered by a mixed group of experts from academia, government, and industry, is to provide participants an overview of the cutting-edge modeling strategies employed in dose-response assessment to quantify uncertainty and variability. The first presentation will introduce the benchmark dose (BMD) methodology and its utilities to quantify various sources of uncertainty in dose-response modeling with a demonstration of the Bayesian BMD modeling system. The second speaker will present an overview of the principles and recent applications of probabilistic dose-response assessment approaches developed under the WHO/IPCS guidance to address uncertainty and variability in quantitative risk assessment. The third presentation will provide an overview together with case examples of Diversity Outbred (DO) mouse population-based *in vitro* systems to demonstrate a data-driven probabilistic approach to derive a chemical-specific uncertainty factor for inter-individual variability. The last speaker will introduce how to predict population distributions of toxicokinetic-relevant physiological quantities that NHANES does not measure based on the measured counterparts using the HTTK-Pop R package that incorporates population variability in high-throughput toxicokinetic modeling. Throughout the course, use of and applications to *in vitro* and high-throughput testing systems will be highlighted, including their relevance to *in vitro* to *in vivo* extrapolation (IVIVE).

1007 AM07: The Basics of *In Vitro* Xenobiotic Metabolism and Drug-Drug Interaction Investigations: Applicability to All Xenobiotics

A. Parkinson. *XPD Consulting, Shawnee, KS.*

In the current landscape of drug development and investigation of environmental chemicals, many personnel with toxicology backgrounds find themselves overseeing not only preclinical safety assessments but also *in vitro* xenobiotic metabolism and interaction studies. Therefore, the goal of this course is to provide attendees with practical perspectives from experts in the field on the approaches and techniques that are available to address the important aspects of xenobiotic metabolism. The first presentation will focus on the experimental design and interpretation of data obtained from studies of *in vitro* inhibition of cytochrome P450 (CYP) and other xenobiotic-metabolizing enzymes. In contrast, the second presentation will focus on the experimental design and interpretation of data obtained from studies of *in vitro* induction of CYP and other xenobiotic-metabolizing enzymes. The third talk will broaden considerations of xenobiotic metabolism, including assessment of the toxicological burden of reactive metabolites, and the experimental design and interpretation of data obtained from studies of *in vitro* reaction phenotyping techniques in human liver microsomes and other test systems derived from humans or toxicologically relevant species. The fourth presentation will discuss *in vitro* approaches for determining the potential for xenobiotics to be substrates or inhibitors of major transporters that are of regulatory interest and interpretation of the data obtained from these studies. The final presentation will discuss the practical implications of the *in vitro* approaches discussed and the current regulatory thinking on their applicability to all xenobiotics to which humans are exposed. The overarching objective of this course is to provide attendees with a solid foundation in commonly used methods to enable the design, execution, and interpretation of rigorous and reproducible *in vitro* xenobiotic metabolism and interaction studies that will withstand regulatory scrutiny and avoid common pitfalls. This course will benefit those whose toxicological interests are expanding to include *in vitro* xenobiotic metabolism, as well as professionals responsible for appraising or evaluating *in vitro* xenobiotic metabolism, interaction studies, and other ADME data for internal decision-making, risk assessment, or submission to various regulatory agencies.

1008 AM08: Timing is Everything: Developmental Exposure Alters the Path of Immune Cell Maturation and Function

A. Venosa. *University of Utah, Salt Lake City, UT.*

There is compelling evidence that exposure to exogenous agents at different stages of development contributes to disease later in life (and across generations), with animal models supporting this concept in reproductive, metabolic, and neurodegenerative diseases. Two major notions link prenatal and early-life exposure to increased risk of disease later in life—namely, the Barker hypothesis and the hygiene hypothesis—while epigenetic reprogramming may extend this susceptibility across future generations. The immune system represents a unique niche of cells tightly entangled with the parenchyma in every tissue, acting as pro-homeostatic sentinels equipped to mount the appropriate response upon exogenous aggression. While the linkage between developmental immunotoxicity (DIT) and susceptibility to later-life diseases is an accepted paradigm, the mechanisms by which exogenous agents impact the developing immune system and change disease susceptibility are not well established. Clinical evidence suggests that the underlying effects of these agents may be masked until triggered by a later-life event (i.e., infectious exposure or aging itself), at which point the immune response may enact a super-responsive state, favoring disease pathogenesis. Recent evidence highlights myriad variables to take into account to accurately study DIT, including the importance of evaluating the appropriate window of vulnerability; establishing whether the toxicant exerts direct and long-lasting effects on the immunological machinery or reprograms the behavior of bystander parenchymal cells; outlining which pathway each environmental agent will be affecting; and, more recently, determining sex-based outcomes to exposure. With basic and translational researchers facing the challenge of elucidating the molecular mechanisms mediating DIT, it is pivotal that regulatory agencies and industry work in unison toward implementing safety protocols that address these factors. Therefore, this Continuing Education course proposes to (1) inform the attendees on the current advances in the design and execution of DIT studies geared at developing preclinical tools to predict risk of adult-life disease; (2) provide the most recent evidence, spanning multiple phylogenetic species (nonhuman primates, rodents, and fish), of DIT across a wide array of exogenous agents; and (3) provide insights on the impact that studying DIT could provide at the regulatory level.

1009 PM09: AAV Vectors on the Move: Safety Assessment and Advancing Sciences in Gene Therapy Second-Generation Products

S. Korte. *Covance Preclinical Services GmbH, Münster, Germany.*

The field of gene therapy has matured in recent years to bring forward a potential treatment or cure for life-threatening monogenetic diseases. The first successful treatments are already available to patients in various indications, and even more are undergoing active preclinical and clinical development. This CE course aims to summarize the great achievements already established for this promising therapeutic modality, will provide insights into the specific considerations for meaningful preclinical safety assessments, and will introduce the regulatory framework, as well as looking into advancements in the field opening up new opportunities and challenges. This CE course will start with a review of the history of adeno-associated virus (AAV) vector development and give a current status of its clinical use and challenges. A number of unique considerations need to be addressed when designing a nonclinical safety assessment program for AAV gene therapies (GTs), including the off-target tissue distribution and transgene expression, persistence, and immunogenicity. Additionally, although AAVs are generally considered nonintegrating, the potential implication, if any, of a low frequency of integration is not yet well understood. Attendees will hear an overview of preclinical safety assessment strategies for AAV gene-based therapies, including dose extrapolation for first-in-human starting dose, and learn about AAV screening approaches in nonhuman primates (NHPs) and case studies of regulatory-accepted toxicity studies via the oral, IV, and subretinal routes. In addition, a case study of the biodistribution and toxicity profile of an occular AAV gene therapy administered by intravitreal injections (IVT) will be shared. The course will expand into questions on impurity profiling of the drug product and conclude with an overview of the regulatory guidelines for GTs and the sharing of regulatory experience in the field. Take advantage of the renowned group of speakers coming together in this course to share their experience in and deep insight of the field of gene therapy with safety specialists from academia and the pharmaceutical industry, as well as regulatory risk assessment experts. This course offers a rare chance to receive guidance in this emerging and promising scientific area and learn about and discuss its particular challenges.

1010 PM10: An Introduction to New Approach Methodologies (NAMs) and Understanding Their Potential to Support Regulatory Decisions

M. Krishan. *Danone North America, Louisville, CO.*

Recent shifts in the global regulatory landscape to consider the use of nonanimal testing methods have led to significant advances in the development of alternative test methods to replace, reduce, and refine animal use. The term *new approach methodologies* (NAMs) broadly describes any nonanimal technology, methodology, approach, or combination that can be used to provide information on chemical hazard and risk assessment. With new opportunities comes new challenges, such as validation of test results, understanding their applicability in different sectors and risk assessments, and global regulatory acceptance of these methods. Despite these challenges, the development, use, and acceptance of these predictive toxicology methods is on the rise. There is a wealth of knowledge and data that is being generated with NAMs; however, there are questions on when, how, and where can we use these NAMs. This CE course will provide an overview of NAMs along with case studies where they are being used or could potentially be used for regulatory risk assessment. The speakers will present on (1) chemical-biological data and analysis tools (Tox21/ToxCast) and examples where high-throughput screening (HTS) methods have been approved for use in regulatory decision-making; (2) read-across approaches and their use in regulatory risk assessment; (3) use of evidence maps and systematic reviews and case studies with a focus on application of each to regulatory risk assessment; (4) use of the adverse outcome pathway (AOP) including most well-developed examples of AOP-supported decision processes for evaluating skin sensitizing potential and a computational model to predict the likelihood of reproductive impairment based on aromatase inhibition; and (5) concepts underpinning Integrated Approaches to Testing and Assessment (IATA) and concrete examples for assessing developmental neurotoxicity (DNT) and carcinogenicity of chemicals used in a variety of sectors. Also, updates will be provided on IATA case study projects currently running at the OECD and a set of resources being developed to support IATA development, evaluation, and regulatory uptake. This course will be useful to those interested in understanding the regulatory application of NAMs.

1011 PM11: Gateway Technologies to Tomorrow's Metal Toxicological Research

W. Zheng. *Purdue University School of Health Sciences, West Lafayette, IN.*

Infotechnology and biotechnology represent two leading technological breakthroughs underpinning the future advances in medical science and human health. Big data algorithms not only offer unique advantages by the machine learning for fast processing of existing data, but more importantly, through learning, they maximize the chances of successful choices and adaptations for accurate analysis of cumulative toxicological data, prediction of flexible outcomes, and influences in policy decisions. The CRISPR technology, on the other hand, allows impeccable gene editing that has already transformed biology and genetics, lending itself to an effective, precise, and cheap method for mechanistic investigations. Applying CRISPR facilitates our understanding of the events underlying xenobiotics' cellular and molecular interactions. However, application of both artificial intelligence (AI) and CRISPR in metal toxicological studies remains in its infancy. For metal quantitation, recent advances in specific fluorescent metal-binding ligands render it feasible to trace the subcellular trafficking of interested metals through live-time cell imaging. Moreover, a variety of animal models for metal toxicity evaluations have been developed in the past several decades, ranging from *Drosophila*, *C. elegans*, and zebrafish to rodents and nonhuman primates. How to choose the right species and animal model(s) for a particular study of metal toxicity represents a new challenge. This advanced course is designed to introduce the audience with novel concepts and technologies in metal toxicological research. The first presentation will briefly review the history of metal toxicology within the context of technology advancement, followed by identifing gaps in the field and illustrating the impact of emerging technologies on the future direction of metal research. The second presentation will focus on the assessment of metals in cellular models and tissues; the speaker will showcase how fluorescent reporters, advanced imaging and spectroscopy, and genetic- and protein-based biomarkers can be used to monitor tissue and cellular distribution of metals. The third presentation will go further toward the precise mechanistic study of metal toxicities; the speaker will provide the overview of CRISPR technology and will cover procedures for investigations of metal-induced neurotoxicities. The fourth presentation will focus on the framework for choosing the most informative animal model to study modes of chemical toxicities, neurotoxic risks, and therapeutic treatment. Finally, the last presentation will introduce the concept and general practice of AI in health research, followed by integrative examples of how to use AI to interpret chemical toxicities as well as the policy regulation. Speakers will discuss these concepts and technologies with details specific to metals having particular human, environmental, and occupational health relevance, such as lead (Pb), manganese (Mn), cadmium (Cd), arsenic (As), silver (Ag), and mercury (Hg). The course will benefit those who desire a learning of advanced technologies for mechanistic interpretation and machine-assisted prediction of metal or chemical toxicities, and technical approaches in utilizing widely available CRISPR and cellular imaging technologies that can be used to support research in metal toxicology. As the course introduces concepts and techniques that are equally applicable to other fields, such as neurotoxicology, nanotoxicology, carcinogenesis, risk assessment, and occupational health, researchers engaged in these wider aspects of the toxicological sciences will benefit by attending this course and acquiring knowledge beyond metals.

1012 PM12: Harnessing the T Cell for Cancer Immunotherapy: A Course on T Cell Redirection

J. L. Lynch. *Janssen Research & Development, Spring House, PA.*

Cancer immunotherapy is an area that has been of great interest in the last few years as several new therapeutic approaches have shown encouraging results in the clinic and subsequent approvals. The normal immune system has a protective capacity against tumor cells (immunosurveillance), while tumors can employ mechanisms that can result in an insufficient supply of activated and/or antigen-specific T cells within the microenvironment (tumor evasion). To overcome this immune-evasive mechanism, T cells can be redirected and expanded within the tumor microenvironment. CD3 redirection, which leverages protein-based therapeutics to simultaneously bind CD3 on T cells and a tumor associated antigen (TAA) on tumor cells, and engineered T cell-based therapeutics to redirect T cells to TAAs are emerging as powerful ways to harness the immune system to combat malignancies.The goal of this course is to provide the investigator with an overview of T cell redirection technologies and how to design a nonclinical safety strategy to understand safety liabilities. An overview of chimeric antigen receptor (CAR) T cells, T cell receptor (TCR) T cells, CD3 bispecifics, and immune mobilizing monoclonal TCRs against cancer (ImmTac) modalities will be provided. In addition, successful nonclinical safety strategies to support first-in-human clinical trials for

these modalities will be shared. Overall, this course will provide a comprehensive overview of T cell redirection platforms, study design, and the challenges associated with these modalities.

1013 PM13: *In Vitro* Approaches to Assess the Toxicity of Inhaled Substances

A. Clippinger. *PETA International Science Consortium Ltd., London, United Kingdom.*

Inhalation is a major route of human exposure to airborne substances, and as such, there are regulatory and nonregulatory needs to assess the potential toxicity of inhaled substances. While the standard regulatory requirement is a rat inhalation toxicity test, anatomical and physiological differences between rodents and humans have led to substantial investment in the optimization of alternative approaches. These alternative approaches can be based on human mechanisms of toxicity, thus better protecting human health while reducing animal use. In this course, speakers from government, contract research organizations, academia, and NGOs, as well as method developers, will discuss progress and challenges associated with various approaches for inhalation toxicity testing. It will include an introductory overview, setting the stage for the remaining talks by discussing the currently used rat inhalation tests and how an alternative approach can be demonstrated to be a valid replacement. Other topics to be covered will be the use of cell culture systems, 3D reconstructed human tissue models, and human precision-cut lung slices, as well as the use of *in vitro* exposure devices for deposition of test chemicals. The final speaker will present a regulatory perspective on processes in place that allow for acceptance of alternative approaches for inhalation toxicity testing, highlighting a successful example. These presentations will explore the value of the air-liquid interface (ALI) for testing, advantages and limitations of different approaches, and case studies of the use of different model systems in both nonregulatory and regulatory paradigms. Overall, a course attendee should learn about the state-of-the-science of *in vitro* approaches for respiratory toxicity testing and gain insight into determining which method is most appropriate, depending on the test substance and purpose of the study. This course is aimed at scientists at all levels from industry, government, and academia.

1014 PM14: The Male Reproductive Tract: Development, Toxicology, and Pathology

V. Sutherland. *NIEHS/NTP, Research Triangle Park, NC.*

The male reproductive system develops *in utero*—in rats during mid-gestation and in humans during the second month of pregnancy—but does not fully mature until puberty. Exposure to xenobiotics (e.g., diethylstilbestrol and phthalate exposure) during any stage, particularly during development and maturation, can adversely affect a male's reproductive potential and play a significant role in development of a diseased state. Understanding what normally happens at these critical stages of development can lend clues to determine when an exposure has happened, what tissues are affected, and if functional capabilities will be impacted. Defining potential effects is routinely performed with guideline reproductive and developmental experiments and in academia with focused studies; however, these assessments do not always include histopathology evaluations, and if they do, the rigor needed for select tissues may not be utilized. Inclusion of histopathology, especially during select stages, may help identify a pattern of toxicities, subtle effects of an endocrine-disrupting chemical, or lesions that can lead to future reproductive issues (e.g., infertility). This additional data can expand our capabilities in characterizing potential modes of action that result in functional changes. Thus, a field that did not routinely assess tissues in more than a functional manner is now exploring the utility of pathology evaluations at stages not previously studied (e.g., juvenile assessment of cell populations in the testes) and appreciating that these tools can assist in recognizing patterns of toxicity. Therefore, a full toxicological and histopathology assessment of the male reproductive tract may provide additional information on functional effects, assist in determining which part of the system was targeted and how to mitigate concerns, and, for select issues, provide an early read on potential problems. This course will cover development and maturation of the male reproductive tract, explaining impacts on function at different time periods (*in utero*, juvenile, and adult) and addressing the potential value of histopathology at both the juvenile and the adult stages. Case studies will be used to highlight the toxicological significance of the effects of xenobiotics on male reproductive system toxicity. Understanding patterns of toxicity (e.g., effects in organ weight linked with findings in other tissues or pathology findings observed in a young animal correlating to outcomes in an adult) and utilizing some of the newer techniques and protocols (e.g., fetal testis explants, biomarkers) will not only provide a better understanding of what endpoints are affected but also may provide us with the tools to design better studies and correlate findings at earlier stages with long-term functional effects. To this end, four speakers, each a world-recognized expert in male anatomy, development, reproduction, and/or pathology, will discuss functional assessments of the male reproductive tract and address the utility of pathology in male reproductive and development evaluations.

1015 Can We Predict and Manage Immune-Related Adverse Events Associated with Cancer Immunotherapy?

Y. Yoshioka. *Osaka University, Osaka, Japan.*

Cancer is a major disease burden worldwide, with considerable impact on society. For several years, there has been intense excitement concerning immunotherapy against cancer. Immunotherapy takes many forms in cancer treatment, including the adoptive transfer of *ex vivo* activated T cells (T cell adoptive immunotherapy) and administration of antibodies that block the so-called immune checkpoint pathways. The recent success of immune checkpoint inhibitors, such as monoclonal antibody blocking of cytotoxic T lymphocyte-associated protein 4 (CTLA-4) and programmed cell death protein 1 (PD1) or its ligand, programmed cell death ligand 1 (PD-L1), has boosted the development of cancer immunotherapy. The Nobel Prize in Medicine 2018 was awarded to Dr. James P. Allison and Dr. Tasuku Honjo for their work on immune checkpoint inhibitors as a new cancer therapy. Although remarkable clinical responses have been observed in cancer immunotherapy, these therapies often have inflammatory side effects leading to immune-related adverse events (irAEs). Immune-related adverse events have occurred with a high frequency in many cases. Although any organ system can be affected, irAEs most commonly involve the gastrointestinal tract, endocrine glands, skin, and liver. The wide range of irAEs associated with cancer immunotherapy can complicate this effective therapy and limit its use in patients with cancer. While the adverse events were controllable in some cases, severely deleterious outcomes (including death) have been reported. The mechanism of toxicity may vary according to the immunotherapy, although the precise pathophysiology underlying irAEs is unknown. Understanding the mechanisms of irAEs is needed to predict and manage these toxicities, which would include identification and validation of reliable surrogate biomarkers. The goal of this Symposium is to present experts who will speak on key topics related to irAEs associated with cancer immunotherapy. The specific topics that will be covered include (1) mode of action of checkpoint inhibitors, immunologic biomarkers, and clinical responses; (2) the potential of autoantibodies as biomarkers for predicting risk to develop autoimmune diseases following treatment with immune checkpoint inhibitors; (3) management of irAEs induced by T cell adoptive immunotherapy; and (4) clinical success of immune checkpoint inhibitors that received market authorization—and current challenges to maximize the efficacy of immune checkpoint blockade and combination therapies. This Symposium containing cutting-edge information will be of interest to many SOT members, including those from the Immunotoxicology, Regulatory and Safety Evaluation, and Clinical and Translational Toxicology Specialty Sections, as well as to other participants from academia, industry, and government regulatory/safety agencies. This Symposium represents another in the continuing annual collaborative sessions co-chaired/organized by the Japanese Society of Immunotoxicology (JSIT) and the SOT Immunotoxicology Specialty Section.

1016 Mode of Action of Checkpoint Inhibitors, Immunologic Biomarkers, and Clinical Responses

H. Haggerty. *Bristol-Myers Squibb Company, New Brunswick, NJ.*

Although the immune system plays a critical role in controlling and eradicating cancer, cancer has developed multiple mechanisms to suppress the antitumor immune responses and evade its wrath, including production of inhibitory cytokines, recruitment of immunosuppressive immune cells, and upregulation of coinhibitory receptors known as immune checkpoints. Recent approvals of monoclonal antibodies targeting two immune checkpoints, cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) and the programmed cell death protein 1 pathway (PD-1/PD-L1), as well as encouraging data emerging from clinical trials, have demonstrated durable responses against a wide array of tumor types and are transforming the way cancer is being treated. However, releasing the breaks of the immune system also can lead to an immune response that is directed not at the cancer but at normal tissue, leading to immune-related adverse events. This lecture will discuss the biological rationale and clinical experience with these checkpoint inhibitors. Furthermore, while there have been many successes, there also continues to be failures, and thus strategies to increase their effectiveness while managing their safety, such as combinations and biomarkers for patient selection, will be discussed.

1017 Autoantibodies as Biomarkers for Predicting Risk to Develop Autoimmune Diseases Following Treatment with Immune Checkpoint Inhibitors

M. Satoh. *University of Occupational and Environmental Health, Japan, Fukuoka, Japan.*

Immune checkpoint inhibitors (ICI), such as antibodies to PD-1/PD-L1, are a new type of cancer immunotherapy. Because ICI enhance tumor immunity, development of autoimmune disease has been reported among the adverse events. However, biomarkers for predicting risk to develop autoimmune diseases remain to be established. Autoimmune thyroid disease is a common autoimmune condition seen in 3%-5% of the general population; thus, subclinical thyroid diseases would not be unusual in patients with cancer. Analysis of autoantibodies in patients with lung cancer revealed that ~15% of them have known autoantibodies of systemic autoimmune rheumatic diseases. Because production of autoantibodies usually precedes clinical manifestation, it may be reasonable to predict that the presence of autoantibodies is associated with the risk to develop autoimmune diseases. Autoantibodies associated with autoimmune thyroid disease and systemic rheumatic diseases were evaluated in lung cancer patients receiving ICI before and during ICI therapy. Thyroid autoantibodies were tested by enzyme-linked immunosorbent assay (ELISA) for antibodies to thyroglobulin and thyroid peroxidase. Autoantibodies associated with systemic autoimmune diseases were examined by ELISA (Ro60, Ro52, Jo-1, CENP-A, CENP-B) and radioimmunoprecipitation using 35S-methionine labeled K562 cells. Among nine cases treated with ICI, three developed hypothyroidism. Two of them had thyroid autoantibodies before ICI therapy and one case developed them after ICI. Six cases without hypothyroidism did not have thyroid autoantibodies before or after ICI therapy, suggesting thyroid autoantibodies are associated with hypothyroidism during ICI and have predictive value. Five cases developed interstitial lung disease (ILD) during ICI therapy. Two of them had anti-Ro52 before ICI and one developed anti-Ro52 followed by ILD. Anti-Ro52 found in ~0.5% of healthy individuals and 11% of lung cancer patients may be associated with the risk to develop ILD after ICI therapy. These results suggest that detection of autoantibodies associated with corresponding autoimmune disease may help in predicting the risk to develop autoimmune diseases.

1018 Immune-Related Adverse Events Induced by T Cell Adoptive Immunotherapy Using Genetically Engineered TCR-T Cells

H. Ikeda. *Nagasaki University, Nagasaki, Japan.* Sponsor: Y. Yoshioka

It is becoming increasingly clear that T cell adoptive immunotherapy with genetically engineered T cells, such as CAR-T therapy and TCR-T therapy, has the potential to control and even cure cancer in some patients. On the other hand, severe irAEs associated with efficacy have frequently been reported in clinical trials. In some cases, the irAE could be attributed to T cell reactivity against normal tissue where the target protein was expressed. Furthermore, on-target irAE such as cytokine release syndrome (CRS) as a consequence of producing supraphysiologic levels of cytokines by engineered T cells upon antigen recognition, and immune effector cells associated neurotoxic syndromes (ICANs), pose a major challenge to this type of therapy. The irAE induced in a phase I clinical trial of T cell adoptive immunotherapy utilizing genetically engineered to express tumor-reactive TCR genes for the treatment of patients with advanced solid tumors will be discussed. A strategy to utilize allogeneic T cells with reduced GVHD toxicity also will be presented.

1019 Nonclincial Paths for Immunomodulators: Current Challenges to Evaluate the Safety of Immune Checkpoint Inhibitors and Combination Therapies

D. McMillan. *US FDA/CDER, Silver Spring, MD.*

Checkpoint inhibitors have created a drastic shift in the immunotoxicology field. Prior immunotoxicology assessments were designed for small molecules and centered on immunosuppression. With the advent of immunomodulators for patients with serious and life-threatening disease, this created a unique safety evaluation challenge. Existing nonclinical models were not especially helpful, as the immunomodulatory antibodies were not very active in those models due to species specificity as well as the lack of any immunostimulatory, pathogenic signal in the animals that was present in the patient population. These unique safety challenges required a flexible approach with a combination of *in vitro* testing and consideration of the immune pathway being altered (which can help predict effects in humans), as well as strict safety monitoring of the patient population. Although there have been a few unexpected adverse events noted with combination therapies, the data to date support a flexible approach that allows for an adequate safety evaluation for products intended for patients with serious and life-threatening illnesses.

1020 Developmental Toxicity of Per- and Polyfluoroalkyl Substances (PFAS): Current *In Vivo* Approaches and Application to Human Health Risk Assessment

J. Conley. *US EPA, Research Triangle Park, NC.*

Per- and polyfluoroalkyl substances (PFAS) hazard and risk assessments are a high-priority focus of health-based agencies on a global scale due to widespread occurrence and exposure. The PFAS chemical class is diverse, in regard to physicochemical and toxicokinetic characteristics, and extensive, with hundreds to thousands of existing structures and additional novel structures introduced annually. The legacy PFAS, perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), have been studied extensively in traditional and alternative animal models; however, little to no data regarding persistence, toxicokinetics, or toxicity are available in the peer-reviewed literature on emerging PFAS with known human exposures, such as the perfluoroalkyl ether acids (e.g., hexafluoropropylene oxide-dimer acid [GenX] or Nafion byproduct 2). Importantly, the specific molecular mechanisms and downstream events responsible for the adverse effects described in rodent studies of PFOS and PFOA, including neonatal mortality, immunomodulation, altered thyroid hormone concentrations, and impaired carbohydrate and lipid metabolism, are relatively unresolved. Further, it is unknown if exposure to emerging PFAS elicit similar developmental outcomes, and how their relative potencies compare with those of legacy PFAS. Thus, research examining critical upstream events, as well as previously unstudied adverse outcomes from early-life exposures, is needed to facilitate screening of PFAS and inform human health and environmental risk assessments. A key assumption has been that many, if not all, of the adverse effects of PFAS are mediated in large part by modulation of peroxisome proliferator activated receptors (PPARs), particularly PPAR-alpha. However, it appears that multiple molecular mechanisms may be involved in the spectrum of effects described for developmental PFAS toxicity. The first three presentations in this session will focus on *in utero* and early life stage exposure studies in laboratory rats and mice to emerging and legacy PFAS. Research presented will cover the current state-of-the-science for *in vivo* effects on neonatal viability, neurological responses to alterations in thyroid hormone concentrations, development of immune competence, and metabolic capacity. Each presentation will pay particular attention to elucidating the specific molecular mechanisms and key events associated with the adverse effects of PFAS exposure. The final two speakers of the session will present current state-level (US) and international (European Union—European Food Safety Authority) regulatory approaches for derivation of human health-based guidance levels. These presentations will include a case study of the utilization of *in vivo* toxicity data for generating a transgenerational exposure model to address critical life stages for PFOA, and the use of epidemiological studies and the potential for incorporating a mixtures-based approach to characterize risk of multiple PFAS in food.

1021 PFHxS and Developmental Neurotoxicity: Does Thyroid Hormone Action Play a Role?

K. O'Shaughnessy. *US EPA, Research Triangle Park, NC.*

Perfluorohexane sulfonate (PFHxS) is an environmental thyroid-disrupting chemical that reduces serum thyroid hormones (THs) in animal models. As thyroid action is required for normal brain development, it is suspected that PFHxS may induce developmental neurotoxicity by endocrine-mediated mechanisms. Using a multidisciplinary approach, we investigate whether PFHxS induces abnormal brain development and function associated with TH dysregulation. Pregnant rats were orally dosed (50 mg/kg/day) from gestational day 6 (GD6) to postnatal day 21 (PN21), and the offspring analyzed. Results show that PFHxS exposure reduced serum THs in both the dams and pups. Serum total thyroxine (T4) was reduced by approximately 75% in exposed neonates. However, remarkably, brain T4 was significantly reduced in the pup brain only on PN0, and not on PN2, PN6, or PN14. Brain triiodothyronine (T3) also was not significantly reduced at any stage tested. We also detected no evidence, transcriptionally or phenotypically, of TH-mediated dysfunction of the cortex. No significant differences in learning and memory were detected in offspring aged to adulthood, as assayed by trace fear conditioning; sensory gating was similarly unaffected. These data suggest that despite significant reductions in serum T4, the neonatal rat brain does not appear to be TH insufficient following PFHxS exposure. These observations may be attributed to chemical action: PFHxS purportedly reduces serum THs by interfering with the function of serum binding proteins. However, unbound

(free) THs are transported across the blood-brain barrier and into the tissue. Thus, these dynamics in hormone transport may explain why brain TH concentrations are largely unaffected by PFHxS exposure at the stages tested. This hypothesis is consistent with clinical presentations of patients and knockout mice possessing loss of function mutations in serum binding proteins. In the future, additional work is warranted to determine if other perfluorinated compounds alter brain TH concentrations at other developmental stages and/or induce abnormal brain development by other mechanisms. *This work does not reflect US EPA policy.*

S 1022 Adverse Developmental Effects of Gestational Exposure to Emerging Perfluoroalkyl Ether Acids: Mechanistic Insights and Potency Comparisons with Legacy PFAS

J. Conley. *US EPA, Research Triangle Park, NC.*

Perfluoroalkyl ether acids (PFEAs) are a subclass of PFAS and are currently used in the production of fluoropolymers following the phase-out of the legacy PFAS perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS). PFEA compounds such as hexafluoropropylene oxide dimer acid (GenX), Nafion byproduct 2 (NBP2), and perfluoro-2-methoxyacetic acid (PFMOAA) have been detected in surface water, drinking water, and/or human serum, yet little to no published toxicity data are available. We previously determined that oral GenX exposure to pregnant Sprague-Dawley rats produced adverse maternal and F1 effects similar to those produced by PFOS, but with lower potency. Here, we assessed the *in utero* toxicity of PFMOAA (0.01-200 mg/kg/d, gestation day [GD] 14-18 and GD 9-13) and NBP2 (0.1-30 mg/kg/d from GD 14-18 and 0.3-30 mg/kg/d from GD 8-postnatal day [PND] 2) for comparison with GenX and the legacy PFAS. PFMOAA was negative for adverse maternal and F1 effects; however, NBP2 reduced maternal weight gain (GD 14-18 and GD8-PND2 dosing), reduced neonatal survival (=10 mg/kg), and reduced pup weight (GD8-PND2 dosing). Based on oral ED_{50}s for neonatal mortality, NBP2 was only ~3-fold less potent than PFOS (9.5 mg/kg for NBP2 versus 3.1 mg/kg for PFOS), whereas GenX was ~35-fold less potent than PFOS. It appears that the spectrum of adverse developmental effects is similar between some of the PFEAs and the legacy PFAS and that the oral potency is also relatively similar for some compounds. Data from our GenX studies indicated that many genes associated with glucose metabolism were significantly downregulated in PND 0 pup livers and impaired liver glycogen deposition of the developing fetus/neonate may be a principle key event for reducing F1 survival and body weight. Ongoing research in our group is investigating the putative mechanism(s) of action (primarily activation of peroxisome proliferator-activated receptor subtypes) and additional key events that lead to adverse maternal and neonatal outcomes, comparison of internal dosimetry for extrapolation with human exposures, and mixture-based effects of *in utero* exposure to multiple PFAS. *Abstract does not necessarily reflect US EPA policy.*

S 1023 Developing an Understanding of the Effects of PFAS on the Immature Immune System

J. DeWitt. *East Carolina University, Greenville, NC.*

Studies of children who have been exposed to PFAS throughout fetal and early life have reported reduced responses to common childhood vaccines. Studies in experimental rodents exposed to PFAS also demonstrate that exposed rodents have a reduced ability to mount an appropriate immune response against novel antigens. The ability of the adaptive immune response against novel antigens is a robust measure of immunotoxicity, which supports that PFAS are able to suppress functional abilities of the developing immune system. A growing body of evidence concerning other developmental immunotoxicological outcomes, including responses such as allergy and asthma, supports that PFAS exposure also can hyperactivate the developing immune system. These multiple lines of evidence support that the developing immune system is a sensitive target of PFAS exposure and that the outcome may depend on critical windows of development during exposure and other aspects associated with the exposure scenario. The focus of this talk will be on immune developmental processes that appear to be sensitive windows for PFAS exposure, the putative mechanisms by which PFAS affect the developing immune system, and how developmental immunotoxicity data can be used as a benchmark for managing health risks of PFAS exposure.

S 1024 Derivation of Health-Protective Water Guidance for Bioaccumulative PFAS Chemicals Requires Incorporation of Placental and Breast Milk Exposure Pathways

H. Goeden. *Minnesota Department of Health, Minneapolis, MN.*

The standard approach for calculation of noncancer health-based water guidance uses a static equation involving the reference dose (RfD, mg/kg-d), a water intake rate (IR, L/kg-d), and relative source contribution (RSC) factor. PFOA, PFHxS, and PFOS, however, bioaccumulate in serum, cross the placenta, and are excreted into breast milk. As a result, chronic maternal exposures can have a large impact on nursing infant exposure. Although exposures during infancy are relatively brief, this life stage is of particular concern because (1) development is a toxicologically sensitive window; (2) infants consume a much greater volume of liquid per unit body weight than older children and adults; and (3) short-term exposures that occur during infancy can result in body burdens that take years to eliminate. The Minnesota Department of Health (MDH) developed a novel, one-compartment, Excel-based toxicokinetic model to simulate daily serum levels from birth through adulthood (attainment of steady-state conditions). The model included indirect exposures via placental and breast milk transfer as well as age-specific liquid intake rates. Two exposure scenarios were evaluated, each starting at birth with a preexisting body burden from placental transfer from a chronically exposed mother: (1) an infant exclusively formula-fed with contaminated water starting at birth, followed by a lifetime of drinking contaminated water; and (2) an infant exclusively breastfed for 12 months, by a mother who continues to drink contaminated water, followed by a lifetime of drinking contaminated water. As seen generally in previous biomonitoring studies, modeling results confirmed breastfed infants accumulate much higher serum levels. Predicted peak serum levels exceeded steady-state levels by up to sixfold, with levels exceeding steady state for over ten years. To ensure protection of the most highly exposed and vulnerable segments of the population, the latest guidance values by the MDH for PFOA, PFOS, and PFHxS incorporated placental and breast milk exposure pathways.

S 1025 The European Food Safety Authority Assessment of PFAS in Food: Preliminary Results and Ongoing Work

T. Haldorsson. *University of Iceland, Reykjavik, Iceland.* Sponsor: J. Conley

In 2018, the European Food Safety Authority (EFSA) published a new risk assessment on PFOS and PFOA in food. After reviewing existing evidence, new tolerable weekly intakes (TWIs) of 13 and 6 ng/kg body weight per day were established for PFOS and PFOA, respectively, based on human studies. These TWIs were 100-1000 fold lower compared with a previous assessment by EFSA from 2008. With respect to early-life exposures, associations with reduced birth weight (for PFOS and PFOA) and reduced antibody response following vaccination (for PFOS and possibly PFOA) were considered critical and likely to be causal. Based on studies in adults, increase in total (and LDL) serum cholesterol (for both PFOS and PFOA) and serum alanine aminotransferase for PFOA was also considered critical and likely to be causal. Increase in serum cholesterol was used as a basis for deriving TWIs. Benchmark dose modeling showed that the derived TWIs were protective for the other three outcomes. Following publication of the opinion, several European agencies that had derived their own health-based guidance values based on animal data raised concerns and identified specific uncertainties in the EFSA opinion. Parallel to this process EFSA published a new guidance document on how to assess combined exposure to multiple chemicals. To address concerns raised and to explore the possibilities of assessing dietary exposures to PFAS as mixture, the TWIs established for PFOS and PFOA were published as provisional. The outcome of this ongoing work, including publication of a risk assessment for PFAS other than PFOS and PFOA, is expected by the end of the year 2019. In this presentation, the scientific basis behind use by EFSA of human studies for deriving TWIs for PFOS and PFOA will be explained. In addition, possibilities, pros, and cons of assessing PFAS as a combined group of chemicals will be reviewed briefly.

S 1026 Lysosome/Autophagy Dysregulation in Toxicity and Disease

S. Lu. *Pfizer Inc., San Diego, CA.*

Lysosomes, first discovered by Dr. Christian de Duve more than five decades ago, are acidic membrane-enclosed organelles filled with hydrolytic enzymes that digest macromolecules from the endocytic, autophagic, and phagocytic membrane-trafficking pathways. Over the past decade, several areas of investigation have blossomed and brought lysosomes back into the forefront

of cell biology. One such area is autophagy, which is now recognized as an essential process for maintenance of organelle integrity, catabolism of lipid droplets, and response to stress. Autophagy dysregulation, including lysosomal dysfunction, has been linked to aging and age-related diseases, including disorders of lipid and glucose metabolism, as well as cardiovascular and neurodegenerative diseases. One exciting recent development is the recognition that lysosomes are the key regulators of signaling processes that regulate metabolism. The key metabolic signaling regulator mechanistic target of rapamycin (mTOR), for instance, needs to be recruited to the lysosomal surface to become activated and to sense cellular nutritional status. In addition, we now have a much better understanding of the mechanisms underlying the regulation of lysosome formation. The transcription factor EB (TFEB), a master regulator of lysosomal biogenesis, drives expression of both autophagy and lysosomal genes. Many compounds can impact autophagic function either by lysosomal accumulation (e.g., tamoxifen and amiodarone) or inhibition of certain machinery (e.g., arsenic and tetanus neurotoxin) required for autophagy flux and fusion with the lysosome. The impact of lysosomal dysfunction by these compounds could lead to toxicity manifestation via several different mechanisms: (1) cell death associated with lysosomal membrane permeabilization; (2) membrane trafficking perturbation, including phagocytosis and autophagy; and (3) signaling modulation, including mTORC1 and Nrf2. In this session, we will focus on the discussion of adaptive changes associated with lysosomal stress, cell death by lysosomal membrane permeabilization, and Nrf2 signaling modulation associated with lysosomal/autophagy impairment. Examples will be presented that showcase the relationship between lysosomal/autophagy impairment and liver injury or cancer. The discussion highlights lysosome dysfunction as an essential mechanism for xenobiotic-induced toxicity, which could have a vast impact on the drug discovery process by providing an alternative means for organ toxicity mediated by physicochemical properties and lysosomal function perturbation besides on-target and off-target effect.

S 1027 Lysosomal Adaptation: How Cells Respond to Lysosomotropic Compounds

S. Lu. *Pfizer Inc., San Diego, CA.*

Lysosomes are acidic organelles essential for degradation and cellular homoeostasis, and recently, lysosomes have been shown as a signaling hub to respond to the intra- and extracellular changes (e.g., amino acid availability). Compounds including pharmaceutical drugs that are basic and lipophilic will become sequestered inside lysosomes (lysosomotropic). Following compound accumulation in the lysosome, many detrimental events can occur, including cell death and the perturbation of autophagy and phagocytosis, which could serve as a potential contributing factor in drug-induced organ toxicity. Lysosomal dysfunction by lysosomotropic compounds also can lead to compensatory responses, including nuclear translocation of transcriptional factors TFEB, TFE3, and MITF. The adaptive changes are protective to the cells under lysosomal stress. Mechanistic studies implicate calcium and mTORC1 modulation involvement in the adaptive changes. These results indicate that lysosomotropic compounds could evoke a compensatory lysosomal biogenic response but with the ultimate consequence of lysosomal functional impairment. This work also highlights a pathway of response to lysosomal stress and evidences the role of TFEB, TFE3, and MITF in the stress response.

S 1028 The Cross Talk of Lysosome, Autophagy, and NRF2

D. Zhang. *University of Arizona, Tucson, AZ.*

The autophagy-lysosome pathway is a key intracellular degradation pathway that plays an integral role in maintaining cell survival under stress conditions. As such, dysregulation of the autophagy pathway is associated with a variety of diseases. Importantly, autophagic dysfunction results in the accumulation of intracellular components, resulting in deleterious effects on the proteostatic, metabolic, and redox balance of the cell. One key protein implicated in autophagy-dysfunction-driven diseases is the cargo adaptor p62/SQSTM1, whose accumulation results in the aggregation of its binding partners and ubiquitinated targets into protein-rich inclusion bodies. Among the proteins sequestered by p62 is kelch-like ECH associated protein 1 (KEAP1), a key negative regulator of the transcription factor nuclear factor erythroid 2-related factor 2 (NRF2). Our lab and others have shown that p62-dependent activation of NRF2 plays an important role in the pathogenesis of numerous disease states, particularly those associated with chronic exposure to the environmental toxicant arsenic, including lung cancer and type 2 diabetes. Critically, arsenic-induced autophagic dysfunction occurs in the later stages of the autophagy pathway, as arsenic exposure prevents fusion of the autophagosome with the lysosome by disrupting formation of the STX17-SNAP29-VAMP8 SNARE complex. Arsenic inhibits SNARE complex formation via enhanced O-GlcNAcylation of SNAP29, with knockdown of OGlcNAc transferase (OGT), the enzyme that adds UDP-GlcNAc residues to proteins, or transfection of O-GlcNAcylation-defective, but not wild-type, SNAP29 into SNAP29 knockout cells preventing arsenic-mediated autophagy inhibition. Further studies also indicate that arsenic inhibits the retrograde and anterograde movement of autophagosomes, endosomes, and lysosomes, indicating the pleiotropic effects that arsenic has on not only autophagic function, but intracellular trafficking as well. Finally, our studies also support the *in vivo* relevance of p62-dependent activation of autophagy and NRF2 in ameliorating a liver fibrosis model. Therefore, NRF2 activation through autophagy upregulation is disease protective, whereas autophagy blockage is promoting arsenic-associated lung carcinogenesis and type 2 diabetes. Our studies indicate the importance of the context-dependent NRF2 activation in human disease.

S 1029 TFEB-Mediated Lysosomal Biogenesis Protects against Alcohol and Acetaminophen-Induced Liver Injury in Mice

W. Ding. *University of Kansas Medical Center, Kansas City, KS.*

Hepatic homeostasis is tightly regulated by autophagy and lysosomal degradation in the liver. We previously demonstrated that activation of autophagy protects against alcohol- and APAP-induced liver injury. Lysosomes sit at the last step of autophagy, which is critical for completing the autophagic process. Lysosomal biogenesis is regulated by a master transcription factor EB (TFEB). In this presentation, we will discuss the recent findings of how alcohol and APAP impair hepatic TFEB function, resulting in decreased lysosomal biogenesis and insufficient autophagy in hepatocytes. Impaired TFEB-mediated lysosomal biogenesis leads to accumulation of damaged mitochondria and excess lipid droplets, which exacerbates alcohol-induced steatohepatitis. Our unpublished data also show that liver-specific TFEB KO mice exacerbated whereas overexpression of TFEB in mouse livers protected against APAP-induced liver injury. Mechanistically, we found that liver-specific TFEB KO mice had high levels of APAP adducts and increased c-Jun N-terminal kinase (JNK) activation. In contrast, overexpression of TFEB increased lysosomal biogenesis and decreased levels of APAP adducts and JNK activation, likely via autophagic removal of APAP adducts. In conclusion, our findings indicate that activation of hepatic TFEB increases biogenesis of both lysosomes and mitochondria that protects against alcohol- and APAP-induced liver injury by removing damaged mitochondria and improving liver repair in mice.

S 1030 Interplay of Mitochondria, Mitophagy, and Lysosomes in Pathophysiology

J. J. Lemasters. *University of South Carolina, Charleston, SC.*

Mitophagy (mitochondrial autophagy) is an essential quality control mechanism that removes for lysosomal digestion damaged, effete, and superfluous mitochondria. In hepatocytes, nutrient deprivation and cellular remodeling initiate mitophagy of normally polarized mitochondria by a phosphoinositide-3-kinase (PI3K)/beclin1-dependent pathway, whereas mitochondrial damage initiates mitophagy by PI3K-independent pathways. Photodamage to individual mitochondria leads to swelling, rupture of outer membranes, and herniation of the inner membrane into the cytosol. Microtubule-associated protein 1A/1B-light chain 3 (LC3) and p62/sequestosome-1 then associate with the bare inner membrane, leading to autophagosomal sequestration and processing into lysosomes. Onset of the mitochondrial permeability transition (MPT) also causes mitochondrial swelling and rupture, which leads to clearance by mitophagy when limited numbers of mitochondria are damaged and to apoptosis and/or necrotic cell death with greater numbers. Conversely, lysosomal disruption can lead to mitochondrial damage and dysfunction. Lysosomal alkalization by inhibition of the vacuolar proton-pumping ATPase by ATP depletion or bafilomycin and lysosomal membrane disruption during acetaminophen hepatotoxicity causes lysosomal release of cheatable iron and uptake of Fe2+ into mitochondria via the mitochondrial calcium uniporter. Inside mitochondria, Fe2+ catalyzes hydroxyl radical formation, oxidative stress, MPT onset, and cell death. In response to acute ethanol feeding, widespread, reversible hepatocellular mitochondrial depolarization occurs to facilitate ethanol metabolism, but that activates mitophagy. Chronically, processing of depolarized mitochondria by mitophagy becomes compromised, leading to release of mitochondrial damage-associated molecular pattern molecules (mtDAMPs) that promote inflammatory and profibrogenic responses associated with alcoholic liver disease. Overall, the interplay between mitochondria, mitophagy, and lysosomes contributes importantly to pathophysiology.

1031 Control of Lysosomal Membrane Integrity: Opportunities for Clinical Intervention

M. Jäättelä. *Danish Cancer Society Research Center, Copenhagen, Denmark.* Sponsor: S. Lu

Lysosomes, with their over 50 hydrolytic enzymes, degrade old organelles and macromolecules for recycling. Leakage of lysosomal hydrolases into the cytosol causes so-called lysosome-dependent cell death, which provides an alternative for cells' normal suicide program apoptosis. In cancer cells, normally cytosolic chaperone, heat shock protein 70 (Hsp70), finds its way into the lysosomes, where it enhances the activity of several lipid hydrolases, thereby stabilizing the lysosomal membrane. Thus, cancer cells can avoid cell death by sending one of their essential proteins to work in a new location. These data have prompted us to develop strategies to inhibit the function of lysosomal Hsp70 by so-called cationic amphiphilic drugs (e.g., antihistamines and antidepressants) to treat cancer and to increase lysosomal Hsp70 activity to treat lysosomal storage disorders and other degenerative diseases. Here, our recent data that have led to clinical trials testing these strategies in patients and identification of signaling pathways that control lysosomal membrane integrity will be presented.

1032 New Data and Tools for Understanding Chemical Distribution *In Vitro*

N. Kramer. *Universiteit Utrecht, Utrecht, Netherlands.*

This session will explore how new experimentally evaluated models for *in vitro* chemical distribution are needed to better implement the US National Academy of Sciences *Toxicity Testing in the 21st Century: A Vision and a Strategy*. Tox21, EU-ToxRisk, and the TransQST are exemplary projects where *in vitro* toxicity testing systems are being adapted to assess the toxicity of compounds, from pharmaceuticals to industrial chemicals. A critical research need for *in vitro* testing is to distinguish between the nominal concentration of the test chemical applied to the assay system and the effective concentration of the chemical at the site of action *in vitro*. Since chemicals are expected to vary in their distribution, it is essential that this is accounted for in determining relative potency in *in vitro* assays, and *in trans*lating *in vitro* findings to *in vivo*. While mathematical models exist to make such predictions, actual experimental data allowing evaluation have historically been scarce. The presenters in this Symposium are collecting new datasets and establishing novel methods to address *in vitro* distribution of chemicals. The session will begin with a presentation on new mathematical models based on physicochemistry to predict *in vitro* disposition. The next three presentations will describe new experiments measuring disposition *in vitro*, with a focus on model evaluation and interpretation of results in the context of high-throughput screening (HTS). These efforts include a major effort by the Tox21 collaboration to evaluate the impact of these issues across a wide chemical space, including both pharmaceuticals as well as other chemicals occurring in the environment and commerce. The session will conclude with a discussion of lessons learned and challenges remaining with respect to *in vitro* chemical distribution and translation to *in vivo* from the EU-ToxRisk and TransQST consortiums. The session will consider (1) What data are available today for evaluating differences between *in vitro* nominal and effective concentrations? (2) What approaches exist for extrapolating from these data to untested and novel chemical structures? (3) What experimental methods are available for measuring *in vitro* disposition? and (4) What is the impact of *in vitro* disposition on chemical risk prioritization?

1033 A Comparison of Kinetic Model Predictions and Analytically Determined Distribution of Test Chemicals in 2D, Sandwich and 3D, Spheroid Hepatocyte Models

N. Kramer. *Universiteit Utrecht, Utrecht, Netherlands.*

The absorption, distribution, metabolism, and excretion (ADME) of chemicals play a central role in quantitative *in vitro in vivo* extrapolation (QIVIVE) studies, as these processes determine the concentration of the chemical at the target organ where the toxic effect is initiated *in vivo*. Although largely ignored, similar kinetic processes determine the target concentration and thus the level of bioactivity of chemicals in *in vitro* assays. Despite chemicals or assays eliciting similar effects at similar nominal concentrations, the bioavailable concentration may vary greatly between chemicals and assays, thus hampering comparisons. A number of partition models have been developed to estimate target concentrations of a chemical *in vitro*. The aim of this study was to review these models in terms of their chemical and assay applicability domains, inclusion of kinetic processes, input parameters, and the extent to which they have been evaluated. Subsequently, model predictions of the distribution of 10 chemicals varying in physicochemical and toxicokinetic properties were compared with measured time-resolved concentrations of these chemicals associated to well plate plastic, exposure medium, cells, and cell attachment matrices in an intrinsic clearance assay with HepaRG cultured as a monolayer, sandwich, and spheroid. The free concentration varied significantly for the lipophilic, quickly cleared chemicals between models as a result of the variation in phases and kinetic processes included by the models. The virtual cell based assay (VCBA) model resulted in distribution-time profile of the chemicals that corresponded with analytical measurements.

1034 Biokinetic Modeling of *In Vitro* Systems for Toxicity Testing and Risk Assessment

C. Fisher. *Certara UK Limited, Sheffield, United Kingdom.*

The vision for toxicity testing and risk assessment in the 21st century aims to increase the use of human-relevant *in vitro* model systems and reduce, refine, and ultimately replace the use of animal models. An important component of successfully implementing this strategy is the use of modeling and simulation to translate the toxic effects and associated concentrations at which these effects are observed from the *in vitro* to *in vivo* situation. Biokinetic modeling allows prediction of the concentrations of chemicals within the cells of *in vitro* test systems. Such mathematical models also allow the assessment of the metabolism, transport, and dissolution/solubility of drugs and other chemicals. The use of such modeling approaches facilitates the parameterization of physiologically based toxicokinetic (PBTK) models enabling the translation of the intracellular concentrations, exerting effects in *in vitro* systems, to predicted concentrations in the tissues under various exposure scenarios. Drawing on experiences from within the EU-ToxRisk program and the TransQST (Translational Quantitative Systems Toxicology) consortium, as well as the wider literature, the advantages and current challenges in using biokinetic and PBTK models as part of an integrated approach to chemical testing and risk assessment will be discussed.

1035 Tox21 Partnership on *In Vitro* Dispositions: Initial Results

D. Crizer. *NIEHS/NTP, Research Triangle Park, NC.*

Understanding the biokinetics of chemicals evaluated in alternative models is an important step in extrapolating these results to humans. In an effort to extrapolate *in vitro* media concentrations to *in vivo* exposures (IVIVE), pharmacokinetic models are used to estimate human oral exposures that would result in blood concentrations equivalent to the nominal media concentrations. One of the uncertainties of this assumption is that the ratio of the chemical concentration in media to cells is equivalent to the ratio of chemical concentration in blood to tissue. Another uncertainty of this assumption is the static nature of the cell culture exposure compared with the kinetic processes occurring *in vivo*. In Tox21, most of the assays employ transformed cell lines cultured in monolayers in plastic wells. These cells have limited metabolic capabilities and the chemical can distribute between the plastic, media, and cells. In contrast, human exposure is a dynamic process in which absorption, distribution, metabolism, and elimination influence blood and tissue chemical concentrations. These initial studies evaluate the *in vitro* distribution of chemicals over 24 hours, the length of many of the Tox21/ToxCast assays. The development of a dataset that quantifies the concentration of chemicals in the media, plastic, and cells provides insight into the magnitude and directionality of the uncertainty in the assumption that nominal media concentrations and blood concentrations are equivalent. To date, MCF-7 cells have been exposed to a diverse set of 10 chemicals. Results from this initial study show that at 24 hours the concentration of chemical in cells compared with the concentration in media can vary from threefold (atrazine) to 128-fold (triphenyl phosphate). Comparisons were made between experimental cellular concentrations and predicted cellular concentrations using the model by Armitage and coworkers. The comparisons showed decent agreement with a log RMSE of 0.88. The Armitage model appears to account for some of the trends observed in our experimental data.

1036 The Influence of *In Vitro* Disposition and Toxicokinetics on the Association of *In Vitro* Bioactivity and *In Vivo* Toxicity Data

G. Honda. *US EPA/NCCT, Research Triangle Park, NC.* Sponsor: J. Wambaugh

This presentation will provide clear, statistical evidence that *in vitro* disposition modeling and physiologically based toxicokinetics (PBTK) enable improved association of *in vitro* bioactivity and *in vivo* toxicity data via *in vitro* to *in vivo* extrapolation (IVIVE). To use high-throughput screening (HTS) assays as an alternative to traditional animal studies, we must link *in vitro* bioactivity concentrations and toxic doses by IVIVE. Previously, it has not been clear whether the use of IVIVE even improves the observed association between *in vitro* bioactivity and *in vivo* toxicity data. Further, there is currently no single, optimal approach to IVIVE. Generally, toxicokinetic models may be used to determine chemical concentrations (e.g., unbound plasma, total plasma, and tissues) that correspond to a dose where a toxic effect was observed *in vivo*, while *in vitro* disposition models may be used to describe the concentrations (i.e., free and cellular) that correspond to a nominal concentration where bioactivity was observed in an HTS assay. We have used an *in vitro* disposition model and a high-throughput, PBTK model to relate *in vitro* bioactivity (ToxCast) and endpoint-specific rat *in vivo* toxicity data. For every possible comparison of *in vitro* and *in vivo* endpoint, the concordance between the *in vivo* and *in vitro* data was evaluated by a regression analysis. We tested various sets of IVIVE assumptions and demonstrate that the combination of PBTK and *in vitro* disposition modeling improves our ability to observe the association between *in vitro* bioactivity and *in vivo* toxicity data. Potency values from *in vitro* screening should therefore be transformed by IVIVE to build better machine-learning and other statistical models for predicting *in vivo* toxicity in humans. *This abstract does not necessarily reflect US EPA policy.*

1037 Applicability Domains and Future of Nonanimal Tests for Skin Sensitization

V. Johnson. *Burleson Research Technologies, Morrisville, NC.*

Allergic contact dermatitis is an undesired side effect observed with many products, including cosmetics, natural extracts, drugs, chemicals, and medical devices. Over the last decades, a great deal of progress has been made in the development of alternative *in vitro* testing strategies to assess these issues, concurrent with the mechanistic understanding provided by the adverse outcome pathway (AOP) framework. The use of animals in toxicology is under ever-increasing scrutiny, with mounting pressure to develop effective alternatives. Efforts should be devoted to developing reliable *in vitro* assays and integrated testing strategies capable of addressing toxicity concerns for a broad spectrum of products and chemicals. This will require a better understanding of the applicability domains of scientifically validated assays and methods that are currently being used so that chemicals can be tested appropriately in these assays to produce valid predictions. In addition, accurate definition of the applicability domains will facilitate modification and improvement of current and new assays to expand these domains, resulting in better coverage of the chemical space for prediction of sensitization potential. The purpose of this Workshop is to cover current knowledge on the applicability domains of these methods and to understand their limitations and the opportunities they offer. The session will open with a brief introduction by the session Chair, followed by four presentations aimed at defining the current state of the applicability domains for *in vitro* approaches as well as recent progress to expand these domains. The first presentation will present the current status of an international collaboration charged with establishing international test guidelines for nonanimal testing strategies that would serve as full replacements to the animal tests for skin sensitization. The approach includes using the current nonanimal methods within their applicability domains to model skin sensitization. The second presentation will define the applicability domains and limitation for the individual OECD Test Guidelines 442C, 442D, and 442E, which address chemical peptide reactivity, keratinocyte activation, and dendritic cell activation, respectively. A complete understanding of the influence of chemistry on these factors is critical for accurate predictions and improvement of current approaches to expand the applicable chemical space that can be tested without the use of animals. The third presentation will focus on *in chemico* assessment of peptide reactivity, presenting a characterization of the currently validated Direct Peptide Reactivity Assay (DPRA) approach while providing insight into the novel Peroxidase Peptide Reactivity Assay (PPRA), which holds promise to expand the applicability domain of peptide reactivity assays to include pre- and pro-haptens requiring metabolism. The final presentation will provide initial data for a novel dendritic cell activation assay, the THP-1 Activation Assay, which is being developed to expand the applicability domain of the current *in vitro* dendritic cell activation assays to include drugs that exhibit limited or no cytotoxicity. Overall, this Workshop aims to better define the applicability domains for nonanimal sensitization testing and identify progress and opportunities for expanding these domains. This Workshop represents an international collaboration between the Immunotoxicology Specialty Section of SOT and the Immunotoxicology and Chemical Allergy Specialty Section of EUROTOX in an effort to communicate and improve the science of alternative approaches for assessing potential for skin sensitization.

1038 Establishing International Test Guidelines for Skin Sensitization: Predictive Capacity and Applicability Domain of Nonanimal-Defined Approaches

N. Kleinstreuer. *NIEHS/NICEATM, Morrisville, NC.*

Following the work done by international consortiums such as Cosmetics Europe and the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM), a project to develop a Test Guideline on Defined Approaches (DAs) for Skin Sensitization, co-led by the US, the EU, and Canada, was officially included on the Organisation for Economic Co-operation and Development (OECD) workplan in April 2017. This work aims to establish Test Guidelines for nonanimal testing strategies (defined approaches) that fall under the Mutual Acceptance of Data (MAD) clause. MAD means that any of the 36 Member countries will accept data generated under OECD Test Guidelines, avoiding redundant testing and ensuring international harmonization. This proposal is the first attempt to establish international test guidelines for nonanimal testing strategies that would serve as full replacements to the animal test for skin sensitization, a regulatory requirement across many jurisdictions and chemical sectors. The OECD national coordinators agreed in April 2018 on a final evaluation framework to be applied to DAs for hazard identification, potency categorization, and eventually quantitative risk assessment, and an expert group was formed to apply this framework to several nonanimal DAs. A subsection of the expert group is specifically examining the applicability domain of DAs, and how it is affected by the individual test elements, both *in vitro* and *in silico* in nature. Additional subgroups are focused on curating reference datasets, in particular human evidence, and characterizing uncertainty for the *in vitro* test components, the DAs, and the *in vivo* data. Based on the progress made in this area, the US Environmental Protection Agency released a draft science policy in 2018 to accept two nonanimal DAs as replacements for the mouse test, for pesticide active ingredients, inerts, and other single-constituent chemicals, and other regulatory authorities are considering similar actions. Work is ongoing to target unresolved challenges for risk assessment, such as potency estimation and assessing DA performance on mixtures. Overall, this project represents a major milestone toward the replacement of animal testing for the endpoint of skin sensitization, both within and outside the US.

1039 Chemistry behind Sensitization: Possible Limitation and Bottleneck of *In Vitro* Methods

R. Landsiedel. *BASF SE, Ludwigshafen, Germany.*

Three *in vitro* methods have gained regulatory acceptance for the prediction of skin sensitization (OECD Test Guidelines 442C, -D, -E). The OECD Test Guideline 442C addresses the molecular initiating event on the adverse outcome pathway (AOP) for skin sensitisation of covalent binding of chemical sensitizers to skin proteins and details the *in chemico* method DPRA. The OECD Test Guideline 442C addresses the second key event in the AOP for skin sensitization, that of keratinocyte activation with the ARE-Nrf2 pathway being central to the response. The guideline details two *in vitro* methods using ARE-Nrf2 luciferase constructs to signal changes in keratinocytes induced by sensitizers, the Keratinosens and Lusens assays. The OECD Test Guideline 442C addresses the key event on the AOP for skin sensitization of dendritic cell activation and details two *in vitro* methods for testing this event, the Human Cell Line Activation Test (hCLAT), the U937 Cell Line Activation Test (U-SENS), and the Interleukin-8 Reported Gene Assay (IL-8 Luc). The applicability domains and limitations of these *in chemico* and *in vitro* methods need to be described to assess their appropriateness for the test substance and the reliability of the predictions. This is a critical aspect that must be considered for industrial users and regulatory agencies. To answer this question, BASF, in collaboration with other academic partners and industrial associations, has evaluated and compared the different methods for their predictive capacities. The purpose of this presentation is to present and discuss the applicability domains for these assays and possible limitation of *in vitro* methods, including the precision of the methods and the predictivities according to the reaction mechanism of the hapten.

1040 The Use of Peptide Reactivity Assays for Skin Sensitization Hazard Identification and Risk Assessment

C. Ryan. *Procter & Gamble, Mason, OH.*

Over the past 20 years or more, investigators have been developing non-animal test methods for use in assessing the skin sensitization potential of chemicals. In parallel with this effort, the key biological events of skin sensitization have been well characterized in an AOP proposed by the OECD. The key molecular initiating event of this AOP is haptenation or covalent modification of epidermal proteins. In this review, the strengths and limitations of the DPRA are described in the context of the applicability domain for this *in chemico* technique. The DPRA has been formally validated and incorporated into an OECD Test Guideline (TG442C). The DPRA shows promise for assisting in hazard identification as well as for assessing skin sensitization potency when used in an integrated testing strategy. Research has shown that chemicals requiring metabolism often fail to produce appropriate results in the DPRA. These pro- and pre-haptens are outside the applicability domain of the DPRA, and predictions are questionable. Recent advances in the *in chemico* space resulted in the development of the PPRA. This assay uses peroxide enzyme systems to provide the metabolic activation of pre- and pro-haptens, resulting in increased predictive value of the peptide reactivity value. The PPRA provides a valuable opportunity to expand the applicability domain for *in chemico* assessment of the key molecular initiating event. This talk will discuss the methodology, applicability, and limitations associated with peptide reactivity assays as valuable tools in the identification of skin sensitizers.

1041 Drug-Induced Hypersensitivity: *In Vitro* Opportunities

E. Corsini. *Università degli Studi di Milano, Milan, Italy.*

Starting from the assumption that allergenic drugs share common mechanisms of cell activation with chemical allergens, it is possible to speculate for drugs, as it has been done for chemicals, that human drug allergens can be predicted through identification of peptide-bound reactive small chemical drugs to drug-specific naive human T cell priming. According to published literature, it also may be possible based on careful selection of molecular markers (e.g., cytokines, surface markers, microRNA) to discriminate between different types of hypersensitivity induced by drugs. For example, the intrinsic capacities of allergens to polarize conventional dendritic cells (cDC) toward type 1 cDC or type 2 cDC, irrespective of local factors such as those determined by cutaneous or mucosal epithelial microenvironments, is a key factor. In currently validated *in vitro* methods (hCLAT, U-SENS, and IL-8 Luc), addressing key event 3 (DC activation), very few drugs have been tested, and all were correctly classified. To extend on the current methods, we developed a method based on CD54/CD86 upregulation in THP-1 together with assessment of IL-8 production to identify allergenic drugs, with encouraging results. The addition of the assessment of IL-8 production proposes to expand the applicability domain for *in vitro* assays addressing the key event of DC activation, as DC production of IL-8 is known to result in chemotaxis of other cellular mediators of inflammation and allergy—namely, neutrophils and T cells—thereby covering both antigen processing and presentation and cell recruitment functions of DCs. Initial testing of the method with known allergenic drugs has demonstrated that the assay correctly classifies these drugs as sensitizers even when metabolic activation is required. Importantly, this assay expands to applicability domain of *in vitro* methods for interrogation of DC activation to chemicals and drugs that show limited or no cytotoxicity, as these chemicals are not well predicted by the hCLAT assay. While without any doubt additional efforts and extensive resources are necessary to improve preclinical testing methodologies, including optimization of the experimental design and interpretation of data, the possibility of using currently *in vitro* methods for the hazard identification of the allergenic potential of drugs will be presented and discussed.

1042 Known Unknowns: Challenges and Approaches for Handling Chemical, Hazard, and Regulatory Uncertainty in Medical Device Safety Assessments

T. Lewandowski. *Gradient, Seattle, WA.*

The regulatory landscape for the safety evaluation, clinical testing, and commercial development of medical devices is undergoing considerable changes, including new requirements for material characterization and chemical risk assessment early on in the development process. In this dynamic environment, extractables/leachables (E/L) analysis is becoming a key tool in biocompatibility assessments to ensure patient safety and establish regulatory compliance. The first speaker will begin the discussion on medical device chemical characterization strategies, a necessary step for understanding potential chemical exposures from medical device components. The presentation will include examples of how information concerning material chemistry and the manufacturing process can reduce the cost and effort associated in resolving "unknown" extractable compounds. The next presentation will focus on predictive toxicology methods (e.g., computational toxicology programs, read-across, Threshold of Toxicological Concern) for evaluating potential risks from extractable compounds. Case studies will be presented to demonstrate the importance of expert judgment when interpreting *in silico* hazard predictions, as well as approaches for justifying a read-across approach for risk assessment of extractable compounds. The third speaker will then discuss the US Food and Drug Administration (US FDA) perspective on the issues raised in the preceeding talks. Agency experience with unique nontargeted analytical methods that generate data adequate for toxicological risk assessment will be presented, which include, but are not limited to, extraction method design, analytical instrument/tool selection, selecting an analytical evaluation threshold (AET), sample manipulation, system suitability, calibration, identification/semi-qualification, and data reporting. The final speaker will present a broader overview of the global regulatory landscape for medical device safety evaluation. Notable activity includes the revision of ISO 10993-1, implementation of the European Union's revised Medical Devices Regulation, and amendments to California Proposition 65. This presentation will cover how new requirements for extractables/leachables analysis will affect the manufacturer's ability to justify the safety of hazardous substances within devices, verify warning label exemption, evaluate biological equivalence of predicate/proposed devices, and support supply chain controls and ensure efficient change management.

1043 Chemical Characterization Strategies for Medical Device Biocompatibility Assessment

A. Kozak. *Cambridge Polymer Group Inc., Boston, MA.* Sponsor: T. Lewandowski

This presentation will discuss modern chemical characterization strategies for the toxicological risk assessment of medical devices. Following the ISO 10993 framework, the process of evaluating medical device materials of construction, manufacturing processes (including cleaning and sterilization), and end use environment to justify selection of extraction conditions and analytical techniques will be discussed. As will be presented, a robust medical device chemical risk assessment workflow considers the device materials of construction and identifies potentially extractable species before testing. This includes reviewing polymer resins and metal alloys, potential additive/impurity profiles, sterilization agents, and manufacturing processing aides such as detergents, fiber spin finishes, and machining oils (whose composition is often proprietary). Such considerations of the product chemistry not only ensure that the analytical techniques selected are well suited to the detection of suspected extractables, but also facilitate identification of compounds and mitigate the cost and effort associated in resolving "unknown" peaks that may not be present in conventional mass spectral libraries. This presentation also will discuss how consideration of device morphology, surface area, and end use conditions also are integral in selecting justifiable extraction conditions. Strategies for sample extract "workup" will be reviewed, with special considerations for mitigating volatile loss while ensuring adequate sensitivity for trace chemical detection. Specific case studies will include dealing with challenging materials of construction, highly porous morphologies, and identification of polymeric sterilization by-products. By considering chemical risk in tandem with the medical device development process, ways whereby medical device manufacturers can avoid surprises and alleviate delays to market or regulatory approval will be highlighted.

1044 Predictive Toxicology Approaches for Medical Device Biocompatibility Assessment

J. Cohen. *Gradient, Cambridge, MA.*

Comprehensive toxicological characterization of extractable/leachable substances is an essential component of a medical device biocompatibility assessment. Chemical analysis often identifies unique or complex extractable chemical structures that lack complete toxicological data packages. Best practices for using new approach methodology (NAM) predictive tools to evaluate these detected chemicals have yet to be formally established. This presentation will provide an overview of predictive toxicology tools currently available for evaluating risks to human health, along with a discussion of potential pitfalls and best practices. The ICH M7 Guideline provides a clear method for applying computational toxicology programs to predict mutagenic potential, which can then be applied to establish an appropriate Threshold of Toxicological Concern. However, such programs must not be used as a black

box. Predictions should be evaluated using expert judgment to support a risk conclusion based solely on computational methods. Furthermore, computational toxicology predictions for other hazard endpoints (e.g., developmental or reproductive effects) are less well studied but are actively under development. Case studies will be presented to demonstrate the role of expert judgment when interpreting *in silico* hazard predictions for mutagenicity and skin sensitization endpoints. Read-across approaches relying on experimental data for chemicals sharing similar structural, physical, and chemical properties, along with a similar anticipated mechanism of action, may provide additional information for establishing appropriate safety limits for extractable compounds lacking data. Additional case studies will present approaches for justifying read-across for risk assessment of extractable compounds lacking toxicity data.

1045 CDRH Scientific Perspective on Material Characterization and Toxicological Risk Assessment of Nontargeted Medical Device Extractables

B. Oktem. *US FDA/CDRH, Silver Spring, MD.*

Medical devices are unique in the diversity of materials of construction, extent/types of tissue contact, and duration of contact. When evaluating the safety of medical device extractables, it is these unique attributes that necessitate medical device-specific analytical/toxicological considerations, which will be presented. In absence of *a priori* knowledge of a material's complete chemical composition, an extractable study, nontargeted chemical analysis, and toxicological risk assessment are performed to determine whether expected or unexpected extractables (e.g., additives, degradants, or impurities) present in/on patient-contacting components of the medical device raise a toxicological concern. Nontargeted chemical analysis generally involves extracting the medical device in multiple solvents of diverse polarities, followed by use of multiple analytical instruments with appropriate sensitivity for identification and semi-quantification. Considerations of unique nontargeted analytical methods that generate data adequate for toxicological risk assessment will be presented, which include, but are not limited to, extraction method design, analytical instrument/tool selection, sample manipulation, system suitability, calibration, identification/semi-qualification, and data reporting. Case studies will demonstrate how risk assessment approaches and considerations may depend on the nature and use of different medical devices (e.g., permanent implant versus skin contact device versus indirect contact devices). The selection and application of the analytical evaluation threshold (AET) also will be discussed. Lastly, the US FDA perspective on the unique chemical/toxicological considerations that aid the analytical chemist and toxicological risk assessor in prioritizing nontargeted extractables for toxicological risk assessment also will be discussed.

1046 Extractables and Leachables Analysis of Medical Devices in a Changing Global Regulatory Environment

W. Christian. *Medtronic, Jacksonville, FL.*

The medical device industry is currently experiencing changes in the regulatory landscape with respect to biocompatibility and hazardous substances requirements, which are aimed at improved patient safety assurance for devices on the market. Recent events in which patient safety was compromised by loose regulations and testing requirements have motivated much of the present-day regulatory reform. Notable activity includes the revision of ISO 10993-1, entry into force of the European Union Medical Devices Regulation, and amendments to California Proposition 65. A common theme among the regulatory reform is the addition of requirements to understand the chemical content of medical devices and, in turn, the toxicological consequences associated with patient exposure to that chemical content. Therefore, in this dynamic regulatory environment, extractables/leachables analysis is becoming a key tool in establishing compliance, though its utility is applicable in more ways than one. An overview of the recent regulatory changes and examples of how extractables/leachables analysis can be utilized to assess patient/user exposure, justify the safety of hazardous substances within devices, verify warning label exemption, evaluate biological equivalence of predicate/proposed devices and also support supply chain controls, ensure efficient change management, and segue into modern *in silico* approaches to evaluating biocompatibility will be presented.

1047 Oligodendrocytes/Schwann Cells: Major Targets in Neurotoxicity and Neurological Diseases

H. Hogberg. *Johns Hopkins University, Baltimore, MD.*

Besides neurons, glial cells represent major targets of neurotoxicants. However, cell-based methods to assess glial toxicity are clearly underrepresented, especially when it comes to oligodendrocytes and Schwann cells. Their role is to form the myelin sheet around axons, which is crucial for neuronal function and one of the key processes in brain development. Significance of myelination cannot be understated, and any damage to myelin results in debilitating diseases. Failure to form or maintain myelin can disrupt neuronal signal transmission or trigger degradation of axons, and a reduction in the velocity of action potentials can lead to physical or mental disability and induce severe neurological symptoms. Potential mechanisms of oligodendrocyte/Schwann cell toxicity are inflammation, thyroid hormone disruption, glutamate excitotoxicity, disruption of cholinergic signaling, and oxidative stress. Moreover, several human neurologic diseases have been associated with dysfunctional oligodendrocytes and myelin deficits, such as schizophrenia, multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), periventricular leukomalacia (PVL), and chemotherapy-induced peripheral neuropathy (CIPN). Unfortunately, there is a lack of effective treatments to treat these disorders, despite decades of research using animal models in drug discovery, and pharmaceutical companies are desperately seeking new human-relevant alternatives. This Workshop will describe *in vitro* assays and nonmammalian species to assess toxicity to oligodendrocytes/Schwann cells and myelination. Moreover, the current and future use of these approaches in toxicity testing and drug discovery will be discussed with national and international perspectives from both academia and industry. The speakers have been selected to present applications of novel assays for oligodendrocyte/Schwann cells/myelination toxicity that mimic various parts of the nervous system and different developmental windows of the nervous system. The introduction will address the significance of myelination for neuronal function and how failure to form myelin and demyelination can lead to adverse outcome and disease. In addition, it will give a brief background and present the agenda of the Workshop, including the overall goals, speaker lineup, and the intended outcome. Firstly, the *in vitro* assay of oligodendrocyte differentiation and maturation from human neural precursor cells (hNPCs) and its use for developmental neurotoxicity (DNT) will be described. The second speaker will present the use of three-dimensional (3D) neural models to assess chemicals' potential to induce demyelination in the more mature central nervous system (CNS). Furthermore, the assessment of de- and remyelination of the peripheral nervous system (PNS) will be addressed using a 3D Nerve-on-a-Chip platform. The next speaker will introduce the use of the nonmammalian species *Xenopus laevis* to study demyelination-remyelination and the quantitative evaluation of behavioral perturbation after chemical exposure. The final speaker will present data on remyelination both in murine *in vivo* and *in vitro* models and describe efforts to determine the significance of these findings to a human *in vitro* model and individuals with demyelinating conditions. The main goal of the Workshop is to shed light and discuss the current status of assays for oligodendrocyte/Schwann cell toxicity and the translation to human adverse outcomes and diseases. Speakers have been encouraged to discuss their data, critical to identify gaps, limitations, and relevance to humans with their approaches. Presentations will be followed by an interactive panel discussion with the session speakers where e.g. limitations, species differences and extrapolation to the *in vivo* situation will be deliberated.

1048 The Human Oligodendrocyte Maturation Assay as a Test for Assessing Thyroid Hormone Disruption *In Vitro*

E. Fritsche. *IUF—Leibniz Research Institute for Environmental Medicine, Düsseldorf, Germany.*

Testing for developmental neurotoxicity (DNT) according to the Organisation for Economic Co-operation and Development/US Environmental Protection Agency guidelines is performed in rats. Current efforts are aiming at setting up a DNT *in vitro* battery for regulatory application that should predict DNT. One mode of action how compounds can interfere with brain development is endocrine disruption. Here, a substance interferes with the production, transport, metabolism, or target cell effects of a hormone. Because thyroid hormone (TH) is crucial for brain development, we established an assay that identifies compounds that interfere with human neural progenitor cell (NPC) or oligodendrocyte TH signaling based on TH target gene mRNA expression. We also characterized the human NPC system for expression of components of the TH pathway, like TH transporters, diodinases, TH receptors, and TH target genes. NPC possess a functional TH signaling machinery that is involved in oligodendrocyte maturation of developing NPC. This test might be used as a screening assay to identify compounds acting as TH disruptors on the

developing brain in a relative short time frame (i.e., five days *in vitro*). Added to the DNT *in vitro* testing battery, tests for endocrine disruption will increase the applicability domain of such a screening effort.

1049 Myelination as an Endpoint for (Developmental) Neurotoxicity in 3D *In Vitro* Models

H. T. Hogberg[1], M. Chesnut[1], S. Gul Akgun Olmez[1], A. Kleensang[1], D. Pamies[2], and L. Smirnova[1]. [1]*Johns Hopkins University, Baltimore, MD; and* [2]*University of Lausanne, Lausanne, Switzerland.*

There is lack of *in vitro* assays that can assess myelination, despite it being an important key process for neuronal function and neurodevelopment and a potential target for neurotoxicants. Lately, it has become evident that more complex *in vitro* cell models, such as 3D test systems, are essential to reproduce the architecture and function of the central nervous system (CNS). The 3D structure is especially crucial for the myelination, as one oligodendrocyte myelinates axons from multiple neurons. We have previously developed different 3D neural models of the CNS using gyratory shaking based on rat primary cells and human induced pluripotent stem cells (iPSC). These models have shown to be relevant for key cellular processes involved in neurodevelopment, including proliferation, differentiation, apoptosis, synaptogenesis, intracellular signaling, and network function. In addition, the models present unique features, as they have shown *de novo* myelination. Both models show increase in myelination over the time of differentiation assessed with quantitative RT-PCR and immunohistochemistry for different oligodendrocyte markers (e.g., MBP, mag, O1, and O4). In addition, 3D reconstruction of confocal z-stacks images and electron microscopy confirm the wrapping of the myelin around the axonal structures. We have exposed both models to compounds shown to induce de- and dysmyelination in animals (cuprizone, pesticides, and flame retardants) at concentrations from 0.1 to 10µM for 7-14 days. Assessment of the different oligodendrocyte markers with RT-PCR and immunohistochemistry after the exposure indicates reductions in myelin formation at noncytotoxic concentrations. These 3D models could therefore be useful tools to assess compounds that induce de- and dysmyelination and have the potential also to screen drugs for remyelination.

1050 A 3D Nerve-on-a-Chip Platform of the Peripheral Nervous System to Assess De- and Remyelination

L. Curley. *AxoSim, New Orleans, LA.* Sponsor: H. Hogberg

The use of engineered 3D organoids has seen tremendous growth as a preclinical drug screening tool because they are more biomimetic and physiologically relevant than 2D assays. When modeling complicated tissues such as the human nervous system, 3D engineered cultures provide marked advantages by recapitulating cell-cell interactions. However, a limited focus has been given to microphysiological systems that mimic peripheral nerves (PNs), even though peripheral neuropathy is implicated in numerous disease states and is a common and significant side effect of many therapies. We have devised a novel method for engineering *in vitro* human iPSC-derived and primary rat 3D nerves that support axon growth analogous to PN anatomy. This *in vitro* nerve can provide clinically relevant metrics such as nerve conduction velocity (NCV) and histological ultrastructure, which are recognized as the gold standard in evaluating peripheral neuropathy. Commonly used spheroid fabrication methods were optimized to create co-culture spheroids of human iPSC-derived neurons and primary human Schwann cells. Over four weeks, the nerves were grown in a 3D environment to remarkable lengths of 5 mm in a growth-directing dual-hydrogel scaffold. Population-level electrophysiological testing revealed the nerve conduction velocity in the biomimetic human nerve to be 0.13±0.02 m/s. Schwann cell migration, ensheathing, and myelination occurred in the co-culture spheroids as confirmed by S-100 immunostaining, and lamination seen in TEM micrographs. This microphysiological model of human peripheral nerve simulated the multifaceted physiology of peripheral nerves, such as long unidirectional axonal outgrowth, myelination, and nerve conduction, and thus can be used for modeling a variety of neuropathic conditions *in vitro*, including myelination and demyelination.

1051 A Simple and Reliable Model to Investigate Myelination, Conditional Demyelination, and Remyelination

B. Zalc. *Sorbonne Université, Paris, France.* Sponsor: H. Hogberg

We have generated a *Xenopus laevis* transgenic allowing conditional ablation of myelinating oligodendrocytes. In this MBP-GFP-NTR line the transgene, GFP reporter fused to *E. coli* nitroreductase (NTR) driven by upstream regulatory sequence of myelin basic protein, is specifically and selectively expressed in myelin forming oligodendrocytes. Since NTR converts the innocuous pro-drug metronidazole to a cytotoxin, addition of metronidazole into the aquarium water induces ablation of oligodendrocytes and demyelination. As tadpoles are transparent, demyelination can be monitored *in vivo* and quantified. For instance, in stage NF52-53 (i.e., 25 days post-fertilization) MBP-GFP-NTR transgenic tadpoles treated for 10 days with metronidazole (10 mM), the number of GFP+ cells per optic nerve significantly decreased from 13.9 + 1.0 to 2.3 + 2 ($p<0.01$). Upon cessation of metronidazole treatment (i.e., after returning tadpoles to normal water) spontaneous remyelination occurred rapidly: the number of GFP+ oligodendrocytes per optic nerve reached 8.3 + 0.9 and 13.3 + 1.5 at 3 and 8 days of recovery, respectively. We confirmed that counting the number of GFP+ cells is a reliable indicator of the extent of myelination/demyelination/remyelination by immunolabeling with myelin-specific antibodies and electron microscopy. Furthermore, we reasoned that demyelination should translate into loss of sensorimotor functions. To challenge this hypothesis, we measured the speed and distance traveled before and after demyelination and during spontaneous remyelination. In addition, to test the functional consequence of demyelination and repair of the optic tract of our transgenic tadpole, we adapted a visual avoidance paradigm, based on a virtual collision test. Quantitative evaluation of behavioral perturbation was confronted to the degree of demyelination-remyelination assayed by counting the number of GFP+ oligodendrocytes in the optic nerve.

1052 Discovery of New Therapeutic Targets for Myelin Regeneration Using Murine and Human Models

I. A. Scarisbrick[1], L. Smirnova[2], T. Hartung[2], and H. Yoon[1]. [1]*Mayo Clinic, Rochester, MN; and* [2]*Johns Hopkins University, Baltimore, MD.*

Myelin dysfunction is increasingly recognized as a prominent feature of diverse neurological conditions affecting the adult and developing central nervous system (CNS). Oligodendrocytes not only generate myelin in the brain and spinal cord thereby enhancing nerve impulse conduction, but also provide trophic and metabolic support to axons. Oligodendroglia are vulnerable to injury in multiple sclerosis and other neuropathologies, leading to conduction block, axonopathy, and permanent neurologic impairment. Although the CNS has an innate capacity for myelin regeneration, this is often incomplete, leaving axons vulnerable to degeneration. We recently discovered that the thrombin receptor, also known as Protease Activated Receptor 1 (PAR1), is rate-limiting in myelin development. Here, we will describe efforts to determine the significance of these findings to individuals with demyelinating conditions using a human 3D BrainSphere model that contains induced pluripotent stem cell (iPSC)-derived neurons, astrocytes, and myelinating oligodendroglia. In addition, we will highlight our efforts to determine if the robust promyelinating effects of blocking PAR1 function developmentally extend to myelin regeneration across both experimental murine *in vivo* and *in vitro* models, with complementary investigation of demyelination and remyelination in the human BrainSphere model. Together, results highlight the urgent need and value of utilizing experimental murine systems that harness the power of genetics in conjunction with human iPSC-derived 3D brain cultures that represent a high-throughput model for screening drug candidates and that represent the first tangible steps toward clinical translation.

1053 Toxicological Exposure and Risk Assessment of Emissions from 3D Printers

T. Thomas. *Consumer Product Safety Commission, Rockville, MD.*

3D printing, also referred to as additive manufacturing, is a rapidly growing technology that is expected to have a significant global impact on the commercialization of consumer products. 3D printers range from large industrial devices to smaller printers that are typically used in homes and schools to provide a wide range of products, including toys, shoes, electronic equipment, automobile parts, and firearms. As these devices become more ubiquitous, questions are arising regarding the health and safety implications and how to mitigate any potential health risks to 3D printer users and consumers of products manufactured through these emerging processes, especially sensitive receptors such as children. The types of base materials used in 3D

printers include thermoplastics, metals, nanomaterials, polymers, and volatile and semi-volatile organic chemicals. The printing process may take several hours, and during this time period, the base materials are subjected to high heat (e.g., 220°C), resulting in a range of chemical by-products and particulates that may be released into indoor environments. Given these unknowns, scientist have begun to conduct studies to characterize and quantity these releases and their specific composition, particle size, and residence time in the indoor environment and produce data that can ultimately be incorporated into robust exposure assessments. *In vitro* and *in vivo* studies the toxicity of the base materials and reactive by-products and particulates. This session will include leading researchers who are conducting critical investigations into the release of compounds of concern from 3D printers and their toxicity potential. This Workshop session will provide an overview of additive manufacturing/3D printers and some key factors associated with these devices that may impact release of and exposure to chemicals of concern. Included in this analysis is the impact of device- and feedstock-related factors that influence emissions, providing important insights on exposure potential, efficacy of control technologies, and design of experimental toxicology studies. The session will describe the impact of ABS thermoplastic emissions on the pulmonary system of rats and their implications for human health, in addition to the release of volatile organic compounds (VOCs) as well as particles and the need to mitigate exposures to these compounds.

1054 Inhalation Toxicity of Acrylonitrile Butadiene Styrene (ABS) 3D Printer Emissions in Rats

M. Farcas. *NIOSH, Morgantown, WV.*

Fused filament fabrication 3D printing with acrylonitrile butadiene styrene (ABS) filament emits billions of particles and numerous volatile organic compounds (VOCs). This study sought to investigate the toxicity of ABS emissions from a 3D printer both *in vivo* and *in vitro*. For the *in vivo* studies, Sprague Dawley rats were exposed to real-time ABS printing emissions or air (control) for 4 h/day, 4 days/week for 1, 4, 8, 15, and 30 days. The average aerosolized particle concentration was 0.24 ± 0.09 mg/m^3, and the average median particle electric mobility diameter was 85 nm with an average geometric standard deviation of 1.6. Benzene was the predominant VOC released during printing. At 24 h after the last exposure, rats were assessed for pulmonary injury, inflammation, and oxidative stress as well as systemic and other organ toxicity. Results showed that among the measured cytokines in bronchoalveolar lavage, only IL-10 and IFN-γ at day 1 and 4, and IL-13 at day 30, of the exposure were increased when compared with the air-control. Moreover, neither pulmonary oxidative stress responses nor histopathological changes of the lungs were found among the exposed rats. There were no significant differences in serum cytokines levels or hematological indices, except for an increase in platelets and monocytes at day 15. Several serum biomarkers involved in liver damage were significantly higher at day 1 of the exposure. For the *in vitro* study, both particles and VOCs were collected into serum-free cell culture medium using an impinger sampler inside a chamber while printing for 1.5 h, followed by characterization of the physicochemical properties, as well as assessment of cytotoxicity, oxidative stress, and cytokine production in human small airway epithelial cells (SAEC). Results showed that particle numbers and VOC concentrations varied between print runs. Based on mixed model regression analyses, at 24 h post-exposure, ABS emissions induced significant dose-dependent cytotoxicity, oxidative stress, and production of proinflammatory cytokines in SAEC. In conclusion, our *in vitro* studies indicated that the emissions from ABS 3D printing induced toxicological effects, which were not substantiated by the *in vivo* studies with the current low exposure concentrations. Thus, more *in vivo* studies with higher dose-response are needed to verify the *in vitro* findings.

1055 3D Printer Emission Inhalation Impairs Systemic Microvascular Function

T. Nurkiewicz. *West Virginia University, Morgantown, WV.*

We have previously reported that inhalation exposure to a variety of xenobiotic particles attenuates arteriolar dilation in the periphery and initiates an inflammatory response characterized by increased leukocyte trafficking. Three-dimensional printing has become routine in industrial, occupational, and domestic environments. Significant amounts of respirable emissions (3DPE) result from this process. We hypothesized that because both particles and gases are generated by this process, that after 3DPE inhalation exposure, the resultant systemic microvascular impacts would be more robust. Sprague Dawley rats were exposed to acrylonitrile butadiene styrene (ABS) 3DPE via whole body inhalation. The exposure parameters were: [3DPE] = 250 µg/m3; 4 hr/exposure; 1-30 days of exposure. The 3DPE mass median aerodynamic diameter was ~45 nm. This produced five calculated target 3DPE total lung burden groups: 2, 8, 16, 30, and 60 µg. Sham-control rats were exposed to filtered air only. Twenty-four hours after the last exposure, rats were anesthetized, and the mesentery was harvested for microvessel isolation. Second- and third-order arterioles were dissected and mounted on glass pipettes, perfused, and pressurized to assess endothelium-dependent (acetylcholine, ACh) and -independent (S-Nitroso-N-acetyl-DL-penicillamine, SNAP) vasoreactivity. Compared with sham-controls, 3DPE inhalation significantly attenuated arteriolar responsiveness to both ACh and SNAP. This was evident in a dose-response manner, and responsiveness was maximally inhibited at the 16 µg/rat lung burden. This 3DPE burden is ~50% less than that for a comparable effect after nano-titanium dioxide inhalation exposures. These results collectively support the notion that 3DPE inhalation exposures cause systemic microvascular dysfunction.

1056 Release of Aerosols from Fuse-Deposition Modeling 3D Printers and Associated Human Exposure

S. Patel. *University of Colorado Boulder, Boulder, CO.* Sponsor: T. Thomas

Owing to a range of factors such as advancement in technology and increased affordability, 3D printers are gaining significant attention and popularization as a consumer product. Although there are many different techniques under the 3D printing definition, fuse-deposition modeling (FDM) consists of running a polymeric filament through a heated nozzle that moves to create the layers of a three-dimensional object. The high temperature of this nozzle causes gaseous and particulate air pollutants to be emitted in indoor environments, with compositions and concentrations that can vary significantly depending on the type of filament, nozzle temperature, printer type, and indoor environment characteristics, such as room size and ventilation rate. Another sparsely explored topic is the fundamental aerosol dynamics underlying particulate matter formation and growth during 3D printer operation, which is limited by instrumentation capability to measure the lower end of the particle size distribution. The objective of this work was to characterize aerosol emissions from the operation of a fuse-deposition modeling 3D printer. We characterized particle size distributions, optically absorbing particulate matter (PM), and total non-methane hydrocarbon emissions from a 3D printer in a chamber using a 1 nm SMPS, five wavelength aethalometer, and a flame-ionization detector, respectively. Effects of filament type on PM characteristics, emission rates, and emission factors were established. Our previous work showed that average aerosol emission rates ranged from ~108 to ~1,011 particles min-1, and rates varied over the course of a print job. Acrylonytrile-butadiene-styrene (ABS) filaments generated the largest number of aerosols, and wood-infused polylactic acid (PLA) filaments generated the smallest amount. Emission factors ranged from 6×108 to 6×1011 per gram of printed part, depending on the type of filament used. Ongoing work includes the application of a numerical model for particle formation (via nucleation) and growth to the experimental data for the estimation of the physical parameters of the semi-volatile emissions from different types of filaments. Lastly, model results will be used to estimate PM levels and resultant exposure when the same 3D printer is used in built environments with varying physical and ventilation characteristics.

1057 Factors Influencing Emissions from 3D Printers

A. Stefaniak. *NIOSH, Morgantown, WV.* Sponsor: Y. Qian

Additive manufacturing (AM), more commonly referred to as 3D printing, refers to several types of technologies that build physical objects layer by layer from a computer file. While some AM technologies remain limited to industrial settings, others, such as fused filament fabrication (FFF) and vat polymerization (VP), are relatively inexpensive and becoming more commonplace in homes, schools, libraries, and other nonindustrial settings. During operation, FFF and VP 3D printers emit particles and organic vapors. On a number basis, particles are dominated by ultrafine sizes (<100 nm) which can deposit in the lung alveoli. Organic vapors include compounds with known inhalation and dermal effects, including immune sensitization and toxicity. Both *in vitro* and *in vivo* data indicate that emissions may cause adverse health effects, including cytotoxicity and cardiovascular effects. Emissions are influenced by device-related (technology type, design, printing parameters) and feedstock-related (physical form, chemistry) factors. This presentation will summarize results from several years (and ongoing) of research on 3D printer emissions. Systematic investigation of device- and feedstock-related factors that influence emissions provides important insights on exposure potential, efficacy of control technologies, and design of experimental toxicology studies.

1058 Emissions from Consumer-Level 3D Printers

Q. Zhang. *Underwriters Laboratories (UL) Inc., Atlanta, GA.* Sponsor: Y. Qian

Consumer-level fused filament fabrication (FFF) 3D printers are widely used in small-scale indoor environments and public spaces. Therefore, concern of potential health impacts of emissions from 3D printers has been raised, especially for vulnerable populations such as children. This study systematically characterized particle and volatile organic compound (VOC) emissions from multiple 3D printers using a standard test method. We found that 3D printing emits high concentrations of particles (especially ultrafine particles) and VOCs, the levels of which were associated with different print conditions like extrusion temperature, filament material, printer brand, filament brand, and color. The particle chemical compositions of 3D printer-emitted particles were similar to or different from the bulk filament material, indicating particle formations associated with the bulk material or additives in filament. A chemical assay (dithiothreitol, DTT) was applied to estimate oxidative potential of the particles emitted from 3D printers; exposure levels of some VOC species also were predicted using a model. Overall, emissions from 3D printing should be mitigated.

1059 The Role of LCN2 in Modulating the Inflammatory and Regenerative Pathways in APAP-Induced Acute Liver Failure

L. E. Mathew, S. Taval, and V. S. Bhave. *Philadelphia College of Osteopathic Medicine, Suwanee, GA.*

Acetyl-para-aminophenol (APAP, Tylenol) is a commonly used analgesic medication that can be found as the main ingredient in over 600 different OTC and prescription medications. APAP overdose is one of the most common causes of acute liver failure (ALF) in USA. Following bioactivation by CYP3A4 and CYP2E1 enzymes, APAP generates a reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI). Under normal doses, this reactive metabolite gets quenched into a non-toxic metabolite by cellular glutathione. However, following an overdose, the unquenched NAPQI covalently binds to liver macromolecules and causes centrilobular necrosis and sterile inflammation. Lipocalin-2 (LCN2) is an acute phase innate immune protein induced in the liver following injury. Recent data from our lab show that LCN2 KO mice are protected from ALF caused by APAP overdose when compared to WT mice. This protection was not due to differences in bioactivation based events but rather significantly less hepatocellular damage (histopathology and ALT) and higher liver regeneration (PCNA) at later stages (24-48h) post APAP overdose. Furthermore, we also demonstrated that LCN2 KO mice undergo increased autophagy as compared to WT mice. Preliminary studies done in our lab investigated the role of IL-17α and LCN2 in an APAP overdose model using enzyme linked immunosorbent assay (ELISA). This study found that LCN2 KO mice induced more IL-17α at 24 hours which correlated with the time point that showed a decrease in liver injury between WT and LCN2 KO mice. Our research suggests that regenerative pathways involving IL-17α may be inhibited in the presence of LCN2. The objective of this study is to investigate the mechanism of how LCN2 contributes to progression of injury in ALF. We hypothesize that LCN2 modulates the inflammatory and regenerative pathways via cytokines, prostaglandins and lipoxygenase pathways. The inflammation pathway will be investigated by measuring levels of 5-lipoxygenase and IL-1alpha in WT and LCN2 KO mice through ELISA. Prostaglandin E2 and IL-10 levels will be measured as anti-inflammatory markers. Regeneration pathways will be investigated by measuring levels of cyclooxygenase-2 (COX2), IL17α, and KI67 in WT and LCN2 KO mice. Findings from this study will identify a novel pathway in progressive phase of injury involving LCN2 and could potentially recognize targets for slowing down or inhibiting the progressive phase of liver injury that leads to ALF due to APAP overdose.

1060 Transfer of Hepatocellular microRNA Regulates Cytochrome P450 Enzymes in Renal Tubular Cells

O. F. Matthews[1], E. E. Morrison[1], J. D. Tranter[1], P. Starkey Lewis[1], K. Park[2], N. C. Henderson[1], D. Williams[3], and J. W. Dear[1]. *[1]University of Edinburgh, Edinburgh, United Kingdom; [2]University of Liverpool, Liverpool, United Kingdom; and [3]AstraZeneca, Cambridge, United Kingdom.*

MicroRNA is released from cells injured by drug toxicity. In this study we tracked the transfer of the hepatocyte-specific microRNA, miR-122, between organs. Our hypothesis was that miR-122 will be transferred from liver to kidney as it is known that the kidney tubules can internalise microRNA containing extra-cellular vesicles. Dicer$^{flox/flox}$ mice were treated with an hepatotropic Cre recombinase-expressing adenovirus (AAV8-Cre) to inhibit microRNA production selectively in hepatocytes (conditional KO (CKO)). MicroRNA expression was analysed by PCR ± FACS sorting and by *in situ* hybridisation, with and without liver injury induced by acetaminophen (150mg/kg and 300mg/kg). A murine model of myocardial infarction was used as a non-hepatic model of microRNA release secondary to tissue injury. To determine the functional consequences of miR-122 transfer we measured the RNA and protein expression and drug metabolising activity of cytochrome P450 2E1 (established miR-122 target and key enzyme responsible for acetaminophen toxicity). In humans we measured microRNA expression in urinary extra-cellular vesicles. Dicer CKO mice had a time-dependent decrease in liver miR-122 (4 weeks post AAV8-Cre treatment, % of baseline miR-122: median 3% (IQR 2 - 6) N=20 P<0.0001). This was accompanied by a substantial decrease in kidney miR-122 (5% of baseline (IQR 2 - 7) N=20 P=0.007) without a change in kidney Dicer expression or other kidney microRNA species. There was no change in Dicer or microRNA in heart, lung or brain. Liver injury increased kidney miR-122 (9.5 fold increase, N=5, P=0.008); this increase was abolished in the Dicer CKO mouse (14 fold difference when AAV8-Cre compared to AAV8-null after 300mg/kg acetaminophen, N=5, P=0.008). FACS sorting demonstrated miR-122 uptake selectively into kidney tubular epithelial cells. Cardiac injury released circulating miR-499, which was also increased in the kidney. Depletion of hepatocyte miR-122 increased CYP2E1 expression and activity in the liver and kidney (2 fold increase in kidney mRNA expression, N=5, P=0.008). In human acetaminophen-induced hepatotoxicity, miR-122 was substantially increased in urinary extra-cellular vesicles (~500 fold). In summary, in normal physiology miR-122 is transferred from liver to kidney and this signalling pathway is up-regulated following hepatotoxicity. Kidney enzyme regulation by liver microRNA represents a new paradigm in drug metabolism.

1061 Mitochondrial Genetics Confer Differences in Susceptibility to Tolcapone Toxicity

S. L. Penman[1], P. Sharma[1], B. Park[1], R. J. Weaver[2], and A. E. Chadwick[1]. *[1]University of Liverpool, Liverpool, United Kingdom; and [2]Institut de Recherches Internationales Servier, Suresnes, France.* Sponsor: R. Weaver, EUROTOX

Idiosyncratic drug-induced liver injury (iDILI) has the potential to pose significant risk to patient health. Tolcapone, was developed for the treatment of Parkinson's disease but was withdrawn from the market due to cases of acute liver failure. Tolcapone is also a known mitochondrial uncoupler. Drug-induced mitochondrial toxicity (DIMT) is an important determinant of iDILI and differences in mitochondrial DNA (mtDNA) could account for the interindividual variation associated with iDILI. Therefore, transmitochondrial cybrids were employed to quantify the effect of mitochondrial haplogroup upon cell sensitivity to tolcapone and also to elucidate the mechanisms underlying such effects. Transmitochondrial cybrids were generated by fusing HepG2 rho-zero cells (devoid of mtDNA) with fresh platelets of a known mtDNA haplogroup, as anucleate mitochondrial donors. Cybrids allow the effects of mtDNA to be assessed against a stable nuclear background. Initial research employed the acute metabolic modification assay to compare the sensitivity of cybrids belonging to haplogroup H and J against HepG2 cells (haplogroup B). Subsequently, further mechanistic investigations were performed including changes in mitochondrial membrane potential (MMP), superoxide levels, mitochondrial morphology and dynamics. Comparison of the IC_{50}ATP values after 2 hours revealed that haplogroup J was significantly more susceptible to tolcapone-induced ATP depletion than haplogroup H (77.8 μM vs. 119.6 μM). Haplogroup J was also more susceptible to MMP loss in both whole cells and isolated mitochondria. However, following 24 hours, haplogroup H was more susceptible to tolcapone-induced ATP depletion than haplogroup B (39.1 μM vs. 86.2 μM). There was a significant difference between the IC_{50}ATP values at 2 hours and 24 hours for haplogroup H but not for haplogroup J and B. Overall, this research has shown that there are complex mechanistic differences in the susceptibility to tolcapone-induced toxicity dependent on mitochondrial haplogroup. The elucidation of compensatory mechanisms of mitochondrial protection within certain haplogroups has the potential to revolutionise Parkinson's disease via the stratification of tolcapone treatment. This mechanistic knowledge is not only valuable for Parkinson's disease but for all testing in which mitochondrial toxicity has been identified.

1062 Sex Differences in Bile Acid Metabolism

D. Rizzolo, B. Kong, A. Brinker, B. Buckley, and G. Guo. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Bile acids (BAs) are diverse signaling molecules that play important roles in lipid and glucose homeostasis, energy expenditure, inflammation, liver and gastrointestinal functions, and bacterial proliferation. There are currently over 30 different BA species known in humans and rodents. These BAs are

capable of interacting to varying degrees with many different receptors, including the farnesoid X receptor (FXR), vitamin D receptor, pregnane X receptor, G protein-coupled BA receptor 1, and sphingosine 1-phosphate receptor 2. However, the full functions of each individual BA *in vivo* remain unclear. Cyp7a1 and Cyp27a1 initiate the two main pathways of BA synthesis, the classical and the acidic pathways, respectively. We have previously reported on the generation and phenotypical characterization of male mice lacking these two key enzymes (double knockout---DKO) by crossbreeding *Cyp7a1*$^{-/-}$ and *Cyp27a1*$^{-/-}$ mice. These mice could be very valuable for the investigation of the differential functions of individual BA species *in vivo*. In order to assess any pharmacological or toxicological differences between sexes in BA signaling, we now characterized female mice deficient in genes *Cyp7a1* and *Cyp27a1*. In the current study, plasma, liver, gallbladder, and intestines were collected from 3-4 month old female wild type (WT), *Cyp7a1*$^{-/-}$, *Cyp27a1*$^{-/-}$, and DKO mice for LC-MS analysis of BA profiles. Additionally, mice were treated with GW4064, a synthetic FXR agonist, to determine if the DKO female mice had an altered responsiveness to FXR activation. We have found that female WT mice had significantly higher plasma BAs than their male counterparts, which is in line with known sex differences. Female *Cyp7a1*$^{-/-}$, *Cyp27a1*$^{-/-}$, and DKO mice had reductions in plasma BAs of 65.9%, 83.1%, and 62.9% respectively, as compared to WT mice. Despite having significantly less BAs than female WT mice, female DKO mice did not have a significant difference in hepatic mRNA expression of genes involved in BA synthesis (Cyp7b1, Cyp8b1), transport (*Slc10a1*, *Abcb11*), or regulation (Shp, Fxrα). Additionally, DKO mice maintained responsiveness to FXR agonism as measured by the mRNA expression of classical FXR response genes (Cyp8b1 and Shp). In summary, the two genes, *Cyp7a1* and *Cyp27a1*, are critical in both male and female mice for BA homeostasis. Together with the male DKO mice, the characterization of female DKO mice can provide a useful tool in the investigation into the differential effects of individual BAs between sexes. *Funding: NIH ES029258, ES007148, DK122725.*

1063 Protease-Activated Receptor-1 Expressed by Hepatic Stellate Cells Drives Coagulation Activation and Fibrosis in Experimental Chronic Liver Injury

L. G. Poole[1], K. S. Baker[1], A. Pant[1], H. M. Cline-Fedewa[1], B. L. Copple[1], R. F. Schwabe[2], J. S. Palumbo[3], and J. P. Luyendyk[1]. *[1]Michigan State University, East Lansing, MI; [2]Columbia University Irving Medical Center, New York, NY; and [3]Cincinnati Children's Hospital Medical Center, Cincinnati, OH.*

Chronic hepatic injury is associated with activation of blood coagulation. Prior studies suggest that activation of coagulation leads to increased thrombin activity, which in turn drives hepatic fibrosis by activating protease-activated receptor-1 (PAR-1) expressed by stellate cells. However, because PAR-1 is expressed by numerous cell types, the specifics of this pathway are largely assumed. We used novel mice to define the precise role of PAR-1 expressed by stellate cells in experimental hepatic fibrosis. Male mice with a stellate cell-specific deletion of PAR-1 (PAR-1$^{flox/flox}$/LRATCre mice) and wild-type littermates (PAR-1$^{flox/flox}$) were challenged twice weekly with carbon tetrachloride (CCl_4, 1 mL/kg i.p.) for 6 weeks. Stellate cell activation and hepatic fibrosis, indicated by α-smooth muscle actin (αSMA) labeling and hepatic collagen staining, were significantly reduced in PAR-1$^{flox/flox}$/LRATCre mice. Importantly, the reduction in fibrosis was not explained by differences in acute CCl_4-induced hepatocellular necrosis. However, to our surprise, stellate cell PAR-1 deficiency dramatically reduced coagulation activation after CCl_4 challenge, as indicated by plasma thrombin-antithrombin complex levels. Consistent with the literature, stimulation of isolated wildtype mouse hepatic stellate cells with PAR-1 agonist peptide had only modest effect on markers of myofibroblast transition. However, PAR-1 activation caused robust induction of mRNA encoding tissue factor (TF), the primary activator of blood coagulation. This effect was synergistically enhanced by treatment with the profibrogenic mediator transforming growth factor-β1. Furthermore, PAR-1 agonist peptide significantly increased TF procoagulant activity in cultured stellate cells. The results are the first to definitively document a role for hepatic stellate cell PAR-1 in experimental hepatic fibrosis. Moreover, the results suggest a novel mechanism whereby stellate cell PAR-1 amplifies intrahepatic coagulation by upregulating TF expression.

1064 An Endocrinized Fibroblast Growth Factor 1 Variant Reverses Nonalcoholic Fatty Liver Disease via Activating AMPK in Type 2 Diabetes

Q. Lin, P. Epstein, L. Cai, and Y. Tan. *University of Louisville, Louisville, KY.*

Nonalcoholic fatty liver disease (NAFLD) is common in type 2 diabetes (T2D) patients. Our recently engineered FGF1 partial agonist (FGF1$^{\Delta HBS}$) exhibits reduced proliferative potential, while preserving the full metabolic activity of native FGF1. This study showed that administration of FGF1$^{\Delta HBS}$ to 2-month-old db/db mice for 2 months lowered blood glucose, improved insulin sensitivity, lowered liver weight, lipid deposition, and inflammation and improved liver function. Simultaneously, FGF1$^{\Delta HBS}$ prevented diabetes-induced oxidative stress, promoted nuclear translocation of antioxidant transcription factor Nrf2 and elevated downstream antioxidant genes. In addition, FGF1$^{\Delta HBS}$ inhibited activity and/or expression of hepatic lipogenic genes SREBP-1, FAS and SCD-1. Furthermore, FGF1$^{\Delta HBS}$ restored hepatic fatty acid oxidation signaling including elevated CPT-1α, PPARα and PGC-1α, increased phosphorylation of AMPK along with AMPK substrates ACC1 and SREBP1. This demonstrates association of FGF1$^{\Delta HBS}$ modified lipid metabolism with activation of AMPK signaling. Mechanistically, hepatic cells treated with palmitate mimicked T2D phenotype of hepatic oxidative damage and lipid disorder, all of which could be reversed by supplementing cells with FGF1$^{\Delta HBS}$. Nrf2 knockdown by SiRNA abolished anti-oxidative actions of FGF1$^{\Delta HBS}$ but did not affect FGF1$^{\Delta HBS}$ actions on lipid metabolic disorder. Whereas, AMPK inhibition, using Compound C or SiRNA knockdown, abolished both the ability of FGF1$^{\Delta HBS}$ to prevent lipid metabolic disorder and produce antioxidative protection. Remarkably, 3 months administration of FGF1$^{\Delta HBS}$ to 9-month-old db/db mice completely reversed late NAFLD and activated Nrf2 and AMPK pathways. Most importantly, liver-specific AMPK knockout almost completely abrogated the preventive effects of FGF1$^{\Delta HBS}$ on NAFLD induced by HFHS diet. Our findings indicate that in addition to glucose-lowering and insulin-sensitizing effects, FGF1$^{\Delta HBS}$ can reverse NAFLD in T2D by activating AMPK, which prevents hepatic lipotoxicity by inhibiting lipogenesis and activating lipid oxidation.

1065 Human CYP2B6 Is an Anti-Obesity Enzyme That Produces Active *a*-Linolenic Acid Metabolites

M. M. Heintz, E. M. Olack, and W. S. Baldwin. *Clemson University, Clemson, SC.*

Multiple factors in addition to overconsumption are believed to lead to obesity and non-alcoholic fatty liver disease (NAFLD) in the United States and elsewhere. Cyp2b-null mice that lack the primarily hepatic Cyp2b enzymes are diet-induced obese, primarily due to increased white adipose tissue, but also contain increased liver triglycerides. Therefore, studies were undertaken to determine whether human CYP2B6 is anti-obesogenic and a putative mechanism. Vivid human CYP2B6 recombinant enzyme was used to determine inhibitors of CYP2B6. Several polyunsaturated fatty acids (PUFAs) including arachidonic acid, linoleic acid, DHA, and α-linolenic acid (ALA) were inhibitors with EC50's below 10μM. LC-MS/MS revealed that CYP2B6 metabolized all PUFAs tested; however, there was a greater than 20-fold preference for metabolism of to 9-HOTre and to a lesser extent 13-HOTre, monohydroxylated products of ALA. This data indicates that CYP2B6 metabolizes a specific PUFA (α-linolenic acid) to a specific metabolite (9-HOTre) with unknown function. Interestingly, cellular incorporation of Nile Red, a triglyceride sensor, is greater in ALA-treated CYP2B6-transfected HepG2 cells than untransfected HepG2 cells, indicating that metabolism of ALA by CYP2B6 increases hepatic lipid accumulation, the opposite of what was expected. Increased lipid localization in ALA-treated CYP2B6-HepG2 cells was confirmed and quantified using confocal microscopy. We recently developed a humanized CYP2B6 mouse on our Cyp2b-null background and provided a 60% high-fat diet to hCYP2B6-Tg and Cyp2b-null mice for 16 weeks. The presence of CYP2B6 reduced weight gain and metabolic disease as measured by glucose tolerance tests, however hCYP2B6-Tg male mice showed increased liver triglycerides, consistent with the data described in the CYP2B6-HepG2 cells. Currently, we are identifying changes in serum oxylipins and hepatic ALA metabolism between hCYP2B6-Tg and Cyp2b-null mice. In addition, several pharmaceuticals and environmental chemicals were screened using the Vivid CYP2B6 recombinant enzyme. Triclosan, diazinon, endosulfan, atrazine, ticlopidine, parathion, chlorpyrifos, jet fuel, nonylphenol, and others were found to be CYP2B6 inhibitors. Overall, this study defines a mechanism by which chemical inhibition of CYP2B6 can increase diet-induced obesity and metabolic disease through reduced production of ALA metabolites and disruption of lipid distribution between the liver and other tissues.

1066 The Sulfate Metabolite of 3,3′-Dichlorobiphenyl (PCB-11) Impairs Cyp1a Activity and Increases Hepatic Neutral Lipids in Zebrafish Larvae (*Danio rerio*)

M. A. Roy[1], P. R. Duche[1], K. C. Hornbuckle[2], and A. R. Timme-Laragy[1].
[1]University of Massachusetts Amherst, Amherst, MA; and [2]University of Iowa, Iowa City, IA.

3,3′-Dichlorobiphenyl (PCB-11) is a lower-chlorinated PCB congener byproduct of diarylide pigment manufacturing, and PCB-11 and its metabolites are detected in human samples. Zebrafish (*Danio rerio*) embryo exposures to 20 µM PCB-11 impair lipid metabolism-related genes, and in co-exposures with the polycyclic aromatic hydrocarbon (PAH) benzo[a]pyrene (B[a]P) inhibits Cyp1a function to exacerbate cardiovascular and craniofacial malformations. In this study, two prevalent PCB-11 metabolites, OH-PCB-11 and PCB-11-Sulfate, were tested in acute exposures to understand if they drive Cyp1a effects observed with PCB-11, and in low concentration chronic exposures to understand if they increase hepatic neutral lipid accumulation. In acute experiments, wildtype AB embryos were statically exposed to 0.02-20 µM OH-PCB-11 or 0.2-20 µM PCB-11-Sulfate from 1-4 days post fertilization (dpf) and the EROD bioassay was used to assess Cyp1a activity, with and without co-exposures to 100 µg/L B[a]P. In chronic experiments, fish were exposed to 0.2 µM of either parent or metabolite compounds from 1-15 dpf, and in a subsequent experiment co-exposed to 10 µg/L B[a]P and 0.002-0.2 µM PCB-11-Sulfate; survival, larval growth, and hepatic lipid accumulation was assessed using Oil-Red-O staining. For acute experiments, 2 and 20 µM OH-PCB-11 was lethal, but fish exposed to 0.02-0.2 µM OH-PCB-11 and 0.2-20 µM PCB-11-Sulfate developed normally with low Cyp1a activity. In co-exposure experiments, 20 µM PCB-11-Sulfate significantly lowered the Cyp1a activity of B[a]P, and these fish developed normally. For chronic experiments, lipid accumulation was significantly increased 30% in fish exposed to 0.2 µM PCB-11-Sulfate, and a trend towards a dose-dependent increase in lipid accumulation was observed in co-exposures with PCB-11-Sulfate and B[a]P, though not statistically significant. These findings indicate OH-PCB-11 is more acutely toxic than PCB-11-Sulfate, but that PCB-11-Sulfate can affect Cyp1a activity and increase hepatic neutral lipid accumulation. Further long-term hepatic studies would better elucidate the effects of this emerging contaminant, particularly in the context of environmentally-relevant mixtures.

1067 Health Effects from Freshly Emitted versus Oxidatively or Photochemically Aged Air Pollutants

C. A. Weitekamp[1,2], T. Stevens[1], M. Stewart[1], P. Bhave[1], and M. I. Gilmour[1].
[1]US EPA, Research Triangle Park, NC; and [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN.

Epidemiology studies over the past five decades have provided evidence that exposure to air pollution is associated with multiple adverse health outcomes, including increased mortality. Air pollution is a complex mixture of particles, vapors and gases emitted from natural and anthropogenic sources as well as formed through photochemical transformation processes. In metropolitan areas, air pollutants from combustion emissions feature a blend of emitted particles, oxides of carbon, sulfur and nitrogen, volatile organic compounds (VOCs), and secondary reaction products, such as ozone, nitrogen dioxide, and secondary organic aerosols. Since many of the primary and transformed pollutants track together, their relative contributions to health outcomes are difficult to disentangle. Aside from the criteria pollutants ozone and nitrogen dioxide and some of the simpler aldehydes (e.g. formaldehyde and acrolein), other products from photochemical processes are a particularly vexing class of chemicals to investigate since they comprise a dynamic ill-defined complex mixture in both particulate and gas phases. The purpose of this poster is to describe and compare health effects of freshly emitted versus oxidatively or photochemically aged air pollutants from existing literature. In some cases, (e.g. single VOCs) photochemical transformation resulted in marked enhancements in respiratory toxicity and mutagenicity through formation of both known and unidentified reaction products, while in other examples (e.g. aging of automobile emissions) the potentiation of respiratory and cardiovascular effects was variable. The variation in experimental design, aging system used, concentration and type of starting agent, and toxicity endpoints make comparisons between different studies exceedingly difficult. A more systematic approach with a greater emphasis on higher throughput screening and computational toxicology is needed to fully answer under what conditions oxidatively- or photochemically-transformed pollutants elicit greater health effects than primary emissions. *The views presented in this document are those of the authors and do not necessarily represent the views or policy of the US EPA.*

1068 Volatile Organic Compound Exposures Are Positively Associated with Liver Apoptosis in a Residential Cohort

T. C. Gripshover, D. W. Riggs, B. Wahlang, S. E. Smith, T. V. Krivokhizhina, R. J. Keith, C. J. McClain, S. Srivastava, A. Bhatnagar, and M. C. Cave.
University of Louisville, Louisville, KY.

More data are required on the potential impact of volatile organic compound (VOC) exposures on liver health in community residents. The actively enrolling Health Environment and Action in Louisville (HEAL) study will determine associations between residential VOC exposures and cardiometabolic syndrome. The objective of this interim cross-sectional analysis of the first 391 HEAL subjects is to determine associations between urinary VOC metabolites (exposure biomarkers) and the circulating hepatocyte apoptosis biomarker, caspase-cleaved keratin 18 (K18 M30, disease biomarker). Consenting subjects were enrolled in HEAL. Serum K18 M30 (normal cutoff <200 U/L) was determined by ELISA. 15 creatinine-adjusted urinary metabolites of 10 parent VOCs were measured by UPLC-MS^2. Generalized linear models were used to test for associations between disease and exposure biomarkers. Final models were adjusted for race, BMI, alcohol use, cotinine-confirmed smoking status, and education level. Interactions were included in the models, followed by subgroup analysis to determine whether associations were modified by demographic characteristics. Final results are presented as % change (95% CI) per interquartile range of VOC metabolite. Results: Mean age was 50.3±12.0 (SD). Mean BMI was 29.9±6.1 kg/m^2. The cohort was 57.8% female, 78.5% white and 22.0% diabetic. Elevated K18 M30 was present in 12.3% of participants. K18 M30 was positively associated with 4 urinary VOC metabolites corresponding to acrolein (3HPMA); acrylamide (AAMA); and 1,3-butadiene (DHBMA and HPMMA) exposures. These associations were modified by sex and by race for three of the four significant VOC metabolites each; and were more positive in males and whites. This interim analysis demonstrated positive associations between specific VOC exposures and hepatocyte apoptosis in the residential HEAL cohort. Race and sex modified these effects. The role of VOC exposures in metabolic liver diseases warrants further investigation. HEAL is still recruiting and all subjects will be analyzed in the future.

1069 *Caenorhabditis elegans* as a Sensor of Urban Dust Toxicity in a Caribbean City

J. Osorio-Martinez, and J. Olivero-Verbel. *Universidad de Cartagena, Cartagena, Colombia.*

Toxic substances from various sources can be associated with the surface of particulate matter suspended in air, forming a heterogeneous mixture that settles as dust. Fine particles of urban dust have high environmental mobility and elevated adsorption capacity for pollutants, representing a hazard health for residents. The objective of this study was to evaluate the toxic effects of sedimented dust extracts from the urban area of Barranquilla (Colombia), the largest Colombian Caribbean city, in *Caenorhabditis elegans*. Urban dust samples (<75 µm) were collected at thirty-five points distributed in five localities, including industrial areas, ports, and high traffic. Aqueous extracts (K-medium) were obtained from dust particles and evaluated on the nematode, measuring lethality, growth, locomotion, and gene expression with GFP transgenic strains. Mercury was determined by direct Hg analysis. Urban dust extracts induced a maximum lethality of 98.8%, with greater toxicity in areas known as Riomar, Metropolitana and Suroriente. Interestingly, nematode size increased in 71.4% of the samples, while locomotion was inhibited up to 61.8%. The highest expression of *mtl*-2, *sod*-4, and *unc*-25 genes was observed after 6 h of exposure. The concentration of Hg ranged between 5 and 139 ppb; however, it did not correlate with any biological output. Lethality displayed a positive association with gene expression for *mtl*-2 ($r = 0.337$, $p = 0.048$) and *unc*-25 ($r = 0.411$; $p = 0.014$), and a negative correlation with locomotion ($r = -0.336$, $p = 0.049$) and growth ($r = -0.523$, $p < 0.01$). In short, *C. elegans* is a sensitive organism capable of responding to the exposure of urban dust particle extracts, being a suitable biosensor for the implementation of warning systems associated with human health risks linked to air pollution. *Colciencias-Unicartagena, 785-2017. Vice-Rectory for Research, 2018-2019.*

1070 Potential Role of Ferroptosis in Toxicity Induced by 9,10-Phenanthrenequinone in Human Lung Epithelial Calu-1 Cells

Y. An[1], Y. Jan[1], D. E. Heck[2], D. L. Laskin[1], and J. D. Laskin[1]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; and [2]New York Medical College, Valhalla, NY.*

9,10-Phenanthrenequinone (9,10-PQ), which is a redox-active polycyclic aromatic hydrocarbon found in diesel exhaust particles and cigarette smoke, plays a crucial role in the adverse health effects triggered by air pollution. The toxicity of 9,10-PQ has been associated with the generation of reactive oxygen species (ROS) via the process of redox cycling. In the present studies, we investigated mechanisms of 9,10-PQ induced toxicity in human lung epithelial Calu-1 cells. 9,10-PQ treatment caused a time- and concentration-dependent decrease in cell viability. This was associated with a decrease in intracellular glutathione (GSH) and glutathione peroxidase (GPX) activity, 9,10-PQ caused an increase in the ratio of GSSG to GSH. 9,10-PQ also increased levels of intracellular ROS and lipid peroxidation products in a concentration- and time-dependent manner, as measured by the CM-H_2DCFDA and BODIPY assays, respectively. These data indicate that 9,10-PQ caused oxidative stress in Calu-1 cells. N-acetyl cysteine (NAC) and β-mercaptoethanol (β-ME) pretreatment inhibited 9,10-PQ induced ROS generation and partially suppressed 9,10-PQ-induced cell death. Regulated cell death characterized by the iron-dependent accumulation of lipid peroxides, referred to as ferroptosis. Ferrostatin-1, a lipid ROS scavenger and specific inhibitor of ferroptosis, and deferoxamine mesylate (DFO), an iron (III) chelator, were found to decrease 9,10-PQ induced ROS production and protect Calu-1 cells from toxicity. In contrast, z-VAD-FMK, a pan-caspase inhibitor, had little or no effect on 9,10-PQ toxicity, indicating caspase-mediated apoptosis was not involved in the actions of 9,10-PQ. Taken together, these data indicated that ferroptosis is a critical cell death pathway induced by 9,10-PQ. *Support: NIH grants AR055073, NS108956, ES004738, and ES005022.*

1071 *In Vitro* Cytotoxicity and Potential Carcinogenesis of Copper Oxide Nanoparticles

M. Ding, T. Barber, J. Aldinger, and J. Arnold. *NIOSH, Morgantown, WV.* Sponsor: Y. Yuan

Occupational exposures to copper nanoparticles and fine particles have been reported to be harmful to human health. There is a possible risk of cancer among industrial workers. Copper (II) oxide (CuO) nanoparticles have not, to date, been extensively examined for potential carcinogenic effects. Mechanisms of CuO-induced pathogenesis, the effect of CuO nanoparticles on cyto-toxicity and carcinogenic effects were investigated. Using the 3-(4,5-dimethylthiazolyl-2)-2, 5-diphenyltetrazolium bromide cellular dehydrogenase activity (MTT Assay) assay, CuO nanoparticles showed a dose-dependent reduction of the dehydrogenase activity (DHA) in the JB6 cell culture medium indicating the cytotoxicity of CuO. The potential carcinogenesis effects of CuO were also examined. The data indicates that chronically exposed human lung epithelial JB6 cells to low-dose CuO resulted in neoplastic transformation using the soft agar assay. *In vitro* genotoxicity test, single cell gel electrophoresis assay (SCGE; also called the comet assay), was used for the detection of the mutagenic potential of nano- and fine-sized CuO. The results suggested that both nano- and fine-sizes CuO induce DNA damage. CuO nanoparticles exhibit greater genotoxicity than fine particles. Understanding complex mechanisms associated with these events may provide insights into the initiation and progression of CuO-induced carcinogenesis.

1072 Serum-Borne Factors Alter Cerebrovascular Endothelial microRNA Expression following Particulate Matter Exposure Near an Abandoned Uranium Mine on the Navajo Nation

K. E. Zychowski[1], B. Sanchez[1], X. Zhou[1], A. S. Gardiner[1], G. Herbert[1], S. Lucas[1], M. Morishita[2], J. G. Wagner[2], J. Harkema[2], C. Shuey[3], and M. J. Campen[1]. *[1]University of New Mexico, Albuquerque, NM; [2]Michigan State University, East Lansing, MI; and [3]Southwest Research Information Center, Albuquerque, NM.*

Commercial uranium mining on the Navajo Nation has left communities on tribal lands in the Southwestern United States with a number of health effects from exposure to residual environmental contamination. There is an association between residential mine-site proximity and circulating biomarkers in residents, however the contribution of mine-site derived wind-blown dusts on vascular and other health outcomes is unknown. To assess neurovascular effects of mine-site derived dusts we exposed mice using a novel exposure paradigm, the AirCARE1 mobile inhalation laboratory, located 2 km from an abandoned uranium mine, Claim 28 in Blue Gap Tachee, AZ. Mice were exposed to filtered air (FA) (n=6) or $PM_{2.5}$ (n=5) for 2 weeks for 4 hours per day. To assess miRNA differential expression in the cerebrovasculature following PM exposure, the serum cumulative inflammatory potential (SCIP) assay was employed. MiRNA sequencing was then performed in mouse cerebrovascular endothelial cells (mCECs) to evaluate transcriptional changes. The most significantly altered miRNAs were validated in the serum. Results indicated 27 highly differentially expressed ($p<0.01$) murine miRNAs following the SCIP assay. Of the 27 highly differentially expressed murine miRNAs, 9 of them (~30%) were significantly altered in the serum and 8 of those demonstrated the same directional change (either upregulation or downregulation) as cellular miRNAs following the SCIP assay. Our data suggest that miRNAs from the systemic circulation may translocate to the endothelium following $PM_{2.5}$ exposure, as approximately 30% of highly differentially expressed cellular miRNAs were validated in the serum. While translocation of miRNAs via exosomes or an alternative mechanism is certainly possible, other yet-to-be-identified factors in the serum may be responsible for significant miRNA differential expression in endothelium following inhaled exposures. Additionally, the most highly upregulated murine miRNAs in the $PM_{2.5}$ exposure group were in the let-7a family. These miRNAs play a prominent role in cell growth and differentiation and our data suggest that mmu-let-7a may contribute to BBB disruption following inhaled dust exposure.

1073 Respiratory Impacts of Hazardous Air Pollutants in Allergic Mice: Sex Differences and *In Vitro* Concordance

S. H. Gavett[1], M. M. Hargrove[2], S. A. Vance[2], P. A. Evansky[1], L. B. Copeland[1], R. D. Grindstaff[1], J. A. Dye[1], J. Zavala[2], M. A. Higuchi[1], and M. I. Gilmour[1]. *[1]US EPA, Research Triangle Park, NC; and [2]Oak Ridge Institute for Science and Education, Research Triangle Park, NC.*

Validation of high-throughput *in vitro* assessments of hazardous air pollutants (HAPs) and other EPA high-priority chemicals requires testing in animal models to demonstrate *in vitro* predictive ability. Acrolein (ACR) and trichloroethylene (TCE) are among several HAPs designated as high priority chemicals within the US EPA Toxic Substances Control Act inventory, and may exacerbate respiratory symptoms in susceptible populations such as asthmatics. Here we evaluated real-time pulmonary responses to ACR and TCE in control and house dust mite (HDM)-allergic male (M) and female (F) mice and subsequent inflammatory biomarkers. On 2 consecutive days, mice were exposed nose-only in head-out plethysmographs to air (20 min) followed by increasing concentrations (25 min each) of ACR (0.1, 0.32, 1.0, 3.2 ppm) or TCE (3.2, 10, 32, 100 ppm), corresponding to ongoing *in vitro* assessments. Separate groups were exposed to air only to compare inflammatory responses. Breathing frequency significantly declined in both M and F HDM-allergic groups at 1.0 ppm ACR on both exposure days (group means 19-30% lower than air baseline) and was sharply lower (39-67%) at 3.2 ppm ACR, while TCE (10-100 ppm) also significantly reduced frequency, though to a lesser extent (12-23%). M mice had higher baseline frequency than F, which declined to a greater extent with increasing ACR concentration. Other parameters of respiratory timing, flows, and volumes indicated overall greater effects of ACR and TCE in M and allergic groups compared with F and control groups. Four hours after final exposure, HDM-allergic F mice had greater indices of allergic inflammation than M mice (e.g. bronchoalveolar lavage (BAL) eosinophils, lymphocytes, albumin, and IL-5), but relatively few differences with respect to HAPs exposure. TCE-exposed HDM-allergic F mice had greater BAL eosinophils and N-acetylglucosaminidase, but lower MIP-2, than ACR-exposed allergic F mice. Effects of ACR and TCE on real-time respiratory physiology correlated reasonably well with cell viability results in BEAS-2B cells (CellTiter Glo viability ATP assay). Assessment of additional HAPs in the allergic mouse model will further determine validity of HAPs effects predicted by high-throughput *in vitro* assays. *This abstract does not represent US EPA policy.*

1074 Plasma from C57BL/6 Mice Exposed to Vehicle Emissions Mediates Alterations in Lipid Accumulation and Renin-Angiotensin Pathway Signaling in 3T3-L1 Mouse Adipocytes

U. Suwannasual, J. Lucero, and A. K. Lund. *University of North Texas, Denton, TX.*

In addition to cardiopulmonary disease, exposure to traffic-generated air pollutants has been implicated recently in the pathogenesis of metabolic disorder and obesity. We have previously reported that inhalation exposure to mixed vehicle exhaust (MVE) results in increased the levels of circulating angiotensin II (Ang II), associated with adipose fat pad weight, increased adipocyte size, and lipid accumulation in C57Bl/6 wild type mice, which is further exacerbated by consumption of a high fat (HF) diet. To investigate mechanisms involved in MVE-mediated alterations in adipocytes, we examined whether circulating factors in the plasma of MVE-exposed mice mediate alterations of the renin-angiotensin system (RAS) signaling or lipid accumulation in adipocyte 3T3-L1 cell culture. Three mo-old male C57Bl/6 mice on either an HF or low fat (LF) diet randomly assigned to inhalational exposure of either filtered-air (FA) or a mixture of 30 μg PM/m^3 gasoline exhaust + 70 μg PM/m^3 diesel exhaust (MVE) for 6 hr/d for 30 d; plasma was collected at the end of the study and was applied to the media of the adipose cell culture and incubated for 48 hours. Adipocytes were measured for cell area, lipid accumulation by Nile Red staining, and RAS member gene expression, by qRT-PCR. Our results show that exposure to MVE + HF diet resulted in a significant increase in cell size and cellular lipid accumulation, associated with significantly increased expression of angiotensinogen (AGT), angiotensin II type 2 receptor (AT_2), and peroxisome proliferator-activated receptors gamma (PPARγ) mRNA. Pretreatment of the adipocytes with an AT_1 receptor antagonist, Losartan, before incubation with the plasma from the exposure study resulted in a significant decrease in AGT, AT_2 receptor, and PPARγ in MVE+HF mice. Thus, our results suggest that exposure to traffic-generated pollution with a concurrent consumption of an HF diet high fat leads to alterations of adipocyte signaling and lipid accumulation associated with metabolic syndrome. Moreover, these alterations appear to be mediated (at least in part) through Ang II -AT_1 signaling pathways. *Funded by NIEHS R15ES026795 to AKL.*

1075 Top-Down Proteomics Reveals Alterations in the Liver Protein Profiles of C57Bl/6 Mice with Inhalation Exposure to Mixed Vehicular Emissions and a High-Fat Diet

L. Schneider[1], R. Koerber[1], J. Lucero[1], J. D. McDonald[2], and A. K. Lund[1]. *[1]University of North Texas, Denton, TX; and [2]Lovelace Biomedical, Albuquerque, NM.*

Traffic-generated emissions are known to induce cardiovascular events, compromise neurological systems, and alter cellular responses and function, many of which are exacerbated when coupled with consumption of a high-fat diet. It has been well documented that exposure to environmental air pollutants can mediate alterations in hepatic transcript and protein expression, which can result from biotransformation reactions in the hepatocytes. Additionally, exposure-mediated alterations of protein expression in the liver are known to contribute to the pathogenesis of diseases in the liver, such as non-alcoholic fatty liver disease (NAFLD), which has been associated with air pollution-exposure in adults and children. Thus, we investigated the hypothesis that exposure to a ubiquitous environmental air pollutant, vehicle emissions, coupled with concurrent consumption of a high fat (HF) diet, significantly alters proteome profiles in the liver. To test this hypothesis, 3 mo-old male C57Bl/6 mice were placed on either a low fat or high fat (HF: 21% fat content by weight), and then assigned to be exposed by whole body inhalation to either filtered air (FA) or mixed gasoline and diesel engine emissions (MVE: 70 μg PM/m^3 diesel exhaust + 30 μg PM/m^3 gasoline exhaust) for 6 hr/d for 30d. Liver tissue was collected, homogenized, and analyzed via top-down proteomics utilizing a Waters XBridge Protein BEH C_4 column installed on an ACUITY UPLC coupled with a SYNAPT G2 q-TOF. Isolated protein samples were processed using a mobile phase gradient (10-90% acetonitrile: water) with 0.1% trifluoroacetic acid. Chromatogram data point display potential statistical expression differences (>20% compared to LF/FA controls) of 111 up-regulated and 138 down-regulated points in the livers from HF/FA animals, 142 up-regulated and 315 down-regulated points in the livers of LF/MVE animals, and 1013 up-regulated and 43 down-regulated points in the livers of HF/MVE animals, when compared to the livers from the LF/FA animals. Ongoing investigation and calculations are being performed to determine the identities of the altered proteins to better understand the milieu resulting from exposure to traffic generated air pollution, combined with an HF diet, in the liver that may contribute to the pathogenesis of diseases such as NAFLD. *Funded by NIEHS R00ES016586 and R15ES026795 (AKL).*

1076 Lipidomic and Epigenetic Alteration for Toxic Mechanisms of Air Pollution on Alzheimer's Disease

J. Seo[1,2], and M. Yang[1,2]. *[1]Sookmyung Women's University, Seoul, Korea, Republic of; and [2]Goodbeing R&D Center, Seoul, Korea, Republic of.*

Air pollution, particularly fine particulate matter, such as $PM_{2.5}$, targets various organs including brain. Therefore, we performed biomonitoring of air pollution with an exposure biomarker, urinary 2-naphthol (NT), and compared lipidomic and epigenetic alterations between 5 Alzheimer's disease (AD) patients and 15 controls (N=20; age=60.75±13.8; 9 men). We analyzed urinary 2-NT and malondialdehyde (MDA), an oxidative stress biomarker, with HPLC/FD and LC/MS/MS and blood C-reactive protein (CRP) and urinary creatinine with a clinical analyzer. Urinary 32 fatty acids were analyzed with GC/MS/MS. For epigenetics, global and specific methylation statuses were analyzed with EpigenTek kit for 5-mC and methylation specific PCR for DNA methylation at *MATP*, microtubule associated protein tau, respectively. As results, we found positive associations between urinary 2-NT levels and $PM_{2.5}$ in their residential areas and among urinary or plasma 2-NT, urinary levels of MDA, and blood levels of CRP (ps<0.05). When we adjusted for age, sex and tobacco smoking, plasma 2-NT levels were somewhat higher in AD patients than controls (OR=31.87, 95% CI=-1.07~3.67). We also found positive correlations between levels of urinary 2-NT and some saturated fatty acids, such as myristoleate or pentadecenoate. In addition, the levels of urinary arachidonic acid involved with tau phosphorylation was associated with *MAPT*-DNA methylation (r^2=-0.15, p=0.04). Therefore, the above lipidomic and epigenetic results provide some potential risks of air pollution on AD.

1077 Toxicomultiomics Profiling: Pulmonary Toxicity Studies with Repeated Exposure of PHMG-p in Mice

K. Kim[1], J. Lee[1], J. Im[1], H. Kim[1], H. Lee[2], J. Park[2], K. Park[2], H. Jeong[3], H. Kim[1], S. Kim[4], D. Hwang[5], H. Kim[6], and B. Lee[6]. *[1]Dankook University, Cheonan, Korea, Republic of; [2]Dongduk Women's University, Seoul, Korea, Republic of; [3]Chungnam National University, Daegeon, Korea, Republic of; [4]Pusan National University, Busan, Korea, Republic of; [5]Seoul National University, Seoul, Korea, Republic of; and [6]Sungkyunkwan University, Suwon, Korea, Republic of.*

Polyhexamethylene guanidine phosphate (PHMG-p) was used as a humidifier disinfectant in Korea. PHMG induced severe pulmonary fibrosis in Koreans. The objective of this study was to elucidate mechanism of pulmonary toxicity caused by PHMG-p in mice using multi-omics analysis. Balb/c mice were intratracheally instilled with PHMG-p by 4-week (0, 0.03, 0.1 mg/kg, 2 times/week) repeated administration. Histopathologic examination of lung was performed with H&E staining. Inflammatory cell infiltration, multifocal, and minimal were observed in response to 0.03 mg/kg of PHMG-p. In addition, mononuclear cell infiltration, multifocal, minimal, fibrosis, and alveolar wall were observed in response to 0.1 mg/kg of PHMG-p. Next generation sequencing (NGS) was performed for transcriptome profiling after mRNA isolation from bronchiol-alveoli. Bronchiol-alveoli proteomic profiling was performed using an Orbitrap Q-exactive mass spectrometer. Plasma metabolites were determined using ^{1}H-NMR. Among up-regulated 47 DEGs and 46 DEPs, changes of 3 mRNA levels were significantly correlated with changes of their protein levels in response to 0.03 mg/kg of PHMG-p. Among up-regulated 643 DEGs and 132 DEPs, changes of 39 mRNA levels were significantly correlated with changes of their protein levels in response to 0.1 mg/kg of PHMG-p. In addition, among down-regulated 613 DEGs and 80 DEPs, changes of 7 mRNA levels were significantly correlated with changes of their protein levels in response to 0.1 mg/kg of PHMG-p. Remarkable biological processes represented by both DEGs and DEPs in response to 0.1 mg/kg of PHMG-p were response to stress, immune system process, defense response, response to external stimulus, and regulation of molecular function. In addition, up-regulated DEGs and DEPs associated with pulmonary fibrosis and asthma were selected in response to 0.1 mg/kg of PHMG-p, the major transcription factors associated with pulmonary fibrosis and asthma were 6 (Lgals3, Egfr, Arg2, Hmox1, Arg1, Serpinh1) and 8 (Lgals3, Spp1, Egfr, Arg2, Hmox1, Arg1, Lrg1, Tnc) species, respectively. And down-regulated DEGs and DEPs associated with pulmonary fibrosis and asthma were 1 (Scgb1a1) and 2 (Ank1, Scgb1a1) species, respectively. On the other hand, there were no DEGs and DEPs associated with pulmonary fibrosis and asthma in response to 0.03 mg/kg of PHMG-p. In metabolomics study, 13 and 23 metabolites (VIP> 0.5) were determined in plasma of response to 0.03 and 0.1 mg/kg of PHMG-p. And then, we performed an integrated analysis with selected metabolites from plasma after screening for DEGs and DEPs associated with pulmonary disease. Glutamate, glycine, creatine, acetate, histidine and choline were selected as major metabolites and were found to be major factors to pulmonary fibrosis and asthma in association with up-regulated DEGs and DEPs in response to 0.1 mg/kg of

PHMG-p. And down-regulated DEG and DEP related metabolites in the high dose group were glutamate, acetate, glycine and choline. Also, glycine, formate, citrate, glycerol, valine, isoleucine, and taurine were selected as major metabolites and were found to be major factors to pulmonary fibrosis and asthma in association with up-regulated DEGs and DEPs in response to 0.03 mg/kg of PHMG-p. Current study could be helpful for identifying toxicity and toxicological indicators caused by inhalation exposure of PHMG-p, a component of humidifier disinfectants.

PS 1078 Exposure to Diesel Exhaust Particles Alters Immune Response and Promotes the Expansion of Proteobacteria in the Lungs of C57BL/6 Mice

S. Daniel, D. Phillippi, J. Lucero, and A. K. Lund. *University of North Texas, Denton, TX.*

Traffic generated emissions have been associated with the development of inflammatory lung disorders such as asthma and COPD. Healthy lungs were initially considered to be sterile, but there is evidence now that suggests the presence of microbes within the airways. A shift in the lung microbiota towards Proteobacteria is observed in multiple lung diseases. The effect of air pollutants on the lung microbiota is currently not well characterized. Although there is an increase in the incidence of lung disorders in heavily polluted regions, the pathogenesis of these diseases or the involvement of the lung microbiota remains largely unexplored. Thus, we investigated whether exposure to diesel exhaust particles (DEP) altered the immune response and microbiota profiles within the lung, as well as whether fat content in diet further contributed to the observed pulmonary outcomes. To do this, male C57BL/6 mice (4-6-week-old) were placed either on a low-fat diet (control) or a high-fat (HF) diet containing 45% fat. Mice were randomly assigned to be exposed via oropharyngeal aspiration to 35μg DEP, obtained from NIST (SRM #2975), suspended in 50μl 0.9% sterile saline or sterile saline only (control) twice a week for 30 days. Our results show that DEP-exposure significantly increased the production of IgA, as determined by ELISA. RT-qPCR analysis of cytokine profiles revealed increased pulmonary expression of inflammatory cytokines - TNFα and IL-10 in DEP-exposed animals vs. controls. Next-generation sequencing and qRT-PCR of bacterial 16S rRNA genes in BALF were performed to identify major bacterial groups. Overall microbial abundance in the lungs of DEP-exposed mice was decreased, with a significant reduction in Firmicutes observed in the DEP+HF diet animals. The relative abundance of *Enterobacteriaceae* belonging to the Proteobacteria phylum was found to be higher in the lungs from DEP + HF diet mice, compared to all other groups. Our results show that exposure to DEP causes a significant increase in the major lung immunoglobulin IgA suggesting the production of a robust immune response. Both pro-inflammatory, TNF-α and anti-inflammatory, IL-10 cytokine appear to be elevated with DEP-exposure. Such immunological changes within the lung likely increase nutrient availability, particularly nitrates, which favor the expansion of bacteria within the Proteobacteria phylum. These results suggest a potential mechanism by which air pollutants alter the lung microbiota, which may contribute to the pathogenesis of lung diseases.

PS 1079 Diesel Exhaust Particulate Matter Exposure Results in Altered Lipid Accumulation and Expression of Receptors Involved in Nonalcoholic Fatty Liver Disease

W. Devakul Na Ayutthaya, U. Suwannasual, D. Phillippi, S. Daniel, and A. K. Lund. *University of North Texas, Denton, TX.*

Recent epidemiology studies report a positive correlation between exposure to traffic-generated air pollution and the pathogenesis of metabolic disorder and obesity. Nonalcoholic fatty liver disease (NAFLD), which often occurs concomitant with metabolic syndrome, is characterized by increased hepatic lipid accumulation and altered molecular signaling pathways involved in inflammation, fatty acid synthesis, and fibrosis. These pathways include signaling through the tumor necrosis factor receptor (TNFR1), adiponectin receptor (adipoR), and the oxidized LDL receptor (LOX-1), in addition to others. Furthermore, signaling through the aryl hydrocarbon receptor (AhR) is also reported to mediate the pathogenesis of NAFLD. We have previously reported that exposure to traffic-generated pollution is associated with increased adipose depots/weights and lipid accumulation in C57Bl/6 mice, which is further exacerbated by consumption of a high fat (HF) diet. To investigate the role of traffic-derived particulate matter (PM) on mediating detrimental hepatic outcomes related to NAFLD, 2 mo-old male C57Bl/6 mice on either an HF or low fat (LF) diet were exposed to either 35 μg diesel exhaust PM (DEP; 30 μl) or vehicle (saline) 2x/wk for 4 wk via OA. Livers were analyzed for lipid accumulation by Nile Red staining and transcript expression of TNFR1, adipoR, LOX-1 and AhR were analyzed by RT-qPCR. Nile Red staining revealed that DEP-exposure significantly increased hepatic lipid accumulation, which was further exacerbated in those on an HF diet. Additionally, transcript analysis showed a significant decrease in hepatic TNFR1 in DEP-exposed and HF-fed animals, compared to controls. AdipoR was significantly decreased in the livers of HF+DEP mice. Interestingly, we observed a significant decrease in hepatic LOX-1 in the HF+DEP group. DEP-exposure increased hepatic AhR mRNA in both the LF and HF diet groups. Thus, our results suggest that exposure to traffic-generated PM leads to alterations of hepatic lipid accumulation and signaling pathways associated with NAFLD and altered biotransformation. *Funded by NIEHS R15ES026795 to AKL.*

PS 1080 Characterizing Atmospheric Particle Toxicity from Biogenic and Anthropogenic Sources Using *In Vitro* Assays

J. E. Monterrosa Mena, F. Khalaj, C. Faiola, and M. T. Kleinman. *University of California Irvine, Irvine, CA.*

Plants emit highly reactive biogenic volatile organic compounds (BVOCs) that can contribute to production of secondary pollutants including secondary organic aerosols (SOA). There are many gaps in understanding how the interaction between biogenic and anthropogenic volatile organic compound (VOC) sources impact SOA yield, particle chemistry, and associated toxicity. While urban greening programs are directed to beautify urban areas and "filter out" atmospheric pollutants like particulate matter and tropospheric ozone, the chemical composition and toxic potential of plant emissions in urban versus clean environments remains an open question. SOA was generated in an oxidation flow reactor (Aerodyne, Inc) from isoprene, α-pinene, limonene, toluene and limonene/toluene mixtures. High oxidation and low oxidation conditions were compared, which mimicked oxidation reactions found in chemically pristine and polluted urban environments, respectively. The *in vitro* cytotoxicity of the produced particles was assed using murine lung macrophage from an established cell line. Cells were exposed to particles for four hours before assessing cell viability and oxidative stress. Cell health was assessed using the Lactate Dehydrogenase assay, reactive oxygen species formation was assessed using the Diogenes Superoxide assay, and nitric oxide release was assessed with the Griess Nitric Oxide assay. Changes in cell health and reactive oxygen species production were observed after exposure. Results show that SOA generated from a mixture of anthropogenic and biogenic sources was less toxic than SOA generated from either biogenic or anthropogenic precursors alone. Furthermore, SOA generated under lower oxidation conditions tended to be more toxic than SOA generated under higher oxidation conditions (as evaluated by O:C ratio). These findings suggest that plants can contribute to air pollution and that and specifics mixtures of VOC sources can impact atmospheric particle toxicity. Finally results from this type of study can be used to inform selections of plants used for urban greening programs, which may ultimately impact human health outcomes.

PS 1081 Advanced Age and a High-Fat Diet Potentiate Responses to Benzene Inhalation in Mice

T. O'Toole, D. Gomes, and S. Srivastava. *University of Louisville, Louisville, KY.*

We have previously shown that mice inhaling volatile benzene (50ppm; 6h/day for 14 days) demonstrated tissue-specific insulin resistance. However, it is unclear if other risk factors for cardiovascular disease influence this outcome. To test this, we fed young (14wk) and old (24wk) mice normal chow or a high fat diet and exposed them to either filtered air or 50ppm benzene for 14d. At this time, insulin levels were measured and tissue levels of proteins and miRNAs impacting insulin signaling pathways were assessed. While young mice eating normal chow and exposed to benzene demonstrated a 1.5-fold increase in fasting plasma insulin compared to mice breathing filtered air, old mice on a high fat diet and exposed to benzene demonstrated a 4-fold increase in insulin levels compared to filtered air controls. Of several miRNAs known to target proteins involved in the regulation of insulin signaling, we observed that mir-125b was increased by 3.6-fold in the liver of high-fat diet, old mice inhaling benzene while this change was 0.9 fold in both old mice on normal chow, and young mice on a high fat diet. Consistently, hepatic levels of the catalytic subunit of PI3-kinase (PIK3CD), a target of mir-125b, were downregulated in high-fat, old mice inhaling benzene. In addition, levels of several miRNAs targeting phosphatase and tensin homolog (PTEN) were downregulated in high-fat, old mice inhaling benzene, but not in other mouse groups inhaling benzene. These results suggest that age and diet are factors that can exacerbate the consequences of benzene exposure and are consistent with the idea that multiple "hits" promote the toxicity of volatile organic compounds.

1082 Uptake and Toxicity of Respirable Uranium-Carbon-Bearing Particulate Matter in A549 Lung Epithelial Cells

E. El Hayek, S. Medina, J. Guo, A. Noureddine, K. Zychowski, R. Hunter, C. Velasco, A. Brearley, M. Spilde, T. Howard, F. Lauer, G. Herbert, M. Wiesse, S. Cabaniss, A. Ali, S. Burchiel, M. Campen, and J. Cerrato. *University of New Mexico, Albuquerque, NM.*

Understanding the toxic effects of respirable uranium (U)-bearing particulate matter (PM) with respect to the site-specific mineralogy is of great importance due to potential health impacts. In this study, U-carbon (C)-bearing particles were synthesized by mixing aqueous U with citrate to create an environmentally-relevant particles similar to PM found near Jackpile Mine, NM where U occurs in a highly enriched organic matter matrix. Cellular uptake and toxicity analyses were conducted following the exposure of the human lung epithelial cell line, A549 cells, to two groups of U-C-bearing particles (microparticles ≤ 10 μm and nanoparticles ≤ 0.6 μm) and to aqueous U at the same range of concentration (0-445 μM). Both microparticles and nanoparticles induced cytotoxicity in comparison to aqueous U which was dependent on U exposure concentration. After 2 hours exposure, microparticles showed four times higher U uptake than nanoparticles for cells exposed to 100 μM U whereas no U uptake was measured in cells exposed to aqueous U. TEM-EDS analysis confirmed the presence of both groups within vesicles of A549 lung cells but with no detectable adsorption on the cell membrane. Microparticles induced a higher DNA damage in A549 cells relative to nanoparticles and aqueous U. However, only nanoparticles showed an ability to interact with the cellular membrane by inducing hemolysis upon 24 h incubation with red blood cells. This study highlights the potential toxicological effects of respirable U-C-bearing particles in both micrometric and nanometric scale and the potential ability to induce nucleus- or membrane-oriented damage.

1083 Exposure to Traffic-Generated Air Pollution Increases Systemic and Adipocyte Renin-Angiotensin Pathway Signaling, Lipid Accumulation, and Inflammation in C57Bl/6M Mice Which Is Exacerbated by Consumption of a High-Fat Diet

A. K. Lund, J. Lucero, and U. Suwannasual. *University of North Texas, Denton, TX.*

Exposure to air pollution is known to contribute to the pathogenesis of cardiovascular disease (CVD). More recent studies have reported a positive correlation between exposure to traffic-generated air pollution and metabolic syndrome and/or obesity in both children and adults. Obesity is strongly correlated with incidence of CVD; however, very limited information exists on the effects of inhaled pollutants on adipocytes or signaling between adipocytes and the cardiovascular system. The renin-angiotensin system (RAS), when dysregulated, is known to mediate pathogenesis in the cardiovascular system, and in adipocytes, through Angiotensin (Ang) II signaling via the Ang II Type 1 (AT1) or Type 2 (AT2) receptor(s). We have previously reported that inhalation exposure to mixed vehicle emissions (MVE) results in increased plasma Ang II, adipocyte size, and adipocyte Angiotensinogen (AGT) and AT-1 expression in C57Bl/6 mice. Thus, we investigated whether MVE-exposure results in altered adipose lipid accumulation and induction of local and vascular inflammatory signaling pathways that contribute to the etiology of obesity and CVD. To test this hypothesis, 3 mo old male C57Bl/6 mice on either a high-fat "Western" diet (HF, 21% fat) or standard (LF, low fat) mouse chow were randomly assigned to inhalation exposure of either filtered-air (FA n=10 per diet) or a mixture of 70 μg PM/m^3 diesel exhaust + 30μg PM/m^3 gasoline exhaust (MVE n=10 per diet) for 6 hr/d for 30 d. MVE exposure resulted in significantly increased adipocyte lipid accumulation (~1.5-fold), as determined by Nile Red staining, which were further exacerbated in MVE+HF diet animals (~5-fold), compared to FA animals. MVE-exposure resulted in significantly increased protein expression at of inflammatory marker, TNF-α, and monocyte/macrophage infiltration (MOMA-2) in both adipose and vascular (aorta) tissue, compared to FA controls. MVE+HF also elevated vascular AT-1 expression that was associated with a 2-fold increase in mRNA expression of vascular adhesion molecular (VCAM)-1, intracellular adhesion molecule (ICAM)-1. These findings indicate that inhalation exposure to traffic-generated pollutants can promote induction of systemic and adipocyte Ang II signaling, lipid accumulation, macrophage recruitment, and inflammation, which are further exacerbated by concurrent consumption of a high fat diet. *Funded by NIH 1R15ES026795 to AKL.*

1084 Exposure to Volatile Organic Compounds Increases Circulating Platelet and Endothelial Cell Microparticles

S. McFall, M. V. Malovichko, R. J. Keith, D. Riggs, A. Bhatnagar, and S. Srivastava. *University of Louisville, Louisville, KY.*

Volatile organic compounds (VOCs) are toxicants abundant in both outdoor and indoor air. VOCs are also present in large quantities at several Superfund and Hazardous Waste Sites. Sources of VOCs include burning of fossil fuels or tobacco products and the use of many household commodities like solvents, paints, and glues. While contribution of VOCs in pulmonary disease and cancer is well-studied, little is known about their effect on cardiovascular disease. We examined the effect of VOC exposure on the abundance of circulatory endothelial microparticles, platelet microparticles, and lung microparticles as biomarkers of cardiovascular and pulmonary injury because they have been shown to be positively associated with vascular injury, thrombosis, and respiratory disease. Generalized linear models were used to measure the associations between 16 urinary VOC metabolites and 7 different subtypes of circulating microparticles (measured by flow cytometry) in peripheral blood of 240 non-smokers. Models were adjusted for age, sex, race, BMI, diabetes, and socioeconomic status. Our data show that metabolites of acrolein, acrylamide, 1,3-butadiene, ethylbenzene, and styrene were positively associated with all the seven types of microparticles – endothelial (<1μm/AnnexinV$^+$/CD144$^+$), activated endothelial (<1μm/AnnexinV$^+$/CD144$^+$/CD62E$^+$), endothelial progenitor cell (<1μm/AnnexinV$^+$/CD144$^+$/CD34$^+$), lung (<1μm/AnnexinV$^+$/CD143$^+$), lung endothelial (<1μm/AnnexinV$^+$/CD143$^+$/CD144$^+$), activated lung endothelial (<1μm/AnnexinV$^+$/CD143$^+$/CD144$^+$/CD62E$^+$) and platelet (<1μm/AnnexinV$^+$/CD41$^+$) ($P<0.05$). These microparticles increased by 20-89% per 2-fold increase in VOC metabolite level. Exposure to crotonaldehyde, nn-dimethylformamide, propylene oxide, and o-xylene did not affect platelet microparticles but significantly ($P<0.05$) increased all other microparticles by 26-98% per 2-fold increase in VOC metabolite level. Metabolites of benzene and styrene also increased several types of microparticles by 15-52% per 2-fold increase in metabolite level ($P<0.05$). Together, these data suggest that VOC exposure causes injury to endothelial cells, platelets, and lungs.

1085 The Relationship between Hypoxia and Diesel Exhaust Particle Toxicity and the Effect of a Novel Oxygenating Therapeutic

A. Dabi, G. V. Aquino, F. Zhang, and E. D. Bruce. *Baylor University, Waco, TX.*

Hypoxia plays an important role in the initiation and exacerbation of several adverse health outcomes, including organ transplant failure, insulin-resistance, chronic wound onset, and traumatic brain injury. The influence of hypoxia on disease outcome is directly linked to the accumulation of hypoxia induced factor (HIF) in low oxygen tissues. This transcription factor induces metabolic changes within cells, and is also intertwined with key inflammatory pathways, thereby contributing to the exacerbation of inflammatory responses during periods of cellular stress. This link to inflammation poses a question as to the effect of hypoxia on the toxicity of certain compounds, due to the established link between cytotoxicity and activation of inflammatory pathways. This study aims to understand this link by examining the effect of low-oxygen conditions on diesel exhaust particles (DEP) cytotoxicity in two human and two rat cell-lines. Furthermore, the effect of a novel oxygenating therapeutic, Ox66™, on the relationship between hypoxia and DEP toxicity will be investigated. To assess these relationships, cells were dosed with DEP, Ox66™, and a mixture of both, and then incubated for 24 and 48 hours in both normoxic and hypoxic (~ 2% Oxygen) conditions. After exposure, toxicity was assessed via lactic acid dehydrogenase (LDH) and tetrazolium dye (MTT) colorimetric assays measuring cell damage and viability, respectively. Proteomic analysis was also carried out to measure the levels of interleukin 6, interleukin 8, and tumor necrosis factor alpha present in cell media following exposure. The results reveal a complex relationship between hypoxia and DEP toxicity that is dependent on both cell-type and exposure-time. Additionally, Ox66™ appears to display antagonistic toxicity with DEP in mixtures in some cell-lines, a trend that is exacerbated in hypoxia, pointing to the possible effect of Ox66™ on the amelioration of the adverse effects of hypoxia on cells.

1086 Exposure to Volatile Organic Compounds Depletes Circulating Angiogenic Cells

B. S. Taylor, and M. V. Malovichko. *University of Louisville, Louisville, KY.*
Sponsor: D. Hein

Volatile organic compounds (VOCs) are organic chemicals present in both outdoor and indoor air. VOCs are also abundant at various Superfund and hazardous waste Sites. Emerging data suggest that VOCs are associated with many adverse health outcomes, including cardiovascular disease. Endothelial cells line the blood vessel and are critical regulators of blood pressure and vascular function. We hypothesized that VOC exposure prolongs endothelial injury by depleting circulating angiogenic cells (CACs) which repair the damaged endothelium. Generalized linear models were used to measure the associations between 16 urinary VOC metabolites and 15 different subtypes of circulating CACs (by flow cytometry) in peripheral blood of 240 non-smokers. Models were adjusted for age, sex, race, BMI, diabetes status, and socioeconomic status. We observed that metabolites of acrolein, acrylamide, acrylonitrile, 1,3-butadiene, crotonaldehyde, nn-dimethylformamide, ethylbenzene, styrene, and toluene were negatively associated with CAC-6 (CD34+/146+; p<0.05-0.000). CAC6 levels were decreased by 12-29% per 2-fold increase in VOC metabolite level. Exposure to acrylamide, acrylonitrile, nn-dimethylformamide, ethylbenzene and styrene also significantly (P<0.05) depleted CAC-4 (45+/31+/34+/133+) and CAC-14 (45+/34+/133+) by 12-47% per 2-fold increase in VOC metabolite level. Several VOCs also depleted the levels of various other CACs to varying degrees. On the contrary, a metabolite of benzene was positively associated CAC-2, CAC4, CAC-10, and CAC-15--12-47% increase per 2-fold increase in VOC metabolite level. Association of xylene metabolites with CACs was quite complex. While o-xylene metabolite was negatively associated with several CACs, an m-and p-xylene mixture showed a positive association with numerous CACs. These findings suggest that by and large VOC exposure depletes CACs and thereby compromise endothelial repair; however, benzene and m- and p-xylene could increase CACs. Further studies are required to understand this paradox.

1087 Inhalation Exposure to Traffic-Generated Air Pollution Results in Renin-Angiotensin System Deregulation in the Kidneys of ApoE -/- Mice

T. Armstrong[1], J. Lucero[1], J. D. McDonald[2], and A. K. Lund[1]. *[1]University of North Texas, Denton, TX; and [2]Lovelace Biomedical, Albuquerque, NM.*

Cardiovascular disease (CVD) is the leading cause of death in the world. Epidemiological studies have suggested a strong association between air pollution and the exacerbation of CVD. The renin-angiotensin system (RAS) is known to contribute to CVD, typically through increased expression of one or more RAS pathway components, including renin, angiotensinogen, angiotensin (Ang) II, or signaling through the Ang II receptor type 1 (AT1). Our preliminary data suggest that inhalation exposure to traffic-generated air pollution may upregulate systemic RAS. Thus, we analyzed whether exposure to vehicle emissions (MVE) mediates altered RAS signaling in the kidney. To do this, 6-8 week old male Apolipoprotein null mice ($ApoE^{-/-}$), were fed a high fat "Western" diet for 30 d to promote atherosclerosis. Mice were then randomly assigned to be exposed to either filtered air (FA) or mixed gasoline/diesel engine emissions (MVE: 200 µg PM/m^3 diesel and gasoline exhaust) for 6 hrs/d, 7 d/wk, for 30 d. To investigate the contributing mechanism of RAS-signaling, a subset of control and exposure mice were assigned to receive either an angiotensin-converting enzyme inhibitor (ACEi), Captopril (4mg/kg/day) in their drinking water or drinking water only (vehicle). MVE-exposure resulted in a 3-fold increase in plasma Ang II, compared to FA controls, which was reduced with ACEi treatment, as measured by ELISA. Compared to FA/vehicle controls, expression of inflammatory mediator tumor necrosis factor (TNF)-α mRNA (2-fold induction) and fibrosis (~1.5-fold higher) were also significantly increased in the kidneys of MVE-exposed $ApoE^{-/-}$mice, as determined by RT-qPCR and Masons Trichrome staining, respectively, which were attenuated with ACEi-treatment. Renal AT-1 mRNA levels were observed to be elevated with MVE exposure; however, they were significantly increased in the MVE (2-fold) and FA-ACEi-treated animals, as were renin levels quantified by immunofluorescence. Renin levels were observed to be highest in the MVE+ACEi mice. The increase in ACEi-mediated induction of AT1 and renin is likely due to a feedback mechanism because Ang II plasma levels are decreased through treatment; however, the RAS appears to be deregulated with MVE exposure in these animals leading to significantly increased levels of renin (3-fold increase in MVE+ACEi vs. FA+ACEi). These findings indicate that MVE exposure results in an increase in renal inflammation/fibrosis, and deregulation of the RAS in the kidney, which may contribute to the pathogenesis of CVD.

1088 The Effects of Inhaled Diesel Exhaust Particulate Matter and Probiotic Treatment on Intestinal Microbiota Profiles and Mucosal Integrity in the Ileum of C57Bl/6 Mice

D. Phillippi, S. Daniel, J. Lucero, and A. K. Lund. *University of North Texas, Denton, TX.*

Recent studies have shown a correlation between air pollution particular matter-exposures and gastrointestinal disorders, which is often associated with alterations in gut microbiota profiles. Alterations in gut microbiota can cause detrimental effects on the mucosal barrier, which not only regulates nutrient absorption but also serves as a physical barrier in defense against pathogens and inflammation. Probiotics have shown promising results in the treatment of gastrointestinal disorders by promoting a healthy and diverse gut microflora. We hypothesize that inhalation of diesel exhaust particles (DEP) will result in changes in gut microbiota and epithelial barrier integrity, which can be mitigated using probiotics in C57Bl/6 mice. Male 4 wk old C57Bl/6 mice fed a high-fat (45%) diet were randomly exposed via oropharyngeal aspiration to 35µg diesel exhaust particles (DEP) suspended in 0.9% saline or saline control twice a week for four weeks. Mice from each exposure were grouped to receive ~0.6g Winclove Ecologic® Barrier 849 probiotic (PRO) treatment or placebo (PLC) via drinking water daily throughout the exposure. qRT-PCR was performed to identify 16s rRNA genes of major bacterial phyla in the ileum. Alcian Blue-Periodic Acid Schiff (AB-PAS) and Hematoxylin and Eosin (H&E) stain were used to determine goblet cells, mucin, and morphology of ileum. Immunofluorescence was performed to determine matrix metalloproteinase-9 (MMP-9) protein expression in ileal tissue. DEP exposure was shown to significantly decrease in *Eubacteria*, *Bacteriodetes*, and *Firmicutes* compared to controls, which was not normalized by PRO-treatment. Preliminary data suggest that DEP-exposure results in reduced goblet cell count and mucin production, and also decreased villi length in the ileum, compared to the controls, which was attenuated with PRO-treatment. Furthermore, MMP-9 is increased in the ileum of DEP- exposed mice, compared to controls, but reduced with PRO-treatment. These findings suggest that exposure to DEP causes significant alterations in microbiota, as well as alterations in the mucosal layer and villi structures, thereby likely contributing to gut dysbiosis. Probiotics effects on MMP-9 expression and villi structure in the DEP-exposed mice suggest microbial changes can influence the effects of environmental particulate matter-exposure on the gut.

1089 Atherogenic Effects of Benzene

M. V. Malovichko, N. Wickramasinghe, W. T. Ablanalp, A. Kalani, A. Bhatnagar, D. J. Conklin, T. O'Toole, and S. Srivastava. *University of Louisville, Louisville, KY.*

Benzene is a ubiquitous environmental chemical and is abundant at multiple Superfund and hazardous waste sites. In occupational settings, exposure to benzene can reach several hundred ppm. It is also present at in copious amounts in automobile exhausts and cigarette smoke. Multiple studies have shown that benzene, induces hematotoxicity. Recent studies by our group and others have shown that exposure to benzene could induce insulin resistance. However, little is known about the cardiovascular toxicity of benzene. Our ongoing population-based studies suggest that urinary metabolites of benzene such as t,t-muconic acid are associated with increased levels of endothelial microparticles and decreased levels of endothelial progenitor cells, suggesting that exposure to benzene may cause endothelial injury and impair the endothelial repair capacity. Our pre-clinical studies show that a six-week exposure to benzene (50 ppm; 6h/day, 5days/week) in 12 week old male C57BL/6 mice increased the circulating levels of endothelial microparticles (60%, P<0,05), lung endothelial microparticles (61%, P<0.05), and activated endothelial microparticles (64%, P<0.05); and increased platelet-leukocyte adducts in the blood by 1.5-fold (P<0.05) as compared with HEPA-filtered air-exposed mice. Twenty-weeks of exposure to benzene (10 ppm; 6h/day, 5days/week) in 8 weeks old male LDL receptor-knockout mice maintained on western diet increased lesion formation in the aortic valves by 1.4-fold (P<0.05) without affecting plasma lipoproteins. Zymography of aortic valves from showed significantly higher gelatinase activity (activation of matrix metalloproteinases; P<0.05) in lesional macrophages of benzene-exposed mice as compared with the air-exposed mice, suggesting that exposure to VOCs destabilizes atherosclerotic plaques. *In vitro* studies suggest that benzene metabolites benzoquinone, hydroxyquinone, catechol, and phenol induce macrophage apoptosis (cleavage of caspase-3), a critical feature of lesion progression and instability. Collectively, these data suggest that benzene-induces endothelial injury, macrophage apoptosis, exacerbation of atherogenesis and thrombosis, which may increase the risk for myocardial ischemia and stroke.

1090 Suppression of cGAS-STinG Pathway or Inhibition of Mitochondrial NOX-2 Reduces Organic Dust-Induced Mitochondrial DNA-Driven Inflammation in Microglia

N. Massey, D. Shrestha, S. M. Bhat, N. Kondru, A. G. Kanthasamy, L. A. Karriker, and C. Charavaryamath. *Iowa State University, Ames, IA.*

Organic dust (OD) exposure in animal production industries poses serious respiratory and other health risks. OD consists of microbial products and particulate matter. OD exposure induced respiratory inflammation is under intense investigation. However, effect of OD exposure on brain largely remains unknown. Recently, we have shown that OD exposure of brain microglial cells induces an inflammatory phenotype with release of mitochondrial DNA (mtDNA). Therefore, we tested a hypothesis that OD-exposure induced secreted mtDNA signaling drives the inflammation. OD samples were collected from commercial swine operations and a filter sterilized OD extract (ODE) was prepared. Mouse (C57BL/6) microglial cell line were treated with medium or ODE (5%) for 48 hours along with either PBS or mitoapocynin (MA, 10 μM, NOX-2 inhibitor). Microglia treated with control or anti-STING siRNA were exposed to medium or ODE. Next, mouse (C57BL/6) pups were euthanized under an approved protocol, organotypic brain slice cultures (BSCs) were prepared and exposed to medium or ODE with or without MA treatment daily for five days. Culture supernatant, cell pellets and mt-free cytosolic fraction were processed to quantify mt-superoxide, mtDNA, cytochrome C, TFAM, mitochondrial stress markers and mtDNA induced signaling via cGAS-STING and TLR9. Data was analyzed using one-way ANOVA and post-hoc tests. A p value of ≤ 0.05 was considered significant. ODE exposure increased the mt-superoxide formation. Next, MA treatment decreased ODE-induced mtDNA release into cytosol. ODE exposure increased the cytochrome C and TFAM levels. ODE increased MFN1/2 and PINK1 but not DRP1 and MA treatment decreased MFN2. MA treatment decreased the ODE-exposure induced mtDNA signaling via cGAS-STING and TLR9. Anti-STING siRNA decreased the ODE-induced increase in IRF3, IFN-β and Iba1 expression. In BSCs, MA-treatment decreased the ODE induced TNF-α, IL-6 and MFN1. Taken together, OD exposure induced mtDNA signaling could be curtailed through mitochondrial NOX-2 inhibition or STING suppression to reduce neuroinflammation. *In part supported by NIH grants ES026892 and ES027245 to AGK and Iowa State University funding to CC.*

1091 Comparison of Secondary Organic Aerosols from Dark Ozonolysis and OH-Initiated Oxidation in Generating Reactive Oxygen Species

J. Wei, T. Fang, C. Wong, S. Nizkorodov, and M. Shiraiwa. *University of California Irvine, Irvine, CA.* Sponsor: M. Kleinman

Secondary organic aerosols (SOA) account for a major fraction of ambient particulate matter, which have significant impact on global climate, air quality and public health. However, the health effects of SOA are still not well understood. The adverse health effects of ambient aerosols are linked to the oxidative potential, known as the capability to generate reactive oxygen species (ROS) *in vivo*. Various acellular assays have been applied for the characterization of oxidative potential, among which electron paramagnetic resonance (EPR) spectroscopy coupled with spin trapping techniques has drawn increasing attention due to its ability of simultaneous quantification of multiple radical species. For lab-generated SOA, OH-initiated photooxidation of precursors, especially biogenic volatile organic compounds (VOCs) has been less investigated in comparison to ozonolysis, especially for health-related studies. Therefore, using EPR spectroscopy, we characterized oxidative potential and radical composition of water reacting with SOA, which were generated from both ozonolysis and OH oxidation. Our preliminary results have shown that SOA from different oxidation systems may introduce highly different radical compositions. To enhance the mechanistic understanding, a kinetic modeling will be utilized to simulate SOA formation and subsequently radical generation from different oxidation pathways. We anticipate that the comparison between different oxidation systems may provide insights into difference in chemical compositions and radical formation mechanisms from associated SOA.

1092 Toxicity Screening of Volatile TSCA Chemicals Using a Novel Air-Liquid Interface *In Vitro* Exposure System

A. M. Speen[1], L. A. Dailey[2], T. Krantz[2], D. Davies[2], P. Evansky[2], J. Harrill[3], J. Hill[4], W. Zander[4], M. Monsees[4], and M. Higuchi[2]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; [2]US EPA/CPHEA, Research Triangle Park, NC; [3]US EPA/CCTE, Research Triangle Park, NC; and [4]US EPA/ORAU, Research Triangle Park, NC.*

Recent amendments to the Toxic Substances Control Act (TSCA) include specific provisions that mandate the US Environmental Protection Agency (EPA) to encourage and facilitate "the use of scientifically valid test methods and strategies that reduce or replace the use of vertebrate animals while providing information of equivalent or better scientific quality and relevance that will support regulatory decisions." Though *in vitro* systems have been employed using submerged cultures, these methods do not allow for the testing of volatile/insoluble organic compounds (VOCs), nor do they effectively mimic the physiology of an airway exposure. Thus, a specialized cell culture exposure system (CCES) was developed that permits cells to be exposed at an air-liquid interface (ALI), allowing for direct chemical-to-cell interaction between aerosol, vapor or gas, presented directly to the cells at a constant flow rate and concentration. This novel system is capable of testing six different chemical concentrations simultaneously to generate concentration dependent response curves on a single plate of cells. In the on-going study, BEAS-2B and 16HBE cell lines, as well as primary normal human bronchial epithelial (NHBE) and MatTek Epi-Airway™ cells are used to assess their comparative responses to a variety of volatile chemicals: 1-bromopropane, carbon tetrachloride, dichloromethane, naphthalene, and 1,3-dichloropropene. Cells are exposed for two hours to six concentrations in half-log dilutions, plus an air (sham) control to generate concentration dependent response curves. Cell viability and cytotoxicity are measured via the CellTiter-Glo assay and lactate dehydrogenase release. Our highest doses per chemical induce < 20% cytotoxicity in the BEAS-2B and 16HBE cell lines, while our lowest doses are targeted for no observed adverse effects. Cell lysates have also been collected for whole transcriptome targeted RNA-Sequencing (i.e., BioSpyder TempO-Seq™) and compared for dose response across cell types. Additionally, trans-epithelial electrical resistance (TEER) and ELISA for IL-8 and IL-6 have been measured in naphthalene and 1,3-dichloropropene exposed cells. All endpoints are collected four hours post-exposure. Overall, the main objective of this study is to evaluate the capability of the transcriptomic data to identify concentration-dependent changes in gene expression for volatile chemicals and to evaluate the ability of the transcriptomic data to group chemicals with similar bioactivity profiles for potential read across applications. *Abstract does not reflect views or policies of the US EPA.*

1093 Combinatory Effects of Various Stress Modalities and Acute Ozone Exposure on Stress-Related Gene Expression in the Hippocampus

P. S. Kodavanti[1], M. Valdez[1,2], D. Freeborn[1], C. Colonna[1,2], and U. Kodavanti[1]. *[1]US EPA, Research Triangle Park, NC; and [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN.*

Underserved and vulnerable communities are often disproportionally impacted by psychosocial stressors and poor living conditions. These communities are more likely to live in housing near contaminated sites and/or closer to busy roadways. Epidemiological studies have shown that children from disadvantaged communities exposed to various environmental contaminants have increased incidence of asthma and obesity, both morbidities that are also related to increased chronic stress. This study sought to identify how community-level stressors (noise, confinement, fear, and other life stressors) can interact with air pollutants to increase susceptibility to stress. A rat model of chronic stress was developed by exposing rats to unpredicted stressors (restraint, Tilted cage, Shaking, Noise, Predator odor) for a period of 2 months and then tested for its susceptibility to ozone-induced (environmental stressor) gene expression changes in the brain region involved in stress adaption (hippocampus). Another set of rats were single housed during this 8-week period, with no environmental enrichment provide, to model "psychosocial" stress. Rats were exposed to filtered air or ozone (0.8 ppm) for 4h followed immediately by necropsy. We designed a qPCR primer-based array for genes related to glucocorticoid, GABAergic, glutamatergic, and adrenergic signaling as well as stress, neurotrophics and the endocannabinoid system. We found that ozone decreased expression of glucocorticoid receptor genes (*nr3c1*, *nr3c2*) independent of stressor. Both stress groups displayed apparent decreases in *fkbp4*, with no effect of ozone. One of the most profound gene expression changes was found with *fkbp5*, where ozone dramatically increased expression independent of stress group. Ozone increased gene expression for *avp*. We found increased expression of *Crhr2* only in the no

stress group, this effect was blocked in all stress groups. Additionally, ozone decreased expression of *bdnf* across all groups. These results demonstrate a glucocorticoid mediated signal (*nr3c1*, *nr3c2*, *fkbp4*, *fkbp5*) in the hippocampus following ozone exposure. *This abstract does not necessarily reflect US EPA policy.*

PS 1094 ERV1/ChemR23 Protects against Ozone-Induced Pulmonary Inflammation and Injury

E. J. Stewart[1], E. Browder[1], M. Hodge[1], B. Luo[1], A. Pal[2], S. Shaikh[2], and K. Gowdy[1]. *[1]East Carolina University, Greenville, NC; and [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Inhalation of ground level ozone (O_3) poses several potential health risks for the global population. Numerus epidemiological studies show that ozone exposure can lead to cardiovascular health problems, aggravate lung diseases such as asthma, and cause damage to the lungs. Ozone is known to induce pulmonary inflammation and injury, but the mechanisms of this damage are poorly understood. In our previous studies, 24 hours post ozone exposure was found to have significant reductions in pulmonary specialized pro-resolving lipid mediators (SPMs). SPMs are involved in the resolution of inflammation and are a broad family of lipid mediators, including resolvins, protectins, and maresins that are derived from eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and arachidonic acid (AA). SPMs regulate pro-resolving pathways through G-protein coupled receptors, such as chemokine-like receptor 1 (ERV1/ChemR23). ChemR23 is a receptor for chemerin, a chemoattractant for macrophages, and EPA-derived SPM resolvin E1. Currently, the role of SPM signaling through these G-protein coupled receptors following ozone-induced pulmonary inflammation and injury is unknown, and the goal of this study is to explore ChemR23 and SPM signaling in this context. Female wild type (ChemR23$^{+/+}$) or ChemR23 deficient (ChemR23$^{-/-}$) mice 8-10 weeks of age were exposed to 1ppm ozone for 3 hours and necropsied 24 hours post-exposure. Bronchoalveolar lavage (BAL) was obtained to measure pulmonary inflammation and injury. Total protein in the BAL was measured as a marker of pulmonary microvascular injury and BAL cellular differentials were quantified to determine cellular infiltrates after exposure. 24 hours post ozone exposure, ChemR23$^{-/-}$ mice showed significantly increased airspace neutrophilia and pulmonary injury via higher BAL protein levels compared to the ChemR23$^{+/+}$ controls. These data suggest that the EPA-derived resolvin E1 receptor ChemR23 plays a significant role in the resolution of ozone-induced pulmonary inflammation and injury. Future studies will uncover if these findings correlate with decreased SPM production 24 hours after ozone exposure, and if a diet supplemented with RvE1 or its parent compound mitigates ozone-induced pulmonary inflammation and injury.

PS 1095 Long-Term Airway Exposure to Environmental Allergens Increases Blood Pressure and Myocardial Vulnerability and Alters Responsiveness to Ozone

A. K. Farraj[1], B. L. Martin[2], J. Dye[1], M. C. Schladweiler[1], W. Williams[1], C. N. Miller[2], M. Khan[1], J. Richards[1], W. K. Martin[3], A. R. Henriquez[2], R. Grindstaff[1], S. H. Gavett[1], M. Gilmour[1], U. P. Kodavanti[1], and M. S. Hazari[1]. *[1]US EPA, Research Triangle Park, NC; [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [3]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Asthma and allergic rhinitis result from the interplay of genetic determinants and exposure to inhaled environmental triggers. While the respiratory impacts of allergic airways disease have been well-studied, the burden on the cardiovascular system has received comparatively little attention. Importantly, epidemiological studies have demonstrated that asthma increases risk for stroke and coronary heart disease. The precise cardiovascular risks associated with allergic airways disease and the biological mechanisms responsible, however, remain unknown. The purpose of this study was to, for the first time, determine the impacts of allergic airways disease on cardiovascular function in an experimental model. To model allergic airways disease, female rats were intranasally instilled for 6 weeks with a mixture of relevant environmental allergens (i.e. house dust mite, aspergillus fumigatus, and ragweed) previously shown to reliably elicit chronic features of asthma. At the conclusion of the allergen regimen, rats were exposed once to 0.5 ppm ozone to assess cardiovascular sensitivity to a prototypical air pollutant. Cardiovascular function, including blood pressure and the electrocardiogram, was constantly monitored using implantable telemetry. Sensitivity to the cardiac arrhythmogenic agent aconitine was also assessed. Preliminary data indicates that pulmonary impacts were characteristic of allergic airways disease. Moreover, long-term exposure to allergens increased diastolic blood pressure ($p<0.05$) and to a lesser extent systolic blood pressure ($p=0.06$) and increased sensitivity to aconitine-induced cardiac arrhythmia ($p<0.05$). Furthermore, ozone decreased heart rate to a similar extent ($p<0.05$) in both saline and allergen-instilled groups and increased sensitivity to aconitine only in the saline-instilled group ($p<0.05$). These findings demonstrate that allergic airways disease may increase cardiovascular risk in part by altering blood pressure and by causing cardiac electrical instability. *This abstract does not reflect US EPA policy.*

PS 1096 Glucocorticoid and Beta-Adrenergic Receptor Antagonists Inhibit O_3-Induced Metabolic Response

D. I. Alewel[1], A. R. Henriquez[1], M. C. Schladweiler[2], C. N. Miller[1], J. E. Richards[2], S. J. Snow[2,3], and U. P. Kodavanti[2]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; [2]US EPA, Research Triangle Park, NC; and [3]ICF, Durham, NC.*

Inhalation of air pollutants has been linked to neuroendocrine stress-induced systemic metabolic and innate immune effects through increased circulating adrenaline and glucocorticoids. We have shown that ozone (O_3) induced pulmonary injury and inflammation are mediated through the activation of beta-adrenergic receptors (BAR) and glucocorticoid receptors (GR). Since air pollution has been linked to increased incidence of diabetes and obesity, assessing the contribution of stress mediators in metabolic homeostasis can aid in understanding the mechanisms. The purpose of this study was to examine if BAR and GR are involved in O_3-induced systemic and liver metabolic alterations. To determine the impact of BAR and GR individually or in combination, we treated 11-13-week-old male Wistar-Kyoto rats with propranolol (PROP), a non-specific BAR antagonist, and mifepristone (MIFE), a GR antagonist. Treatments began 7 days prior to air or O_3 (0.8 ppm x 4 h) exposure and ended the day of exposure. Animals received injections of 1) saline or PROP (10 mg/kg/day, i.p.); 2) corn oil or MIFE (30 mg/kg/day, s.c.) or 3) both PROP+MIFE. O_3-induced hyperglycemia was mitigated by MIFE and PROP+MIFE but not PROP alone, however, both drugs reduced O_3-induced glucose intolerance. Circulating cholesterol (CHOL) and free fatty acids (FFA) increased after O_3 exposure as we have observed in other studies. This effect on CHOL was mitigated by MIFE and PROP+MIFE, but not PROP. O_3 effect on FFA was mitigated by MIFE and/or PROP. Liver expression of genes involved in glucose and lipid metabolic processes showed O_3-induced increases in glucose 6-phosphatase (G6pc) and hexokinase-2. The effect on G6pc was mitigated by MIFE suggesting a role of GR in O_3-increased gluconeogenesis. Neither PROP nor MIFE had any effect on O_3-induced increases in carnitine palmitoyl transferase 2, peroxisome proliferator activated receptor alpha and gamma, and decreased steroid responsive element binding factor 2. In conclusion, while GR activation played a major role in O_3-induced glucose and lipid metabolic changes, BAR inactivation was associated with mitigation of peripheral glucose uptake. Thus, O_3-induced homeostatic metabolic changes support epidemiological observations, and could contribute to metabolic syndrome in susceptible individuals. *This abstract does not reflect the US EPA policy.*

PS 1097 Ozone Inhalation Impacts Placental Biomarkers and Uterine Artery Function

R. A. Salazar[1], M. Garcia[1], J. Begay[1], T. Wilson[1], T. Young[1], S. N. Lucas[1], G. Herbert[1], A. Ottens[2], and M. J. Campen[1]. *[1]University of New Mexico, Albuquerque, NM; and [2]Virginia Commonwealth University, Richmond, VA.*

Adverse environmental stressors in the early stages of life can increase the risk of developing chronic diseases and may play a significant role in cardiovascular disease in adulthood. Respectively, air pollution exposure has become an area of interest and is being recognized as an important risk factor associated with adverse pregnancy outcomes. Recently, the placenta, as a target organ for maternally-inhaled pollutants has gained recognition as a potential mediator of adverse birth outcomes related to ambient air pollution, such as ozone. The present study examined the mechanism(s) by which inhaled pollutants may contribute to adverse cardiovascular conditions. We investigated effects on the uterine artery in this context, by reviewing its pathology and how particulate air pollution has a toxic effect on development and the causes of adverse pregnancy outcomes. We evaluated both inflammatory and oxidative stress markers following maternal ozone exposures. We began this project by evaluating how serum from ozone exposed rats caused uterine artery contractility and compared the results to serum from filtered air exposures. We determined that serum from ozone-exposed rats caused a ~20% net increase in uterine artery contractility when compared to serum from filtered air exposure. *In vivo*, this was seen as increased uterine artery resistance index, as assessed by ultrasonography. During preliminary studies filtered air (FA)-exposed rats also showed enhanced uterine artery vasodilation when treated with acetylcholine as compared to 0.3ppm and 1ppm ozone exposed rats. We further analyzed placental gene expression by quantitative polymerase chain reaction (qPCR). Our genes of interest included: chemokine

ligand 1 (CXCL-1), chemokine ligand 2 (CCL2), collagen type 1 alpha 1 chain (COL1A1), transforming growth factor beta 1 (TGFB1), frizzled class receptor 1 (FZD1), cyclooxygenase 1 (COX1), cyclooxygenase 2 (COX2), chemokine ligand 2 (CCL2), and matrix metalloproteinase 10 (MMP10). Patterns of key transcript changes (MMP10, Col1a1, and FZD1) aligned with human mRNA changes in preeclampsia, supporting the potential that early (gestational day 10) exposures could promote or exacerbate gestational hypertension later in pregnancy.

1098 CD163 Protects against O_3-Induced Oxidative Stress and Pulmonary Injury

S. W. Reece[1], E. A. Browder[1], M. X. Hodge[1], B. Luo[1], B. J. Kilburg-Basnyat[1], H. Zhu[2], T. J. McMahon[2], R. M. Tighe[2], and K. M. Gowdy[1]. *[1]East Carolina University, Greenville, NC; and [2]Duke University Medical Center, Durham, NC.*

Epidemiological studies have reported that exposure to elevated ambient concentrations of ozone (O_3) is associated with adverse pulmonary and cardiovascular health outcomes. However, the underling biological mechanisms mediating O_3 associated adverse health effects are unknown. O_3 induces oxidative stress in the lung leading to pulmonary inflammation and injury. This pulmonary inflammation and injury correlates with increased levels of damage associated molecular patterns (DAMP). Recently we have found that O_3 exposure is associated with increased levels of the DAMP cell free hemoglobin (CFH). CFH is endocytosed by CD163, a scavenger receptor exclusively expressed on macrophages/monocytes; the uptake results in the up-regulation of heme oxygenase 1 (HO-1). Therefore, we hypothesize that O_3 -induced oxidative stress increases CFH in the airspace and that CD163 is critical for protecting against this DAMP induced injury. Methods: C57BL/6J (WT) and CD163$^{-/-}$ male mice were injected with vehicle or 100 mg/kg of N-Acetyl-Cysteine (NAC) and then, 1h later, exposed to either filtered air (FA) or 1ppm O_3 for 3h. BAL and blood samples were obtained 6h or 24hr post exposure and bronchoalveolar lavage (BAL) cell counts, CFH, and total protein were measured. Real time PCR was used to measure HO-1, proinflammatory cytokine, and chemokine levels in lung tissue. Results: After O_3 exposure, WT mice had a significant increase in CFH in the BAL which was augmented in O_3 exposed CD163$^{-/-}$ mice. Additionally, O_3 exposed CD163$^{-/-}$ mice had greater pulmonary inflammation and injury compared to WT mice as evidenced by increased BAL neutrophils, macrophages, and total protein. CD163$^{-/-}$ mice exposed to O_3 also had significantly lower levels of HO-1 when compared to WT controls. In WT mice, NAC pretreatment did not alter O_3-induced pulmonary inflammation or injury whereas NAC pretreatment of CD163$^{-/-}$ mice significantly decreased BAL protein. Our findings suggest that the mitigation of O_3-induced oxidative stress is dependent on CD163 due to its ability to clear excessive DAMPs such as CFH. Future studies will examine the underlying mechanism of CFH-augmented oxidative stress and its relationship to monocyte/macrophage efferocytosis.

1099 Exacerbation of Sepsis-Induced Acute Lung Injury (ALI) by Ozone Is Regulated by Macrophage Phenotypic Switching

J. Radbel[1], K. Vayas[2], O. Le-Hoang[1], E. Abramova[2], C. Guo[2], A. Gow[2], J. D. Laskin[2], and D. L. Laskin[2]. *[1]Rutgers, The State University of New Jersey, New Brunswick, NJ; and [2]Rutgers, The State University of New Jersey, Piscataway, NJ.*

Ozone (O_3) is an urban air pollutant known to cause alveolar epithelial barrier damage and altered pulmonary functioning. EPA compliant levels of O_3 are linked to an increased incidence of acute respiratory distress syndrome, a severe form of acute lung injury (ALI). We previously showed that O_3 exacerbates sepsis-induced ALI by promoting neutrophil accumulation in the lung. In these studies, we analyzed the role of resident and inflammatory macrophages in this pathogenic response. Male C57Bl/6J mice were exposed to O_3 (0.8 ppm) or air for 3 h followed 24 h later by i.v. lipopolysaccharide (LPS) (2.5 mg/kg) to model bacterial sepsis or PBS control. Bronchoalveolar lavage (BAL) was collected 24 and 48 h later, and fluid analyzed for markers of lung damage (protein, IgM, phospholipids). BAL cells were magnetically separated based on Cd11b expression and subsets characterized by flow cytometry as resident alveolar macrophages (CD11b^{-}CD45^{+}SiglecF^{+}Ly6G^{-}CD11c^{+}F4/80^{+}), inflammatory macrophages (Cd11b^{+}CD45^{+}SiglecF^{-} Ly6G^{-}CD11c^{-}F4/80^{+}) and neutrophils (CD11b^{+}CD45^{+}SiglecF^{-}Ly6G^{+}CD11c^{-}F4/80^{-}). Lung damage was significantly increased in mice exposed to O_3+LPS at 24 h relative to the other groups, a response correlated with increased numbers of neutrophils. At this time, *Nos2, Il1β, Cxcl1, Ccl2,* and *Ptgs2* mRNA expression was upregulated in resident macrophages. By 48 h, lung damage abated and resident macrophage expression of these genes decreased, while *Il4* and *Arg1* expression increased suggesting a switch from an M1 (proinflammatory) to an M2 (anti-inflammatory) phenotype. In O_3+LPS treated mice, infiltrating macrophages increased in the lungs at 24 and 48 h post exposure. Whereas at 24 h, these cells were mainly *Nos2* and *Ptgs2* positive, by 48 h they were *Arg1* positive indicating a similar phenotypic switch from a pro- to an anti-inflammatory phenotype. These results suggest that the O_3 exacerbation of ALI is due to early pro-inflammatory activation of resident and infiltrating macrophages, which release reactive nitrogen species and recruit neutrophils into the lung. Subsequent resolution of injury occurs as a consequence of macrophage phenotypic switching. *Supported by NIH ES004738, ES005022, IRSS Donald E. Gardner Toxicology Education Award.*

1100 Independent Roles of Beta-Adrenergic and Glucocorticoid Receptors in Systemic and Pulmonary Effects of Ozone

U. P. Kodavanti[1], S. J. Snow[2], M. C. Schladweiler[1], C. N. Miller[3], A. D. Ledbetter[1], J. E. Richards[1], and A. R. Henriquez[3]. *[1]US EPA, Research Triangle Park, NC; [2]ICF, Durham, NC; and [3]Oak Ridge Institute for Science and Education, Research Triangle Park, NC.*

The release of catecholamines is preceded by glucocorticoids during a stress response. We have shown that ozone inhalation produces homeostatic stressor effects through adrenergic receptor (AR) and glucocorticoid receptor (GR) activation by these adrenal-derived stress hormones. In this study, we 1) inhibited beta AR (BAR) while inducing GR or 2) inhibited GR while inducing BAR to examine the role of each receptor without the interactive effects of the other following ozone exposure. The treatment with each antagonist began 7 days prior to exposure to assure complete inhibition of receptors while agonist treatment occurred only 1 day prior. Twelve-week old male Wistar-Kyoto rats were treated daily with saline or propranolol (PROP; a non-selective BAR antagonist, 10 mg/kg, i.p.) starting at day 1 and with saline or dexamethasone sulfate (DEX; GR agonist; 0.02 mg/kg) starting at day 6 and during each day of air or 0.8-ppm ozone exposure (day 7 and day 8; 4h/day for 2 days). In the second experiment, rats were treated with saline or mifepristone (MIFE; GR antagonist, 30 mg/kg, s.c.) starting at day 1 and with saline or clenbuterol (CLEN; BAR agonist; 0.02 mg/kg) starting at day 6 and during each day of the same 2-day air or ozone exposure, followed by necropsy within 2 hours. DEX and PROP+DEX decreased adrenal, spleen and thymus weights in all rats. Ozone increased plasma epinephrine with minimal drug-treatment effect. DEX decreased and MIFE increased corticosterone levels. Ozone-induced increases in lung injury, protein leakage, inflammation and lavage fluid IL-6 were inhibited by PROP and exacerbated by CLEN. DEX and ozone decreased circulating lymphocytes, while MIFE and MIFE+CLEN reversed this effect. DEX exacerbated, while MIFE, PROP or MIFE+CLEN inhibited, ozone-induced hyperglycemia and glucose intolerance. Ozone inhibited glucose-induced insulin release with each drug having variable effect. In summary, 1) activating BAR, even with inhibition of GR, exacerbated ozone-induced pulmonary effects and inhibiting BAR attenuated these effects; and 2) activating GR exacerbated ozone systemic effects, even when BAR was inhibited. These data provide further insights on the independent role of BAR in pulmonary effects and roles of both BAR and GR in systemic metabolic effects of ozone. *Does not reflect the US EPA policy.*

1101 Identification of Candidate Extracellular Vesicle microRNA Regulators of Ozone-Induced Airway Inflammation

G. J. Smith[1], A. Tovar[1], M. Kanke[2], P. Sethupathy[2], and S. N. Kelada[1]. *[1]University of North Carolina, Chapel Hill, NC; and [2]Cornell University College of Veterinary Medicine, Ithaca, NY.*

Inhalation exposure to the air pollutant ozone (O_3) is associated with airway inflammation, exacerbation of existing respiratory diseases, and heightened susceptibility to respiratory infections. O_3 rapidly oxidizes components of the airway surface to form biologically active molecules that initiate these adverse effects. The precise mechanisms by which secondary O_3-airway surface liquid reaction products elicit inflammation and impair host defense are not fully known. Extracellular vesicles (EVs) are nano-scale, lipid membrane enclosed particles known to transport microRNAs (miRNAs) that can regulate mRNA expression in recipient cells. We hypothesized that EV-miRNAs regulate the transcriptional program of airway cells (e.g., epithelial cells and macrophages) in a manner that contributes to O_3-induced inflammation. To explore this, we exposed female C57BL/6J mice to filtered air (FA), 1, or 2 ppm O_3 by inhalation and 21 hours later collected bronchoalveolar lavage fluid (BALF) and isolated conducting airways (CA) for markers of airway inflammation, EVs, and airway macrophages (AM) and airway epithelia, key O_3-responsive cell types. We isolated EV-small RNAs and total RNA from AM for RNA sequencing (RNA-seq). O_3 exposure caused significant increases in airway EVs as measured by Nanoparticle Tracking Analysis (NTA) in parallel with traditional

markers of inflammation, such as inflammatory cells (macrophages and neutrophils) and protein in the BALF. Analysis of AM and CA mRNA and EV-miRNA by RNA-seq revealed an abundance of O_3-induced transcriptomic changes, including 693/971 differentially expressed AM mRNAs, 903/2148 differentially expressed CA mRNAs, and 59/149 differentially expressed EV-miRNAs in O_3 exposed mice (1/2 ppm O_3 vs. FA). Several differentially expressed EV-miRNAs in the O_3 groups, including miR-2137, miR-501, and miR-34a, exhibited concentration response patterns of expression. Integrative analysis of EV-miRNA and AM mRNA expression data identified EV-miRNAs 99a-5p and 22a-3p as candidate regulators of AM transcriptomic responses to O_3, targeting several genes including *Igf1r* and *Sp1*, respectively. In contrast to AM, we did not identify putative EV-miRNA regulators of CA gene expression through our bioinformatic analyses. In summary, our data show that O_3 exposure alters AM and CA gene expression, EV release, and EV-miRNA content, suggesting further investigation of EVs – specifically how they affect AM function - may provide insight into the mechanisms of O_3-induced respiratory inflammation and impaired host defense.

1102 Exosomal microRNA Expression Is Associated with Ambient Ozone Exposure in Coronary Artery Disease Patients

H. Chen[1], D. Diaz-Sanchez[2], and H. Tong[2]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [2]US EPA, Research Triangle Park, NC.*

Exposure to ambient air pollutants such as ozone (O_3) and particulate matter (PM) is associated with increased cardiovascular morbidity and mortality, but the underlying biological mechanisms have yet to be described. Emerging evidence shows that gene regulation by microRNAs (miRNAs) may play a role in air pollution-induced cardiovascular risk. This study aims to explore the association between exposure to ambient air pollutants and exosomal miRNA changes related cardiovascular disease. Fourteen participants with coronary artery disease were enrolled in this panel study. Each participant had up to 10 visits and their plasma samples were collected and measured for expression levels of exosomal miRNA 21 (miR21), miR126, miR146, miR150, and miR155 using quantitative RT-PCR. Daily 24-hr measurements of O_3 and $PM_{2.5}$ were obtained from central monitoring stations up to 4 days prior. Mixed effects models adjusted for temperature, humidity, and medications were used to assess the association between miRNA changes and ambient air pollutant levels. Expression of miR21 was negatively associated with ambient O_3 levels with a 3-day lag while miR150 expression was positively associated with a 1-day lag and 3d- and 5d- moving average ($P<0.05$). miRNA changes were not significantly associated with ambient $PM_{2.5}$ levels up to 4-day lag time. Further analysis indicated that β-blocker usage significantly modified the association between ozone exposure and exosomal miRNA levels where the association was more prominent among non-users. Conclusions: Exposure to ambient O_3, not $PM_{2.5}$, was associated with changes of exosomal miRNA levels in plasma. Ambient O_3 exposure may cause cardiovascular effects through altering miRNA levels in coronary artery disease patients. *This abstract of a proposed presentation does not necessarily reflect US EPA policy.*

1103 Ozone-Derived Oxysterols Impair Lung Macrophage Phagocytosis by Adduction of Phagocytosis Receptors

P. F. Duffney[1], H. H. Kim[2], N. A. Porter[2], and I. Jaspers[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]Vanderbilt University, Nashville, TN.*

Ground-level ozone is a common air pollutant found in photochemical smog and is known to cause pulmonary inflammation and suppress bacterial clearance in the lung. However the mechanism driving these effects are not fully understood. Ozone reacts with cell-derived cholesterol to form oxysterols, including the highly reactive secosterol A (secoA). SecoA or its aldol condensation product secosterol B (secoB), can adduct to lysine residues resulting in covalent modification of proteins, yet, the significance of secoA/B adduction on cellular function in lung macrophages is not known. We hypothesize that adduction of macrophage proteins by secoA/B results in impaired protein function. Protein adducts from human BAL macrophages were identified using an alkynyl-tagged secoA (20μM). Adducted proteins were identified using "click" chemistry to isolate alkynyl-tagged proteins followed by identification using mass spectrometry. Adduct confirmation was done using western blot. Binding of the phagocytic receptors CD206, CD64, and CD16a was measured via an in-house binding ELISA. The effect of oxysterols on phagocytosis was measured by the uptake of pH sensitive zymosan bioparticles in THP-1 macrophages and uptake of opsonized bacterial bioparticles in BAL macrophages. We identified over 100 proteins that formed adducts with secoA in BAL macrophages, including CD206, a known factor in macrophage phagocytosis and marker of M2 polarization. Treatment of recombinant human CD206 with secoA or secoB resulted in decreased binding to a known CD206 ligand. Similarly, the binding of Fc receptor member CD64 was impaired by secoA. Interestingly, binding of another Fc receptor, CD16a, was unaffected by oxysterols suggesting that not all endocytic receptors are affected by secoA treatment. *In vitro* experiments showed that uptake of both zymosan (mediated through CD206) and opsonized bacteria (mediated through Fc receptors) were impaired with oxysterol treatments. Our work shows that oxysterol adduction of the phagocytic receptor CD206 results in impaired receptor binding to target ligands. This represents a novel mechanism for impairing phagocytosis in ozone exposed macrophages.

1104 Altered Transcriptomic Effects of Ozone across the Brain following Maternal High Fat-Diet

M. Valdez[1,2], D. Freeborn[1], B. Chorley[1], U. Kodavanti[1], and P. Kodavanti[1]. *[1]US EPA, Research Triangle Park, NC; and [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN.*

Obesity affects more than one-third of US adults and is one of the leading causes of preventable death. Previously, we have found that dams fed a high fat diet (HFD) for 6-weeks prior to breeding and through postnatal day (PND) 32, generated offspring with significantly elevated susceptibility to ozone (O_3) when exposed as adults. We concluded that poor maternal diet choices may alter offspring's susceptibility to air pollutants. We hypothesized that maternal HFD would alter the transcriptome of the hypothalamus (HYP) and impact the effect of O_3 on global gene expression in both HYP and hippocampus (HIP). A 6-week pre-breeding HFD treatment was performed alongside a control diet (CD) on Long Evans dams and continued through PND 30 when all offspring were switched to control diet. At PND 40, rats were exposed to filtered air or ozone (0.8 ppm for 5 hr), followed by necropsy. Total isolated RNA (RIN score > 6) was prepped for using a PrepX RNA-Seq kit (Takara) and sequenced on an Illumina NextSeq 500 for 75 single-read cycles. Sequencing data was aligned to rn6 Ensemble Transcripts (r97), outliers identified by principal components analysis, and differentially expressed genes (DEGs) were determined by DEseq2 using a false discovery rate cutoff of <0.05. In the HYP, HFD increased expression of *PCDH20*, which encodes for a non-clustered protocadherin involved in neuronal diseases. O_3 exposure blocked this increase. HFD also increased expression of *ACADSB* in the HYP, which is involved in dietary protein processing. Exposure to O_3 reversed this expression. Within the HYP of CD, O_3 exposure resulted in 17 DEGs, 11 of which were also altered in the HYP of HFD exposed to O_3. In the HIP, the O_3 induced only 7 ozone-mediated DEGs identified in CD. O_3 influenced the expression of the majority of the DEGs. The most consistent effect of ozone across both brain regions was an increased expression of the lipid droplet storage factor, *Plin4*. These results indicate that ozone induces changes in gene expression in both the HYP and HIP and maternal diet may interact with these expressions. *This abstract does not necessarily reflect US EPA policy.*

1105 Susceptibility to Ozone-Induced Metabolic and Immunological Alterations in Rat Models of Social Isolation and Mild Chronic Stress

S. J. Snow[1,2], A. R. Henriquez[3], M. C. Schladweiler[2], C. N. Miller[2], and U. P. Kodavanti[2]. *[1]ICF, Durham, NC; [2]US EPA, Research Triangle Park, NC; and [3]Oak Ridge Institute for Science and Education, Research Triangle Park, NC.*

Underserved vulnerable communities are disproportionally impacted by psychosocial stressors and poor living conditions. Epidemiological studies have shown an interaction between psychologically stressed individuals and air pollution exposure. Our lab and others have recently demonstrated that ozone exposure activates neuroendocrine stress response pathways leading to systemic metabolic and inflammatory responses. The purpose of this study was to identify whether community level stressors (i.e. noise, uncomfortable living conditions, confinement, fear) can interact with ozone to increase susceptibility for immunological and metabolic diseases. Male, 4-week-old Wistar-Kyoto rats were randomized into 3 stress groups: No Stress (NS) - control group; Social Isolation (SI) - single-housed; Chronic Stress (CS) - single-housed and subjected to mild randomized stressors (i.e. restraint, tilted cage, shaking, intermittent noise, and predator odor) 5 days/week for 8 weeks. Animals were then exposed acutely to filtered air or ozone (0.8 ppm) for 4h followed by necropsy. After 3 weeks on the stress protocol through the end of the study, the CS group had significantly decreased body weight compared to the NS and SI groups. This corresponded with increased adrenal weight and urine corticosterone and metanephrine levels measured in the CS group, suggesting the chronic stress protocol was successful. In air-exposed rats, SI and CS tended to cause depletion of circulating thyroid stimulating hormone (TSH), luteinizing hormone (LH), prolactin, follicle stimulating hormone, and brain-derived natriuretic factor (SI>CS), but not adrenocorticotrophic hormone. SI also in-

duced more severe systemic inflammation than CS, as evidenced by increases in circulating cytokine levels (i.e. IL-1β, IL-4, IL-5, IL-6, IL-10, IL-13, and IFN-γ) regardless of exposure. Ozone exposure led to increases in plasma corticosterone levels (NS and SI), plasma epinephrine (CS), and urine corticosterone and catecholamine metabolites (all groups). Exposure to ozone also led to increases in serum glucose, leptin, and branched-chain amino acids; increases in BALF IL-6 and TNF-α; and decreases in serum TSH, prolactin, and LH, with small influence of CS and SI. Systemic inflammation and some pulmonary effects of ozone were exacerbated by SI. Collectively, these data suggest that the degree to which psychosocial stressors affect the neuroendocrine system will likely sway the adverse metabolic and inflammatory responses induced by ozone exposure, a challenge stressor. *Does not reflect the US EPA policy.*

1106 Depletion of CD11b$^+$ Alveolar Macrophages Exacerbates Lung Injury and Oxidative Stress following Ozone Inhalation

C. R. Gardner[1], A. Murray[1], L. C. Smith[1], K. Vayas[1], E. Abramova[1], J. A. Cervelli[1], A. Sowinski[1], S. Koo[1], T. Banota[1], M. Napierala[2], J. D. Laskin[1], and D. L. Laskin[1]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; and [2]Uniwersytet Medyczny im. Karola Marcinkowskiego w Poznaniu, Poznan, Poland.*

Ozone (O_3) is an urban air pollutant known to cause lung inflammation, injury and oxidative stress. CD11b$^+$ macrophages accumulate in alveolar and interstitial regions of the lung following O_3 exposure and have been characterized as Ly6C^{hi} proinflammatory and Ly6C^{lo} anti-inflammatory/wound repair. To assess the role of CD11b$^+$ macrophages in O_3 toxicity, we used mice with a transgenic diphtheria toxin (DT) receptor under the control of the CD11b promoter (CD11b-DTR). Mice were treated ip with DT (25 μg/kg) to deplete CD11b$^+$ monocytes/macrophages. After 1 h, mice were exposed to air or 0.8 ppm O_3 for 3 h in whole body chambers. Mice were euthanized 24 h later and bronchoalveolar lavage fluid and lung collected. Following exposure of DT-treated CD11b-DTR mice to O_3, numbers of CD11b$^+$ Ly6C^{hi} proinflammatory alveolar macrophages increased relative to non-DT treated mice, while Ly6C^{lo} anti-inflammatory alveolar macrophages decreased. This correlated with increases in BAL protein levels indicating exacerbation of O_3-induced lung injury in DT-treated CD11b-DTR mice. O_3-induced oxidative stress, as reflected by increases in YM-1 expression, also increased in these mice. O_3 exposure also caused an increase in CD11b$^+$ Ly6C^{hi} and Ly6C^{lo} interstitial macrophages in lungs of non-DT treated mice; both inflammatory macrophage subpopulations were significantly reduced after DT administration to the mice. This was associated with decreased expression of inducible nitric oxide synthase in the lung consistent with fewer proinflammatory macrophages migrating into alveolar spaces from the interstitium following O_3 exposure. Conversely, DT administration had no effect on O_3-induced neutrophil accumulation in the lung. These data indicate that inflammatory monocyte-derived macrophages that localize in the alveolar regions of the lung after O_3 exposure are derived from monocyte and interstitial macrophage precursors; moreover, these cells play a key role in dampening O_3-induced oxidative stress and alveolar epithelial barrier dysfunction. Elucidating the role of inflammatory macrophage subpopulations in O_3 toxicity is key to understanding mechanisms of lung injury and developing approaches for mitigating tissue damage. *NIH ES004738, AR055073 ES005022; EUH 778051; MSHEP 3899/H2020/2018/2.*

1107 Cardiac microRNAs Relevant to Inflammation, Endothelial Function, and Myocardial Function: Impact from Ozone Exposure and Dietary Supplementation

H. Tong[1], M. C. Schladweiler[2], and U. P. Kodavanti[2]. *[1]US EPA, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

Air pollution exposure has been associated with adverse cardiovascular effects. Fish oil (FO) and olive oil (OO) supplementation attenuates the cardiovascular responses to air pollutants in human subjects. MicroRNAs (miRNAs) are a key regulating factor for gene expression. We examined the influence of ozone (O_3) on miRNAs relevant to inflammation, endothelial function, and cardiac function and the impact of dietary supplementation with FO and OO on O_3-induced changes in miRNAs expression in rat hearts. Male Wistar Kyoto rats were fed either a normal diet (ND), a diet enriched with 6% FO or OO starting at 4 weeks of age. Eight weeks following the start of these diet, animals were exposed to filtered air (FA) or 0.8 ppm O_3, 4 hr/day for 2 consecutive days. Selected miRNAs of inflammation, endothelial and cardiovascular function were assessed in cardiac tissues to examine the effects of diets and O_3 exposure. Cardiac miRNAs were altered by both diet and O_3 exposure. Specifically, O_3 exposure was associated with up-regulation of miR-150 and miR-208a and down-regulation of miR-107 and miR-145 in ND, as well as down-regulation of miR-150 in FO and up-regulation of miR-21, miR-29 and miR-486 in OO. O_3-induced up-regulation of miR-150 and down-regulation of miR-21 were attenuated by both FO and OO. These results suggest that acute O_3 exposure-induced inflammation and cardiac and endothelial dysfunction may be mediated by effects of O_3 on miRNA expression, and dietary supplementation with FO or OO may alleviate these adverse effects in rats. *This abstract of a proposed presentation does not necessarily reflect US EPA policy.*

1108 Systemic Inflammation and Peripheral Organ Injury after Ozone Exposure in Diabetic Rats Receiving Atherogenic Diet

M. C. Schladweiler[1], S. J. Snow[2], A. R. Henriquez[3], B. Vallanat[1], C. Fisher[4], J. E. Richards[1], and U. P. Kodavanti[1]. *[1]US EPA, Research Triangle Park, NC; [2]ICF International Inc., Durham, NC; [3]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; and [4]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Exposure to air pollutants is associated with increases in cardiometabolic diseases among susceptible individuals. While we have shown that ozone induces neuroendocrine stress-mediated homeostatic alterations in multiple organs, susceptible individuals with altered stress response may be predisposed to exacerbation of chronic diseases. The purpose was to determine the susceptibility of diabetic rats on control or atherogenic diets to acute ozone-induced systemic and peripheral organ changes in immunological and metabolic processes. Healthy, male Wistar and Wistar-derived Goto-Kakizaki (GK) rats, genetically predisposed to non-obese type 2 diabetes, received control or high-cholesterol atherogenic (HCA) diet beginning at 4 weeks of age for 12 weeks. Following the 12 week diet regimen, rats were exposed to air or 1 ppm ozone, 6h/day for 1 or 2 days and responses were analyzed at the end of each exposure. GK rats on the control diet were predisposed to hyperglycemia and glucose intolerance and increased body fat percentage relative to their Wistar counterparts; however, serum cholesterol and triglycerides levels were comparable between both strains. HCA diet increased circulating cholesterol, low-density lipoprotein, and insulin in both strains regardless of exposure. Increases in insulin levels found in GKs on the HCA diet were exacerbated after ozone exposure. Circulating lipase increased with HCA diet in both strains (Wistar>GK) and exposure groups. Likewise, circulating aspartate and alanine amino transferases increased in both strains receiving HCA diet with ozone exacerbating effects in GK rats, indicating liver injury. Circulating cytokines such as IFN-gamma, TNF-alpha, IL-6, and KC/GRO increased in both strains on HCA diet, and ozone, exacerbated these responses. Gene expression for metabolic markers was assessed using targeted Illumina sequencing in liver and muscle for both strains on control diet. Principle component analysis indicated strain differences in lipid and glucose metabolic markers and marked ozone effects in both liver and muscle, suggesting differential ozone impact in GK rats. These data provide insights into how ozone may exacerbate peripheral metabolic and systemic inflammatory changes in susceptible individuals on an unhealthy lipid-rich diet. *Does not reflect the US EPA policy.*

1109 Valproic Acid Blunts Lung Injury, Oxidative Stress, Inflammation, and Altered Pulmonary Mechanics Induced by Inhaled Ozone

J. Lee, V. R. Sunil, K. Vayas, E. Abramova, A. Murray, A. Venosa, J. Cervelli, J. D. Laskin, and D. L. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Ozone is an air pollutant known to cause oxidative stress and inflammation in the lung. This can contribute to lung injury and aberrant pulmonary functioning. In the present studies we assessed the effects of valproic acid (VPA), a histone deacetylase inhibitor with antioxidant and antiinflammatory activity, on ozone-induced pulmonary toxicity. Female C57B16/J mice (18-22 g) were exposed to air or ozone (0.8 ppm, 3 h) in whole body chambers. This was followed 0.5 and 24 h later by i.p. administration of PBS control or VPA (300 mg/kg). Mice were euthanized 48 h later and bronchoalveolar lavage (BAL) and tissue collected. Ozone exposure resulted in increased levels of protein, surfactant protein-D (SP-D), IgM and cells in BAL, indicative of lung injury and inflammation. Ozone also caused oxidative stress as measured by disruption of SP-D structure, and increases in lung heme oxygenase-1 (HO-1) and 4-hydroxynonenal (4HNE)-modified proteins. Treatment of mice with VPA significantly reduced ozone-induced increases in BAL SP-D levels and blunted alterations in SP-D structure; HO-1 and 4HNE modified protein expression was also decreased. Flow cytometric analysis of BAL lung cells showed that ozoneinduced injury and oxidative stress were associated with increases in proinflammatory macrophages in the lung. These cells expressed ARL11 and TNFα, demonstrating that they are activated. VPA treatment reduced the number of activated macrophages accumulating in the lung in response to

ozone; VPA also suppressed the accumulation of monocytic and granulocytic myeloid-derived suppressor cells (MDSC). Ozone-exposure caused alterations in pulmonary function, including increases in central resistance and elastance; this was abrogated by VPA. Taken together, our data demonstrate that VPA is effective in reducing ozone-induced lung injury, inflammation and oxidative stress, and mechanical dysfunction. These findings may be useful in the development of therapeutics to treat oxidant induced lung injury. *Supported by Rutgers SURF/ASPET, NIH ES004738, AR055073, and ES005022.*

1110 Characterization of Acute Ozone-Induced Leukopenia through Flow Cytometric Quantification of Immune Cells

A. R. Henriquez[1], W. C. Williams[2], S. J. Snow[3], M. C. Schladweiler[2], M. N. Colette[2], and U. P. Kodavanti[2]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; [2]US EPA, Research Triangle Park, NC; and [3]ICF International Inc., Durham, NC.*

Acute ozone (O_3) inhalation concurrently increases circulating stress hormones, corticosterone and epinephrine, and decreases leukocytes (leukopenia) in rats. These two biological events correlate with the activation of the neuroendocrine stress response. We hypothesized that glucocorticoid-induced apoptosis in circulating lymphocytes was responsible for O_3-induced leukopenia. To examine the dynamic changes in circulating leukocyte subpopulations we quantified live, apoptotic (early and late) and necrotic granulocytes, monocytes (classical and non-classical), and lymphocytes (B and T [T helper and T cytotoxic]) using flow cytometry (n=8) in 12-13 weeks old male WKY rats exposed to air or O_3 (0.0, 0.4 and 0.8 ppm) for (30 min, 1h, 2h and 4h). To evaluate if circulating changes correlated with those taking place in immunological organs where maturation of leukocytes occurs, thymus and spleen cell populations were also analyzed. Generally, for those leukocyte subpopulations affected by O_3 exposure, the responses were dose and time dependent. Circulating lymphocyte count was significantly decreased after O_3 exposure (0.8 ppm, 2h and 4h). At 4h, this decrement was more extensive in B than in T cells (~50% and ~20% [for both T helper and T cytotoxic]). Circulating classical monocytes, also known as inflammatory monocytes, decreased after 4h of exposure (~60% and ~80% at 0.4 and 0.8 ppm respectively). Circulating granulocytes increased after 30 min of O_3 exposure (at both 0.4 and 0.8 ppm) but tended to decrease after 2h of exposure in 0.8 ppm O_3-exposed rats suggesting a rapid mobilization of these cells into peripheral organs. No significant ozone-induced changes were detected in cell populations for thymus and spleen at any time point. Also, the assessment of cells undergoing apoptosis or necrosis yielded no significant alterations in blood, thymus or spleen. Our results indicate that O_3-induced leukopenia is not mediated by cell death of lymphocytes or any other subpopulation, but rather by the mobilization of such cells. This study provides insights on how O_3 exposure favored the decrease of specific leukocytes subpopulations such as classical monocytes and B lymphocytes that could explain the nature of O_3-induced immune effects in the respiratory system. *This abstract does not reflect the US EPA policy.*

1111 Lung Epithelial Cell Susceptibility Driven by Surfactant Protein-C Mutation Enhances Ozone-Induced Toxicity

Y. Tomer[1], M. Kopp[1], K. Vayas[2], C. Gardner[2], M. Beers[1], A. Gow[2], D. Laskin[2], and A. Venosa[3]. *[1]University of Pennsylvania, Philadelphia, PA; [2]Rutgers, The State University of New Jersey, Piscataway, NJ; and [3]University of Utah, Salt Lake City, UT.*

Ozone is a ubiquitous air pollutant that causes moderate parenchymal stress and monocyte/macrophage inflammation in healthy individuals. These effects are heightened in susceptible populations including the elderly and patients affected by interstitial lung disease (i.e., pulmonary fibrosis, PF). Pulmonary fibrosis is a degenerating disease characterized by progressive disruption of the alveolar architecture interspersed with episodes of acute inflammatory exacerbations. Mutations in the alveolar epithelial type-2 cell-specific Surfactant Protein C (SP-C) gene (*SFTPC*) have been identified in a subset of PF patients, with the Ile->Thr substitution at position 73 (SP-C^{I73T}) as the most prevalent. To investigate the susceptibility of SP-C mutant populations to acute ozone exposure, we leveraged a novel inducible SP-C^{I73T} transgenic mouse. Low-level SP-C^{I73T} expression produces moderate enlargement of the alveolar septae, AT2 cell hyperplasia, and minor inflammation beginning at 16wk and deteriorating with time. Conversely, SP-C^{I73T} induction results in extensive polycellular inflammation, decline in respiratory function and lung remodeling, distinctive features of acute exacerbations. Population RNA-sequencing and targeted cytokine analysis of bronchoalveolar lavage fluid show that AT2 cells initiate monocyte/macrophage recruitment and activation via canonical (CCL-2, CX_3CR1) and non-canonical (IL-5, Eotaxin, and CCL-17) pathways during SP-C^{I73T} acute exacerbations. Consistent with these findings, RNA-sequencing of $SiglecF^{lo}CD11b^{+}CD64^{-}Ly6C^{+}$ monocytes indicate highly inflammatory (*inos*, *Il-6*) and pro-fibrotic (*col1a1*, *col1a2*) phenotype. Pharmacologic (intravascular clodronate liposomes) and genetic ($CCR2^{ko}$ mice) monocyte ablation resulted in reduced inflammatory burden and improved survival following SP-C^{I73T} exacerbations. Acute low-dose ozone exposure (0.8ppm, 3h) of SP-C^{I73T} mice resulted in heightened alveolar septal disruption, edema and perivascular immune cell infiltrate compared to SP-C^{WT} cohorts. These responses were observed in mice undergoing acute exacerbations, as well as aged SP-C^{I73T} cohorts (52 wk) expressing low levels of mutant protein. Taken together, our findings highlight intimate crosstalk between epithelial and inflammatory monocytes during acute exacerbations. In addition, these data support the notion that epithelial dysfunction aggravates respiratory symptoms induced by ozone exposure. *Grant support: P30ES013508 (MFB), VA 1I01BX001176 (MFB), ES004738 (DL), ES005022 (DL).*

1112 Effects of Chronic Pulmonary Inflammation on Ozone-Induced Alterations in the Lung Microbiome

E. R. Parchuke, E. V. Abramova, L. J. Kerkhof, D. L. Laskin, and A. J. Gow. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Ozone (O_3) is a ubiquitous urban air pollutant known to cause pulmonary inflammation and constriction of the airways. The effects of O_3 are particularly severe in those with pre-existing lung disease, potentially via a "2-hit" mechanism involving alterations in the pulmonary microbiome. In these studies, we examined the effects of O_3 exposure on the microbiome in mice lacking *Sftpd* which exhibit chronic pulmonary inflammation. C57Bl6/J (Wt) mice and *Sftpd -/-* mice were exposed to air or O_3 (0.8 ppm, 3 hr); bronchoalveolar lavage fluid (BAL) was collected 24 hr later. Flow cytometry was used to identify lung macrophages (CD45+/SiglecF+/F4/80+) as resident alveolar macrophages (AM) (Cd11b-/Cd11c+) or inflammatory macrophages (IM) (Cd11b+/Cd11c+), or neutrophils (PMNs) (CD45+/SiglecF-/Cd11b+/Ly6G+) in BAL. Significantly fewer AM were detected in *Sftpd -/-* mice (75 ± 2.6%*) relative to Wt (91 ± 1.8%). O_3 exposure caused a greater loss of AM in *Sftpd -/-* mice (62 ± 2.9%*#) than Wt (88 ± 3.2; this correlated with a greater percentage of IM (9.8± 0.9% vs 2.2 ± 1.0%*). However, O_3 had no effect on these responses. Significant neutrophilia was observed in *Sftpd -/-* mice (8.9 ± 0.6%*#) compared to Wt (4.3 ± 0.6%#) after O_3 exposure. This was associated with increased disruption of the lung lining fluid. Thus, the BAL phospholipid content in *Sftpd -/-* was increased relative to Wt (51 ± 11 μg vs 8.23 ± 18 μg*). Moreover, this was exaggerated following O_3 exposure (89 ± 12 μg*) relative to Wt (31 ± 10 μg). As inflammatory cell activation is known to affect the pulmonary microbiome by regulating turnover, changes to the lung lining fluid alter the growth capacities of different microbes, we next profiled microbial diversity within the lung of these mouse strains and the impact of O_3 exposure. Baseline differences in microbial populations were observed between Wt and Sftpd -/- mice (3.8 vs 2.7 Simpson index). A loss in microbial diversity was observed in Wt mice (2.2) 48 hr following O_3 exposure, with an expansion in microbial species in *Sftpd -/-* mice (7.5). As the increase in diversity is proposed to occur as a result of the change in growth conditions, we investigated growing bacteria using stable isotope probing. A significant shift in the expanding microbial populations was detected in both strains following O_3 exposure. These data demonstrate that O_3 alters inflammatory cell activation and BAL lipid content and the pulmonary microbiome in a manner that is exaggerated by chronic inflammation. (*p<0.05 vs Wt, #p<0.05 vs air). *Supported by NIH Grants: HL086621, ES004738, ESO05022 and ES029254.*

1113 Role of PPARγ in the Resolution of Ozone-Induced Lung Injury

L. C. Smith, C. Malcolm, E. Abramova, M. Ge, K. Vayas, A. J. Gow, and D. L. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Ozone is a ubiquitous urban air pollutant that causes airway inflammation and hyperresponsiveness in both healthy and susceptible populations. Macrophages play a role in ozone-induced lung injury by regulating the acute initiation and later resolution phases of the inflammatory response. The distinct activities of macrophages are mediated by subpopulations broadly classified as M1/pro-inflammatory and M2/anti-inflammatory that sequentially accumulate in injured tissues. RNA-seq analysis of alveolar macrophages revealed that exposure of mice to ozone resulted in alterations in inflammatory and lipid metabolism pathways, and down-regulation of PPARγ, a nuclear transcription factor important in M2 macrophage activation, inflammation resolution, and tissue repair. We hypothesized that administration of a PPARγ agonist would reduce ozone-induced lung injury by regulating macrophage activity and tissue repair. Female C57BL/6J mice were treated with rosiglitazone or vehicle control by daily intraperitoneal injection beginning 24 hr

prior to exposure to ozone (0.8 ppm, 3 hr) or air. Mice were euthanized 24, 48, and 72 hr post ozone. Bronchoalveolar lavage fluid (BAL) was collected and analyzed for total protein and phospholipid content. BAL was enriched for alveolar macrophages by gentle lung massage and isolated cells analyzed by flow cytometry and qPCR. Ozone caused increases in total protein and phospholipid content in BAL, consistent with lung injury. Rosiglitazone treatment resulted in decreases in BAL protein levels at 48 hr and phospholipid content at 72 hr when compared to ozone-only exposed mice, suggesting accelerated injury resolution. Flow cytometric analysis showed increases in both M1 and M2 macrophages in lungs of ozone-exposed animals throughout the time-course; reduced numbers of these cells were observed in rosiglitazone-treated animals at 72 hr. These results were consistent with reduced mRNA expression of pro- and anti-inflammatory genes Ptgs2 and Arg1, respectively, in macrophages at 72 hr. mRNA expression of Caveolin 1, a downstream target of PPARγ involved in lipid catabolism, was reduced in macrophages in response to ozone but sustained in rosiglitazone-treated animals. Collectively, these results suggest that PPARγ accelerates the resolution of ozone-induced lung injury by regulating inflammatory signaling and lipid metabolism in alveolar macrophages. *Supported by NIH Grants ES004738, ES005022, ES029254, ES007148, HL086621, and ES030984.*

PS 1114 The Influence of Acute Ozone Exposure and Hepatic Vagotomy on Glucose and Fatty Acid Metabolism

C. H. Colonna[1,2], A. R. Henriquez[1,2], J. House[3], J. C. Corton[2], S. Snow[4], M. Schladweiler[2], U. P. Kodavanti[2], and P. S. Kodavanti[2]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; [2]US EPA, Research Triangle Park, NC; [3]NIEHS, Research Triangle Park, NC; and [4]ICF, Durham, NC.*

Air pollution exposure has been linked to augmented incidences of metabolic diseases like obesity and insulin resistance. We have previously shown that acute ozone (O_3) exposure is associated with increased circulating stress hormones and impaired glucose and fatty acid metabolism. In a previous study, Affymetrix array data indicated 2335 genes changed after ozone exposure in healthy rats. Comparing these gene expression changes to a database of ~10K microarray comparisons from chemical exposure in rat liver demonstrated that ozone induced a set of glucocorticoid receptor-regulated genes, indicating the contribution of increased hypothalamic-pituitary-adrenal axis activation after ozone exposure. The aim of this study was to 1) characterize ozone-induced metabolic changes in the liver and 2) determine if these effects are altered by hepatic vagotomy that would reduce parasympathetic influence on metabolic processes. Male 12-week old Wistar-Kyoto (WKY) rats underwent sham surgery or hepatic vagotomy 4-6 days prior to air or ozone exposure (0.0, or 1.0 ppm; 6 hrs/day for 1 or 2 days). Glucose tolerance testing was performed immediately following the first day of ozone exposure, and circulating metabolic hormones and lipids were measured in the serum at both time points. Ozone-induced hyperglycemia, glucose intolerance, and increased circulating cholesterol, triglycerides, and leptin were sustained in vagotomized rats. Hepatic vagotomy did decrease circulating insulin in ozone exposed rats only. Liver global gene expression changes were determined using Illumina RNA-sequencing in sham and vagotomized rats. Inhibition of cholesterol biosynthetic genes after ozone exposure in healthy rats suggested suppression of SREBP2 consistent with increases in circulating cholesterol in ozone-exposed rats. In conclusion, ozone induced metabolic alterations were correlated with hepatic glucocorticoid activation, and vagus denervation exerted a modest influence on ozone-induced metabolic effects. *This abstract does not necessarily reflect US EPA policy.*

PS 1115 Effects of Ozone-Generated Microvesicles and MV-MiR-199a-3p on Inflammatory Lung Responses in Alveolar Macrophages

J. M. Carnino[1], H. Lee[1], K. Vayas[2], V. R. Sunil[2], D. L. Laskin[2], and Y. Jin[1]. *[1]Boston University School of Medicine, Boston, MA; and [2]Rutgers, The State University of New Jersey, Piscataway, NJ.*

Ozone is an urban air pollutant and highly reactive oxidant which generates free radicals and oxidizes cellular components. In addition to direct ozone-induced alveolar damage, evidence suggests that lung macrophages have displayed either a protective or destructive role in the lungs following ozone exposure. Extracellular vesicles (EVs) play an essential role in intercellular communication via the transfer of EV cargo. Accumulating evidence suggests that EVs regulate a variety of human diseases through their effects on cell-cell crosstalk. The purpose of this study was to investigate the role of ozone-induced EVs in macrophage activation and lung inflammation. Microvesicles (MVs), a sub class of EVs, are the main type of EV detected in broncho-alveolar lavage fluid. Using nanoFACS, we found that both air- and ozone-generated MVs are primarily derived from epithelial cells. Through functional assays, we found that treatment of mice *in vivo* with ozone-induced MVs upregulates the expression of multiple inflammatory cytokines. To delineate the mechanisms by which ozone-induced MVs induce macrophage classical activation or lung inflammation, we focused on the regulatory mechanism of miR-199a-3p, a microRNA which was significantly increased in expression within MVs after ozone exposure. To introduce miR-199a-3p mimics into MVs, a modified method of calcium chloride transfection was used. We found that MV-miR-199a-3p induces expression of IL-1β in macrophages. Previously, we have reported that epithelium-derived MVs can be taken by lung macrophages and transfer MV-miRNAs into the recipient cells. Interestingly, miR-199a-3p level in ozone-stimulated macrophages was highly upregulated compared to macrophages obtained from air-control mice, however, the level of precursor miR-199a-3p was not significantly increased. This result suggests that elevated mature miR-199a-3p level in ozone-induced macrophages results from MV-mediated delivery of mature miR-199a-3p. Collectively, ozone-induced MVs potentially lead to acute upregulation of inflammatory cytokines in both mice lung tissue and macrophages. We also uncovered that mature miR-199a-3p may be selectively-packaged into MVs after ozone exposure and transferred to recipient macrophages, ultimately resulting in pro-inflammatory activation of macrophages and lung inflammation.

PS 1116 Ozone Exposure Exaggerates Lung Inflammation in Adult Mice with Muco-Obstructive Airway Disease

T. Vo, A. Kidder, B. Lewis, S. Patial, and Y. Saini. *Louisiana State University, Baton Rouge, LA.*

Airway surface liquid (ASL) layer is essential for the proper functioning of muco-ciliary clearance system. In addition, ASL layer acts as a physical barrier between reactive ozone and resident cells in airspaces including macrophages and epithelial cells. The lipids and proteins constituents of ASL are oxidized by ozone into reactive inflammatory mediators. We speculated that the inflammatory response to ozone is proportional to the concentration of lipids and proteins in the ASL layer. Accordingly, we hypothesized that the hyperconcentration of ASL constituents in muco-obstructive airways of mice will enhance their susceptibility to ozone-induced lung injury. Further, we hypothesized that *Scnn1b*-Tg exhibit exaggerated inflammatory responses to ozone inhalation. Here, the *Scnn1b*-Tg mouse model that manifest ASL dehydration and hyperconcentration was employed. Wild-type (WT) and *Scnn1b*-Tg adult mice were exposed to filtered air (FA) or 0.8 ppm of ozone for three weeks (4 hours/night). Total and differential cell count of bronchoalveolar lavage fluid (BALF) estimation, BAL cytokines estimation, histopathological analysis and macrophage activation were performed. Inflammatory cells as well as cytokines in BALF from FA-exposed *Scnn1b*-Tg mice were significantly higher as compared to both WT groups. Further, ozone exposed WT mice had significantly increased number of inflammatory cells and cytokines in BALF, and had exaggerated morphological activation of macrophages. These responses were heightened in ozone-exposed *Scnn1b*-Tg mice. Our ongoing analyses reveals that the latter group has increased mRNA message related to inflammatory responses. These data indicate that superimposition of ozone onto the ASL dehydration results in exaggerated inflammatory responses in the airspaces.

PS 1117 Pulmonary Impacts and Responsiveness to Ozone Inhalation after Exposure to an Environmental Allergen Mixture

B. L. Martin[1], J. Dye[2], M. C. Schladweiler[2], W. Williams[2], C. N. Miller[1], M. Khan[2], J. Richards[2], W. K. Martin[3], A. R. Henriquez[1], R. Grindstaff[2], S. H. Gavett[2], M. I. Gilmour[2], U. P. Kodavanti[2], M. S. Hazari[2], and A. K. Farraj[2]. *[1]Oak Ridge Institution for Science and Education, Oak Ridge, TN; [2]US EPA, Research Triangle Park, NC; and [3]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Multiple lines of evidence link exposure to air pollution with increased asthma-related morbidity and mortality. While several mechanisms have been postulated from experimental findings, many of the rodent asthma models fail to elicit features of chronic disease, bringing in to question pathophysiologic relevance. Recently, an approach using intra-airway exposure to a mixture of relevant environmental allergens, including house dust mite, *Aspergillus fumigatus*, and ragweed, has been shown to reliably elicit chronic features of asthma. The goal of this study was to determine the pulmonary and ventilatory impacts of short-term and chronic treatment with such an allergen mixture in female rats and assess respiratory sensitivity to a prototypical air pollutant. Female Wistar rats were repeatedly intranasally instilled with either the allergen mixture or saline alone. Pulmonary and systemic inflammatory markers were assessed in both short-term (2 weeks; ST) and long-

term (6 weeks; LT) allergen treatment cohorts. Shortly after the final allergen challenge, the LT cohort was exposed once for 2 hours to 0.5 ppm ozone. The allergen mixture caused an increase in bronchioalveolar lavage fluid (BALF) eosinophils and lymphocytes, interleukin (IL)-1 β, IL-4 IL-5, IL-10, tumor necrosis factor-alpha (TNF-α), and keratinocyte chemoattractant (KC)/growth-regulated oncogene (KC-GRO), as well as a decrease in interferon (IFN)-γ compared to saline in the ST cohort. No such changes were evident in the LT cohort. By contrast, ozone exposure in allergen-instilled rats, but not saline-instilled rats, in the LT cohort, caused an increase in BALF IL-13, IFN-γ and KC-GRO. Ventilatory data collected using double chamber plethysmography and histopathologic changes are currently being analyzed. In summary, mixed allergen exposure caused a lung inflammatory and cytokine response that shifts over time with repeated challenge, but that still confers exaggerated sensitivity to ozone after long-term allergen treatment. *This abstract does not reflect US EPA policy.*

1118 Acute Effect of Wildland Fire Smoke Exposure on Systemic Oxidative Stress among Wildland Firefighters in Midwestern United States

C. Wu, and O. Adetona. *Ohio State University, Columbus, OH.*

Wildland firefighters (WFFs) repeatedly experience exposure to elevated levels of wildland fire smoke (WF smoke), which is composed of a wide variety of health-damaging compounds such as $PM_{2.5}$ (particulate matter with diameter less than 2.5 microns) and carbon monoxide. Previous studies reported that occupational WF smoke exposure is associated with increased systemic oxidative stress among the firefighters. However, such information is geographically limited to southeastern and western regions of the United States, and their personal occupational exposure level to $PM_{2.5}$ in WF smoke is much lower than the levels observed in the present study. The objective of the study is to investigate changes in oxidative stress (i.e. 8-isoprostane and 8-OHdG) in urine samples collected from WFFs after WF smoke exposure. Between 2016 and 2018, a total of 19 wildland firefighters (17 males and 2 females with aged 34.63 ± 7.21 years) employed by USDA-Wayne National Forest were recruited. Spot urine samples (n = 120) were collected from the subjects right before (pre-shift), immediately after (post-shift), and next morning of prescribed burn (burn days) and regular work shifts (non-burn days). Samples were collected on a total of 27 and 15 person-days on burn and non-burn days, respectively. Urinary 8-isoprostane was determined using commercially available enzyme-linked immunosorbent assay (ELISA) kits. Difference in cross-shift changes (i.e. pre vs. post, pre vs. next morning, and post vs. next morning) in systemic oxidative stress compared between burn and non-burn days was assessed using linear mixed effect model. About 70% of WFFs had an increased urinary 8-isoprostane level after WF smoke exposure during the prescribed burns. The levels of urinary 8-isoprostane at post-shift and next morning are 1.26 and 1.22-fold higher than pre-shift on burn days, respectively, although the increases are not significant ($p = 0.15$ and 0.50, respectively). Ratio of 8-isoprostane level at post to pre-shift on burn days is marginally higher than the ratio on non-burn days ($p = 0.07$). Results suggest that WF smoke exposure during the prescribed burns is capable of inducing acute oxidative stress response among the WFFs and such acute response could be sustained for at least 24 hours, presumably due to their elevated exposure to WF smoke.

1119 Particle Filtration Ameliorates Respiratory Suppression Induced by Smoldering Smoke Emissions from Burn Pit Materials

S. A. Vance[1], Y. H. Kim[2], J. A. Dye[3], L. B. Copeland[3], W. C. Williams[3], M. J. Schladweiler[3], C. King[3], M. I. Gilmour[3], I. Jaspers[2], and S. H. Gavett[3]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; [2]University of North Carolina, Chapel Hill, NC; and [3]US EPA, Research Triangle Park, NC.*

Exposure to smoke from combustion of synthetic materials in municipal solid waste or military burn pits may be associated with reduced respiratory function or pulmonary inflammation, similar to effects observed after wildfire smoke exposures. We examined the comparative respiratory and inflammatory effects in mice of acute exposures to smoke generated by smoldering combustion of military burn pit-related materials, including plywood (PW), cardboard (CB), plastic (PL; a mixture of LDPE, HDPE, PET and PS), or a mixture (MX) of PW, CB and PL, and assessed the role of smoke particulate matter (PM) using HEPA filtration. Female Balb/cJ mice were exposed 1 hour on each of 2 consecutive days to whole or filtered smoke or clean air in a nose-only exposure tower. Combustion emissions contained ~40 (whole) or ≤ 0.2 (filtered) mg/m^3 PM for all four exposure types, while CO (range 35-75 ppm), other gases and volatile organic compounds were unaffected by filtration. Respiratory function was assessed by head-out plethysmography 20 min before, during, and 10 min after exposure. All unfiltered smoke had significant effects on respiration relative to pre-exposure, including expiratory time (Te; increased 164-265%), minute volume (decreased 45-60%), and breathing frequency (decreased 45-63%). Whole PL exposure had greater effects than CB, PW, or MX on at least 1 exposure day. HEPA filtration significantly improved breathing parameters during PW, PL, and MX exposures, but there were no significant differences between whole and filtered CB smoke exposures. The average increase in Te on both days for whole PW relative to pre-exposure (199%) was reduced to 82% with filtration, while Te increased 168% with whole CB and 148% during filtered CB. A few relatively small changes in lung lavage and complete blood count indices were detected 4 hours after final exposure to PL and MX, however real-time respiratory function was the more sensitive and robust indicator of these smoke exposure effects. Our data suggest that material type influences respiratory responses to burn pit combustion emissions and that PM filtration provides substantial but incomplete protection. *This abstract does not represent US EPA policy; DoD award #W811XWH-18-1-0731 to I.J.*

1120 Effects of Proteins and Humic-Like Substances on Iron-Mediated OH Radical Formation in Human Lung Fluids

D. H. Gonzalez[1], A. J. Ghio[2], J. Bauman[3], and S. E. Paulson[1]. *[1]University of California Los Angeles, Los Angeles, CA; [2]US EPA, Chapel Hill, NC; and [3]California State University, Northridge, CA.*

Inhalation of particulate matter is hypothesized to contribute to health effects by overproducing reactive oxygen species (ROS) and inducing oxidative stress. Fe(II) has been shown to contribute to ROS generation in simulated lung fluids containing physiological amounts of ascorbate. Atmospheric humic-like substances (HULIS) have been shown to chelate Fe(II) and significantly enhance ROS generation, but there have been no studies investigating this chemistry using physiological lung fluids derived from humans. Here, we investigate iron-mediated OH generation both from the dominant proteins that interact with iron in lung fluid, albumin and transferrin, and fulvic acid, a surrogate for HULIS. We find that albumin is capable of enhancing OH generation from inorganic Fe(II) and that transferrin attenuates this enhancement. We estimate the rate constants for albumin-Fe(II) and fulvic acid-Fe(II) mediated O_2 to O_2^- reduction (1.8 ± 0.1) M^{-1} s^{-1} (pH = 5.5, T = 37 °C), enhancements of about 20 and 30 times the rate for free iron. OH generation measured from fulvic acid-Fe(II) in human bronchioalveolar lavage fluid (n = 8) correlates reasonably well ($r^2 = 0.5$) with expected generation based on concentrations of Fe(II), albumin, transferrin, SRFA and ascorbate, suggesting that fulvic acid enhances OH formation, and that albumin and transferrin moderate the effect. We propose that fulvic acid, and thereby HULIS, is capable of mobilizing Fe(II) away from albumin thereby increasing the formation rate of O_2^- and ultimately of OH. *Supported by a Switzer Environmental Graduate Fellowship.*

1121 Contributions of TRPA1 and V3 to Wood Smoke $PM_{2.5}$-Induced Mucus Overproduction by Human Bronchial Epithelial Cells

T. A. Memon, N. D. Nguyen, K. L. Burrell, E. Rapp, C. E. Deering-Rice, and C. A. Reilly. *University of Utah, Salt Lake City, UT.*

Transient receptor potential (TRP) ion channels are activated by a range of stimuli including changes in temperature, noxious chemicals, and flavors such as mint and cinnamon. There are 28 human TRPs, and the roles of different TRP channels in regulating the adverse effects of inhaled toxicants in lung epithelial cells are poorly understood. We have previously shown that chemicals present in wood smoke particulate matter < 2.5 μm ($WSPM_{2.5}$) collected from burning pine wood can selectively activate TRP channels TRPA1 and TRPV3. Using pine $WSPM_{2.5}$ as a model air pollutant, it was found that activation of both TRPA1 and TRPV3 contributes to $WSPM_{2.5}$ induced mucus overproduction, specifically the gel-forming glycoprotein MUC5AC, by primary human bronchial epithelial cells (HBECs). In addition, the stable overexpression of TRPV3 in HBECs amplifies $WSPM_{2.5}$ induced expression of MUC5AC, while knockdown of TRPV3 prevents the induction of MUC5AC. Similarly, activation of TRPA1 stimulates MUC5AC production while its inhibition attenuates MUC5AC overproduction. Accordingly, pine $WSPM_{2.5}$ treatment of C57BL/6 mice induced *Muc5ac* expression, which was not observed in *Trpv3*-/- mice. These results show that concurrent activation of TRPA1 and TRPV3 by WSPM plays a crucial role in promoting mucus overproduction and hypersecretion by HBECs. Identifying molecular targets and mechanisms responsible for mucus overproduction may facilitate the development of novel mucolytic treatments for acute inflammatory and chronic obstructive pulmonary diseases. *Support: ES017431 and ES027015.*

1122 High-Fructose Diet Alters Cardiovascular Function One Day after a Single Wood Smoke Exposure in Adult Wistar-Kyoto Rats

G. Little[1], M. Hazari[2], B. Martin[1], A. Farraj[2], M. Harmon[3], C. King[2], and Y. Kim[3]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; [2]US EPA, Research Triangle Park, NC; and [3]University of North Carolina, Chapel Hill, NC.*

Wildfires are extreme events that have a significant potential to harm both healthy individuals and those with underlying conditions like cardiovascular disease. We previously demonstrated that exposure to a single episode of wildfire smoke can alter homeostatic function and worsen cardiovascular responses in healthy animals. However, it is not well established how diet affects the cardiovascular response to wildfire smoke. High-fructose (HF) intake has been associated with the development of obesity, inflammation, increased oxidative stress, and autonomic imbalance. Therefore, this study examines the effects of a HF (30% fructose, 0% sucrose) diet on cardiovascular responses to wood smoke (WS) in Wistar-Kyoto rats. We hypothesized that a HF diet would alter basic metabolism, body composition and hemodynamic function of the heart, and worsen the subsequent response to WS. Eight-week old Wistar Kyoto rats were placed on either a HF or normal diet (ND) for seven weeks. Body composition was measured every three weeks for fat, lean, and fluid compartment percentages, and animal resting energy metabolism was analyzed using an indirect calorimeter. Each group was exposed to 0.5 mg/m^3 of flaming WS or filtered air (FA) for one hour. Twenty-four hours after the exposure, rats were anesthetized, and cardiac function was determined with echocardiography. There were no significant changes in body composition or metabolic rate in HF rats compared to the control. HF rats exposed to WS and FA had significantly lower cardiac output than the ND rats. However, there was no difference in ejection fraction between the groups, and fractional shortening was only marginally higher in the HF group exposed to FA. The ND group exposed to WS had a significantly higher stroke volume when compared to the control. Exposure to WS caused SDNN to increase and RMSSD to decrease in ND rats, on the other hand, HF rats exposed to WS only had an increase in the latter and showed a trend towards increased SDNN. There were no significant differences in frequency domain parameters. This data indicates that a HF diet alters baseline cardiovascular function even in the absence of metabolic or body composition changes in Wistar Kyoto rats and suggests that diet can predispose the cardiovascular system to adverse effects during and after a single exposure inhalation. *This abstract does not reflect US EPA policy.*

1123 Emission Toxicity of Spruce and Lignite Combustion in Residential Heating Using Thermophoretic ALI Exposure System

T. Ihantola[1], M. Ihalainen[1], H. Hakkarainen[1], T. Rönkkö[1], K. Kuuspalo[1], A. Leskinen[1], O. Sippula[1], R. Zimmermann[2], J. Tissari[1], J. Jokiniemi[1], M. Hirvonen[1], and J. Pasi[1]. *[1]University of Eastern Finland, Kuopio, Finland; and [2]Helmholtz Virtual Institute of Complex Molecular Systems in Environmental Health, München, Germany.* Sponsor: M. Viluksela

Biomass combustion is one of the actions that can be taken to lower CO_2 emissions from residential heating. Even though European Union has been shifting more towards biomass, in some countries, solid fossil fuels are still used widely and even low-grade ones such as lignite are used in residential heating. Combustion emissions have many known health consequences, but it is not clear how coal compares to wood fuel in small scale combustion. In addition, the effect of atmospheric aging on the toxicity of emissions is not fully known. We studied spruce and lignite combustion emissions with and without aging on co-cultured cells in thermophoretic air-liquid interface (ALI) exposure system. Co-cultures consisting of alveolar epithelial A549 cells that were cultivated in basolateral side of inserts for 72 hours, and monocyte THP-1 cells, which are differentiated into macrophages prior transfer, are transferred into apical side 24h before exposure. Exposure were done on cell with medium containing HEPES buffer for an hour at air flow of 150ml/min. The medium was collected after exposure and fresh medium added. After 24h post-exposure both the changed medium and cells were collected for toxicity experiments. Toxicological analyses from cells were viability, mitochondrial superoxide, genotoxicity. Cell media were used for cytokine measurements. We found the cell viability being most affected by the aging process, whereas fresh samples showed no effect of the exposure. Mitochondrial superoxide analysis showed an increase after exposure to aged lignite smoke, compared to clean air and fresh lignite samples. CXCL1 analyzed from medium collected immediately after exposure showed aged emissions to activate more secretion, which was still detected after 24h post incubation period. Interestingly, there were no evident difference in genotoxicity between the fuel types or the aging of the emission. Together our results showed that lignite combustion samples present slightly higher responses in our exposures than wood combustion samples and the aging process increases the overall toxicity of the both combustion emission.

1124 Transient Receptor Potential Vanilloid-3 (TRPV3) and Ankyrin-1 (TRPA1) Regulate Wood Smoke $PM_{2.5}$-Induced Endoplasmic Reticulum Stress and Cytotoxicity in Lung Epithelial Cells

N. D. Nguyen, T. A. Memon, K. L. Burrell, M. Almestica-Roberts, C. E. Deering-Rice, and C. A. Reilly. *University of Utah, Salt Lake City, UT.*

Inhalation of particulate pollutants can promote and exacerbate pulmonary inflammatory diseases. A frequently cited effect of particles on lung epithelial cells is disruption of endoplasmic reticulum (ER) homeostasis, causing a pathological stress response (ERS). Transient receptor potential (TRP) ion channels often localize to the ER of lung epithelial cells where they regulate ER calcium homeostasis, and thus ERS and associated effects on cell functions and viability. Wood smoke $PM_{2.5}$ (WSPM) activates TRPV3 and TRPA1, and this study shows that TRPV3 is located on the ER of primary human lobar bronchial epithelial cells (HBECs). Further, treating cells with pine WSPM resulted in a time-dependent activation of all regulatory arms of the ERS response; PERK/EIF2αK3, ATF6α, and IRE1. Interestingly, HBECs treated with pine WSPM upregulated TRPV3 mRNA transcripts and downregulated TRPA1 transcripts, and inhibition of TRPA1 partially protected cells from WSPM-induced ERS and cytotoxicity, while inhibition of TRPV3 exacerbated ERS response and cytotoxicity. These data suggest that activation of TRPA1 plays a direct role in initiating ERS and TRPV3 negatively regulates ERS. Further, overexpression of TRPV3 conferred resistance to ERS and associated downstream cellular events, including cell cycle arrest at G2. The protective effect on ERS was most evident with WSPM, which also activates TRPV3. Collectively, these results suggest that TRPV3 and TRPA1 play opposing roles in mediating the WSPM-induced ERS response. These findings provide new insight on the physiological functions of TRPV3 and TRPA1 in the lung epithelium, and expand our understanding of mechanisms by which HBECs regulate life and death signals when exposed to cytotoxic agents such as WSPM.

1125 Lung Toxicity of Particulate Matter from Smoldering Combustion of Simulated Military Waste

Y. Kim[1], C. King[2], S. Warren[2], I. George[2], J. McGee[2], M. Hays[2], M. Higuchi[2], D. DeMarini[2], S. Gavett[2], I. Jaspers[1], and I. Gilmour[2]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

A burn pit was a common way to get rid of waste at the United States military bases in Iraq and Afghanistan between 2001 and 2011. Consequently, many deployed military and civilian personnel were exposed to burn pit smoke. While there is a higher prevalence of respiratory conditions in veterans returning from service in these locations, the relationship to burn pit smoke exposure is not well understood. We used a quartz-tube furnace coupled to a multistage cryotrap system to collect smoke particulate matter (PM) from a simulated smoldering military burn pit. We burned four materials common to burn pits: plywood (military spec wooden box), cardboard (military spec weather resistant box), plastic (a mixture of LDPE, HDPE, PET and PS), and mixture (a mixture of plywood, cardboard and plastic). PM in smoke was chemically analyzed and assessed for lung toxicity in mice via oropharyngeal aspiration and mutagenicity in *Salmonella* strain TA98 +/-S9. Combustion efficiency ranged from 68% to 78%. The plastic burn simulations emitted the highest PM mass, followed by the mixture, the plywood and the cardboard. PM was comprised of 42% to 64% total carbon and very low levels of polycyclic aromatic hydrocarbons (<0.1 wt%). On an equal mass basis (100 µg of PM condensate), PM from burning plywood induced small but significant lung toxicity (neutrophil influx) at 4-h post-exposure. A significant alteration in lung ventilatory parameters was also observed in mice exposed to the plywood and cardboard smoke PM at 4-h post-exposure. No effects on the lungs were observed with exposures to other smoke PM. None of the PM samples showed significant mutagenic responses. Previously we have reported that lung toxicity of biomass smoke PM is significantly greater for flaming than smoldering combustion, on an equal mass basis (Kim et al., EHP 126: 017011, 2018). Similarly, here we demonstrate that PM in smoke derived from smoldering combustion (low temperature and flameless) of different burn pit materials caused minimal or no lung toxicity and mutagenicity following acute exposures. Further studies are needed to evaluate lung toxicity of flaming

combustions of these and other materials by both instillation and inhalation routes of exposures. *This abstract does not represent US EPA policy; DoD Award # W81XWH-18-1-0731 to I.J.*

1126 Analysis of Long-Term Effects from Wildfire Smoke in a Rural Montana Community

A. Orr, and C. T. Migliaccio. *University of Montana, Missoula, MT.*

As wildfires continue to affect the Western United States, the need for expanding research on the effects of wildfire smoke exposure is warranted. Historically, studies on the effects of wildfire smoke exposure have been retrospective analyses of visits to providers, emergency departments, and hospitals, using ICD codes for cardiovascular and respiratory designations. The present study is designed to assess the long-term effects of wildfire smoke through a series of screenings considering physiological, psychological, and social health dynamics. This interprofessional research is focused primarily on the rural community of Seeley Lake, MT, which experienced unprecedented levels of smoke exposure from July 31 to September 18, 2017, with a daily average of >220 ug/m3. From 2017 to 2019, multiple health screenings were performed in Seeley Lake. In the first three years of this study, 103 different participants have been screened. Based on spirometry data, participants showed decreased lung function in 2018, with a slight improvement, but still significantly decreased, in 2019. The results also illustrate that the health effects are more pronounced in individuals above the age of 65, where their respiratory values were consistently below predicted values. Another component of the research consisted of two validated behavioral screenings, which calculated either mood states or depression scores for each individual. The mood state screenings completed on the day that the smoke cleared in 2017 showed more positive results, while subsequent years showed decreased scores. In contrast, the depression screening which addresses a larger time frame showed that people were more depressed in 2017 (while the fire was burning), and were less depressed in 2018 and 2019. This research highlights how inhalation toxicology can be applied to assess the prolonged effects of wildfire smoke exposure in rural communities.

1127 Burn Pit Components Exhibit Variable Toxicity on Human Bronchial Epithelial Cells

K. L. Rogers[1], T. Mascenik[1], Y. Kim[2], I. Gilmour[1,2], S. Randell[1], and I. Jaspers[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

Burn pits are areas designated for disposal of military waste by open air combustion without proper waste management protocols. This system was prevalent in Afghanistan and Iraq from 2002-2009, where an estimated 60,000 pounds of solid waste was burned daily. Exposure to toxic compounds from burn pit synthetic waste combustion may be associated with airway diseases and decreased respiratory function. We hypothesized that burn pit condensates would have a dose-dependent cytotoxic effect on human bronchial epithelial cells *in vitro*. Military waste materials, such as plywood, plastic, cardboard, and mixtures of these three components with and without diesel fuel were combusted under controlled conditions in quartz tube furnace system and emissions were collected in a serial cryotrap system. A solvent exchange was performed to transfer the emission condensates into cell culture media. Human donor bronchial epithelial cells were cultured on 96-well plates and co-incubated with the various condensates at 0.25, 0.5, 1,5, 10, 25, 50, 75, and 100 ug/cm^2 particulate concentrations for 24 hours. Cytotoxicity was assessed on a fluorescent plate reader using lactate dehydrogenase and adenylate cyclase assays. Plastics exhibited the greatest cytotoxic response, followed by the mixture and mixture containing diesel, with the least cytotoxicity seen in cells exposed to condensates from plywood and cardboard emissions. RNA analysis revealed exposure to condensates altered inflammatory (IL-8) and stress (HMOX-1) responses, with the mixture having the greatest effect. These results indicate that materials commonly disposed of in burn pits can be cytotoxic to airway epithelial cells and can possibly cause adverse respiratory health effects.

1128 Molecular Mechanisms of Wood Smoke Exposure in an Organotypic Model

N. Mallek[1], and S. McCullough[2]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

Wood smoke exposure causes airway inflammation and oxidative stress, which contributes to cardiopulmonary disease and early mortality; however, the molecular mechanisms responsible for these adverse effects are unclear. To date, epithelial cell monocultures have been widely used for identifying the molecular mechanisms involved in toxicity. While epithelial cells serve as the barrier between the host and the environment, they are only one of many cell types within the airway that cooperatively affect lung function. We hypothesized that trans-epithelial (TE) exposure to wood smoke condensate (WSC) would induce both the oxidative stress and pro-inflammatory response in airway fibroblasts. To test this hypothesis, we developed a Transwell-based *in vitro* organotypic model that recapitulates both *in vivo* cellular architecture and intercellular signaling. The model consists of an apical epithelial cell layer (16HBEs) and a basolateral fibroblast cell layer (IMR90s). Primary human bronchial epithelial cells and primary human lung fibroblasts are used when applicable. We assessed epithelial cell barrier integrity via trans-epithelial electrical resistance, fluorescein-labeled dextran permeability, and tight junction protein immunofluorescent staining. Importantly, the epithelial cell layer displays a high electrical resistance, low compound permeability, and polarized tight junction proteins. We then investigated the effects of TE WSC exposure on the kinetics of gene expression and protein expression for pro-inflammatory and oxidative-stress responsive genes. We found an increase in pro-inflammatory transcript expression (e.g. IL-8, IL-6), and an increase in oxidative-stress responsive genes (HMOX-1, NQO1). Changes at the protein level reflect transcript levels with peak protein expression (e.g. HMOX-1, 8-10 hours) following peak transcript expression (e.g. HMOX-1, 4-6 hours). Next, we examined the effects of repeat TE WSC exposure on airway fibroblasts. Preliminary data suggest differential gene expression between single exposure and repeat exposure. Differentially expressed genes display either a tolerance phenotype (e.g. HMOX-1) or a susceptibility phenotype (e.g. IL-8). Our results indicate an active role for airway fibroblasts in the toxicological response to wood smoke exposure, and facilitate new insights into the molecular mechanisms of toxicity.

1129 Diesel Exhaust Particle Exposure Causes Inflammatory Responses in Heart and Brain Despite Subtle Lung Inflammation

C. G. Hsu, A. Elder, and B. C. Berk. *University of Rochester, Rochester, NY.*

Air pollution is a significant threat to public health and even short-term exposures pose an acute cardiopulmonary risk to susceptible individuals. Emissions from gasoline and diesel engines are major contributors to airborne fine and ultrafine particulate matter (PM) in the urban environment. These particles are readily deposited in the lung and can have a large surface area to which organics adsorb easily. However, the pathways by which an insult to the lung can lead to adverse cardiovascular outcomes are not well understood. This study was designed to test the hypothesis that lung inflammation induced by diesel exhaust particles (DEP) - used here to model submicrometer carbonaceous exhaust PM - initiates a systemic inflammation in heart and brain. Mice (C57 BL/6, male, 10-12 weeks) were exposed to filtered air or DEP (NIST SRM 1650b, 0.5 mg/m^3, 4 hr/day, 1-4 days). Bronchoalveolar lavage fluid (BALF) was collected 24 hr after the last exposure (1, 2, and 4 days) to measure the number and type of cells. Following exposure, DEPs were visible in alveolar macrophages of BALF. DEP inhalation significantly increased the number of macrophages, but not polymorphonuclear neutrophils. Nod-like receptor family pyrin domain-containing 3 (NLRP3), interleukin 1 beta (IL-1β), interleukin 6 (IL-6) and monocyte chemoattractant protein-1 (MCP-1) gene expression were measured as indicators of the inflammatory response in lung, heart and brain tissue by real-time PCR. NLRP3 and IL-1β gene expression in heart, but not in lung, was elevated in response to DEP exposure. DEP inhalation also induced increases of IL-6 and MCP-1 gene expression in brain. These exciting results indicate that DEP can induce significant inflammation at distant sites despite little inflammation in lung tissue. Further studies are required to prove the specific role of alveolar macrophages and to identify the mechanisms for cardiovascular inflammation after DEP exposure. *Funding sources: 1R01HL134910-01 and P30ES001247.*

1130 Urban $PM_{2.5}$ Pollution Disrupts Cellular Physiology in Human Lung Cells: Role of the Unfolded Protein Response

M. Eggleston, A. Nyguen, N. Grooms, R. S. Martin, and R. Coulombe. *Utah State University, Logan, UT.*

Ambient particulate matter with a mean diameter of ≤2.5μm ($PM_{2.5}$) poses a serious public health risk, in part, because $PM_{2.5}$ can penetrate the deep lung, enter general circulation, and be widely distributed throughout tissues. Epidemiological studies have consistently associated exposure to ambient $PM_{2.5}$ air pollution to increases in all-cause mortality, cardiopulmonary and cardiovascular disease, stroke, diabetes, cancer, and Alzheimer's disease. The normally picturesque Cache Valley of Northern Utah frequently experiences some of the highest $PM_{2.5}$ concentrations in the United States. However, the

exact mechanism(s) of Cache Valley's $PM_{2.5}$ (CVPM) toxicity have yet to be fully characterized. We recently demonstrated that CVPM exposure is associated with endoplasmic reticulum (ER) stress, which triggers the unfolded protein response (UPR), a highly conserved stress-response mechanism. The purpose of this study was to focus on the dynamics of CVPM-elicited ER stress and UPR in cultured human lung (BEAS-2B) cells exposed to CVPM (1µg/mL and 12µg/mL; 24 hours). All experiments were conducted in parallel with diesel exhaust particles (DEP) as a positive control. RNA sequencing with KEGG pathway analysis confirmed significant upregulation (FDR adjusted p=0.05) in genes strongly associated with UPR activation, such as *BiP/GRP78*, *PERK*, *IRE1*, and *ATF6*. Flow cytometry revealed that CVPM (12µg/mL) caused significant cellular effects related to UPR activation, including reductions in mitochondrial membrane potential and alterations in intracellular Ca^{2+} homeostasis, as evidenced by a significant influx of Ca^{2+} in the cytosol and mitochondria, likely from the ER network. In most experiments, 1µg/mL DEP elicited similar results to CVPM at 12µg/mL, suggesting that CVPM is less potent than DEP. Taken together, these results support our hypothesis that a principal toxic mechanism of CVPM pollution involves ER stress and the UPR. *This research supported by the Marriner S. Eccles Foundation, GE Healthcare, and Utah State University.*

1131 Diesel Exhaust Particles Reduce Airway Epithelial Barrier Integrity through a Reduction of the Tight Junction Protein Tricellulin

T. Smyth, J. Veazey, S. Eliseeva, and S. Georas. *University of Rochester, Rochester, NY.*

Early life exposure to airborne particulate matter (PM) has been increasingly linked to the development of asthma. While changes in the expression of junctional proteins in lung epithelium has been seen in asthmatics, the impact of PM on their expression has received little attention. We investigated whether exposure to diesel exhaust particles (DEP), a major component of PM, would affect epithelial barrier function by reducing the expression of the tight junction protein Tricellulin. Standard reference material 2975 Diesel Particulate Matter (DEP) was purchased from NISTand suspended inculture media. Monolayers of the human bronchial epithelial cell line 16HBE14o- were grown on collagen coated Transwell inserts and treated with 25 µg/cm^2 DEP for 6 hours. Changes in barrier function were assessed by measuring transepithelial electrical resistance (TEER) and permeability of 4 kDa FITC-Dextran. Changes in tight junction protein levels were assessed by Western blotting of whole cell lysates. Neonatal Balb/c mice (postnatal day 4-7) were exposed to 255±50 µg/m^3aerosolized DEP or filtered air for 2 hours per day for 5 consecutive days, and sacrificed 2 weeks later. Lungs were collected, homogenized and analyzed by Western blot or RT-qPCR. Six-hour treatment of 16HBE14o- cells with DEP significantly reduced epithelial barrier function as measured by reduced TEER (584±54 versus 994±33 Ohms, n=5, p<0.05) and increased permeability to 4 kDa FITC-Dextran (26.0±1.8 versus 15.7±0.7 ug, n=5, p<0.05). These changes coincided with a significant reduction of Tricellulin protein as measured by Western blot (67±8% normalized band intensity versus vehicle, n=5, p<0.05). Neonatal Balb/c mice (pnd 4-7) exposed to aerosolized DEP presented with a significant reduction in Tricellulin in the lung two weeks post exposure as measured by Western blot (65±20% normalized band intensity versus filtered air, n=7, p<0.05) and RT-qPCR (63±26% of filtered air mRNA expression, n=12, p<0.05).Taken together, exposure to DEP caused a significant reduction in the expression of the tight junction protein Tricellulin. This reduction correlates with significant reduction in barrier function *in vitro* as measured by TEER and permeability to 4 kDa FITC-Dextran. Neonatal exposure to DEP caused a lasting reduction of Tricellulin at both the mRNA and protein level, suggesting early life exposure to DEP may cause a stable change in lung barrier structure and function.

1132 p.p1 Oxidative Potential of Particulate Matter and Generation of Reactive Oxygen Species in the Epithelial Lining Fluid p.p1

T. Fang, P. Lakey, R. Weber, and M. Shiraiwa. *University of California Irvine, Irvine, CA.* Sponsor: M. Kleinman

p.p1 Reactive oxygen species (ROS) play a central role in adverse health effects of atmospheric particulate matter (PM). Respiratory deposition can lead to the formation of ROS in the epithelial lining fluid due to redox reactions of PM components with lung antioxidants. As direct quantification of ROS is challenging, PM oxidative potential is more commonly measured using antioxidant surrogates including dithiothreitol (DTT) and ascorbic acid, assuming that the decay of surrogates corresponds to ROS formation. However, this assumption has not yet been validated and the lack of ROS quantification in the respiratory tract causes major limitations in evaluating PM impacts on oxidative stress. By combining field measurements of size-segregated chemical composition, a human respiratory tract model, and kinetic modeling, we quantified production rates and concentrations of different types of ROS in different regions of the epithelial lining fluid by considering particle-size-dependent respiratory deposition. The extrathoracic region is found to have higher ROS concentrations compared to the bronchial and alveolar regions. While H_2O_2 and O_2^- production is governed by Fe and Cu ions, OH radicals are mainly generated by organic compounds and Fenton-like reactions of metal ions. In winter when affected by biomass burning, model comparisons suggest that humic-like substances (HULIS) contribute to ROS formation substantially. We found that PM oxidative potential is a good indicator of chemical production of H_2O_2 and O_2^-, but does not represent OH generation. These results provide rationale and limitations of the use of oxidative potential as an indicator for PM toxicity in epidemiological and toxicological studies.

1133 Particulate Matter ($PM_{2.5}$) Exposure Promotes Myofibroblast Differentiation through an NF-κB Dependent Mechanism

N. Craig, J. Berens, and S. Huang. *University of Michigan, Ann Arbor, MI.* Sponsor: J. Colacino

Exposure to particulate matter has been linked to deleterious health outcomes including lung cancer and asthma. Epidemiologic studies show that exposure to $PM_{2.5}$ leads to a worsening of Idiopathic Pulmonary Fibrosis (IPF), a deadly lung disease of unknown etiology. Recent work suggests that exposure to $PM_{2.5}$ promotes the development of pulmonary fibrosis *in vivo*. However, the mechanism by which $PM_{2.5}$ contributes to the development of IPF is unknown. Here, we seek to elucidate the mechanism by which $PM_{2.5}$ promotes myofibroblast differentiation, an important process in the development of pulmonary fibrosis. A cell line of primary human lung fibroblasts were cultured and exposed to varying concentrations of $PM_{2.5}$ (.001 to 10 µg/cm^2) for up to 6 days. Cells were treated with $PM_{2.5}$ obtained either from the National Institute of Standards and Technology (collected in the Washington, DC area in 1976-1977; DC-$PM_{2.5}$), or from manual samplers that collected $PM_{2.5}$ from the rooftop of Peking University in Beijing, China (B-$PM_{2.5}$) in 2015. Cell lysates were analyzed for the expression of smooth muscle actin (SMA), fibronectin, and collagen. To determine the signaling mechanisms, each exposure was preceded by the addition of an NF-κB inhibitor, an AhR inhibitor, an antioxidant (N-acetylcysteine) or a vehicle control. A single exposure to either DC-$PM_{2.5}$ or B-$PM_{2.5}$ did not induce any measurable change in α-SMA, a marker of myofibroblast differentiation. However, when cells were exposed to repeated low doses of DC-$PM_{2.5}$, we observed an increase in α-SMA protein expression. The effect of B-$PM_{2.5}$ was similar, but occurred at higher doses. The $PM_{2.5}$ induced increase in α-SMA protein expression was blocked by pretreatment with an NF-κB inhibitor, but not by the AhR inhibitor or by N-acetylcysteine. Exposing fibroblasts directly to $PM_{2.5}$ *in vitro* resulted in myofibroblast differentiation. These changes occur in response to longer, repeated exposures but not in response to shorter exposure periods, or to a single $PM_{2.5}$ exposure, suggesting that longer exposure durations with repeated exposures may be necessary to accurately model chronic disease. The necessity of repeated exposures indicates that the initial $PM_{2.5}$ exposure may sensitize the fibroblasts to further environmental insults. The effectiveness of an NF-κB inhibitor in blocking these effects implies that $PM_{2.5}$ is acting through NF-κB signaling to promote myofibroblast differentiation. *This work was supported by HL127203 from NHLBI.*

1134 Ambient Particulate Matter-Induced Cardiac Mitochondrial Damage in C57/B6 Mouse

Q. Jiang[1], L. Shi[1], N. Lv[2], A. Ji[1], M. Gao[1], X. Xu[1], Z. Xu[1], Y. Zheng[1], and L. Cui[1]. [1]*Qingdao University School of Public Health, Qingdao, China; and* [2]*Qingdao University School of Pharmacy, Qingdao, China.*

Ambient particulate matter-induced cardiac mitochondrial damage in C57/B6 mouse Ambient particulate matter exposure is associated with elevated cardiovascular risk in general population, and mitochondria damage accounts for a large part of cardiotoxicity. To evaluate the potential cardiac mitochondrial damage following particulate matter (PM) exposure, an individual ventilated cage (IVC) system is utilized to expose C57/B6 mouse to either ambient air with particulate matter pollution (From 2018-2019 winter, Shijiazhuang, China), or filtered clean air for 21 or 42 days. To explore the potential molecular mechanism, WY 14,643 and GW6471, agonist and antagonist for the important fatty acid metabolism modulator, peroxisome proliferator-activated receptor alpha (PPARa), were administered to the animals along with the ambient PM exposure. At desired time points, heart tissues were collected, mitochondria were isolated, and then the mitochondrial membrane potential was assessed. Additionally, electron microscopy was utilized to visualize the mitochondria in myocardium. To explore the role of PPARa signaling, co-immunoprecipitation was performed to assess the association between PPARa

and peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1α). The results indicated that exposure to ambient PM for 21 or 42 days effectively abolished the mitochondrial membrane potential. Decreased mitochondria quantity in myocardium and structural damage were also observed. PPARa agonist WY 14,643 co-treatment alleviated such changes, while PPARa antagonist GW6471 seemed to exacerbated the toxicities. Co-immunoprecipitation revealed decreased association between PPARa and PGC1a following exposure to ambient PM, while cotreatment with WY14,643 restored the association. In summary, ambient PM exposure induced mitochondria damage in C57/B6 mouse myocardium, including abolished membrane potential, decreased mitochondria quantity and structural damage. The underlying mechanism is associated with interruption with PPARa signaling pathway. *This work was supported by National Natural Science Foundation of China (Grant No.81872591, 91643203, 81502835).*

PS 1135 A Systematic Review and Analysis of Personal and Ambient $PM_{2.5}$ Measurements: Implications for Epidemiological Studies

S. R. Boomhower, J. E. Goodman, W. Li, and C. M. Long. *Gradient, Boston, MA.*

In epidemiology studies, ambient measurements of $PM_{2.5}$ (*e.g.*, from central-site outdoor air monitors) often are used as surrogates for personal exposures. However, estimating personal $PM_{2.5}$ from ambient measurements introduces uncertainty, and it is unclear the degree to which ambient $PM_{2.5}$ reflects personal exposures. We conducted a systematic review and statistical analysis of epidemiology studies to determine the extent to which ambient $PM_{2.5}$ is correlated with personal $PM_{2.5}$. We conducted a literature search in PubMed and Scopus for peer-reviewed studies reporting both personal and ambient measurements of $PM_{2.5}$ in North America published between January 1, 2009, and September 4, 2019. Two independent reviewers completed data extraction, which included recording geographic variables, sample characteristics, ecological variables, ambient $PM_{2.5}$ measurements, personal $PM_{2.5}$ measurements, and ambient-personal $PM_{2.5}$ correlations. Twenty-three studies were identified. Overall, personal $PM_{2.5}$ concentrations were higher than ambient concentrations. The median personal $PM_{2.5}$ concentration was 17.9 $\mu g/m^3$ (range: 2.0-92.2 $\mu g/m^3$), and the median ambient $PM_{2.5}$ concentration was 15.8 $\mu g/m^3$ (range: 6.0-33.3 $\mu g/m^3$). There was a moderate-to-strong relationship between personal and ambient $PM_{2.5}$ concentrations; median personal-ambient $PM_{2.5}$ correlation coefficients were 0.57 (range: 0.09-0.83). Stratified analyses suggest that geographic and other variables may influence the relation between personal and ambient $PM_{2.5}$. For example, studies that report controlling for environmental tobacco smoke (ETS) reported an approximate personal-ambient correlation of 0.78 on average, whereas studies that did not measure or did not report measuring ETS reported an approximate personal-ambient $PM_{2.5}$ correlation of 0.09 on average. Our study informs the interpretation of both past epidemiology studies in which health effects were associated with ambient $PM_{2.5}$ and future studies with regard to accounting for error in estimating $PM_{2.5}$ exposures.

PS 1136 Chemical Composition across $PM_{2.5}$ Filters: Potential Impacts for $PM_{2.5}$ Toxicology Research

A. Sidwell, O. Black, and C. Roper. *University of Mississippi, University, MS.*

Toxicology research into the impacts of exposure to air pollution often requires the extraction of fine particulate matter ($PM_{2.5}$) from filters. In order to generate relevant toxicity data, there is a growing interest in validating that laboratory procedures create samples that are truly representative of samples collected from the environment. The ability to run multiple analyses on the same filter sample is beneficial to provide a robust characterization of $PM_{2.5}$ both from a compositional and toxicological viewpoint. Frequently, $PM_{2.5}$ filters are cut into pieces to allow for different methods of analysis, some of which destroy the sample like inductively coupled plasma mass spectrometry (ICP-MS). The goal of our study is to identify if portions of the same filter have similar elemental concentrations and thus provide information on if splitting a single filter for chemical analysis and toxicology testing provides data that can be used for associations between the two data sets. We will cut $PM_{2.5}$ collected filters (n=15) into 4 equal portions and analyze each portion for elements (n ~ 25) via ICP-MS. We anticipate that there will not be a significant difference in elemental concentrations between the quadrants from the sample filter. Our preliminary data from testing two sample filters split into quadrants for elements (n=14) mainly supports this. However, we observed significant differences between arsenic concentrations on different quadrants of the same filter. We are in the process of continuing to investigate these findings and the possible implications for toxicology testing. Our study will demonstrate the feasibility of allocation of the different portions of a $PM_{2.5}$ filter for multiple analyses and the potential impacts on $PM_{2.5}$ toxicity findings.

PS 1137 Toxicological Evaluation of Exhaust Emissions from Light-Duty Vehicles Using Different Fuel Alternatives in Sub-Freezing Conditions

H. I. Hakkarainen[1], M. Sainio[1], T. Ihantola[1], T. Rönkkö[1], P. Aakko-Saksa[2], P. Koponen[2], and P. Jalava[1]. *[1]University of the Eastern Finland, Kuopio, Finland; and [2]VTT Technical Research Centre of Finland Ltd, Espoo, Finland.*
Sponsor: M. Viluksela

Emissions from road traffic are under constant discussion since the they are still posing a major threat to human health despite of the stricter emission targets and regulations. Although, the new passenger car regulations have been very effective towards the particulate matter (PM) emissions, the aged car fleet remain as a large source of the PM emissions. Moreover, PM emissions from multiple new type of bio-based fuels are still uncertain and the sub-zero running temperature has shown to affect the emissions. Overall, toxicological studies on these PM emissions and effect of temperature conditions are inadequate. In the present study we show that exhaust gas PM from four newly regulated passenger cars fueled by different fuels in sub-zero temperature, induce toxicological responses *in vitro*. We used exhaust gas volume-based PM doses to give us better insight on the real-life exposure and included one older diesel car to estimate the efficiency of the new emissions regulations. From the newly regulated cars, one fueled with gasoline had the both highest exhaust PM concentrations and toxicological responses, while the one fueled by higher ethanol blend resulted in slightly lower exhaust gas PM concentrations and notably lower toxicological responses compared with gasoline exhaust PM. Modern diesel and compressed natural gas fueled vehicles had overall the lowest exhaust PM concentrations and toxicological responses. Results of the present study show that toxicity of the exhaust gas PM differ by the fuels used. Additionally, the PM emissions and their toxicity were vastly higher from older diesel car, indicating the efficiency of the new emissions regulations.

PS 1138 A Comparison of Lung Particle Deposition and Clearance in $ApoE^{-/-}$ Mice versus Normal and Heterozygous Littermates

S. R. Renusch, J. E. Monterrose Mena, I. T. Hasen, D. A. Herman, R. J. Arechavala, and M. T. Kleinman. *University of California Irvine, Irvine, CA.*

Air pollution and particulate matter (PM) has been associated with increased incidences of cardiovascular disease leading to increased daily mortality and hospital admissions. Apolipoprotein E-deficient mice ($ApoE^{-/-}$) are a well-studied mouse model for cardiovascular disease and atherosclerosis due to the buildup of cholesterol particles in their blood. However, data now suggests that high non-HDL cholesterol may cause disordered trafficking of cholesterol and phospholipids throughout the lung thereby altering immune cell clearance rates bringing into question the efficacy of $ApoE^{-/-}$ mice in inhalation exposure studies. Therefore, the objective of this study is to quantitate particle clearance of inhaled 0.02µm and 1µm fluorescent microspheres in $ApoE^{-/-}$ mice compared to their wild type and heterozygous littermates while also determining the levels of immune cells residing pre- and post-exposure in each animal variant. Male mice (n=8/cohort) were exposed to re-aerosolized 0.02µm and 1µm fluorescent microspheres for 3 hours per day for a total of 4 days. The lungs, lymph nodes, and plasma of all animals were collected one hour following the last exposure period and prepared for subsequent cell sorting and immunohistochemistry (IHC) analysis. Our hypothesis was that $ApoE^{-/-}$ animals will have the same deposition but less clearance of the 0.02 µm and 1 µm fluorescent microspheres from the lung when compared to heterozygote and wild type littermates. Data suggests that there are differences between $ApoE^{-/-}$ mice when compared to their wild type littermates, and it has been demonstrated that alveolar macrophages eat 1µm fluorescent microspheres in *in vitro* experiments. The particle deposition vs. particle size was calculated using Multiple Path Particle Dosimetry (MPPD) for mouse and showed that 0.02 µm and 1µm fluorescent microspheres will deposit 44% and 2% of the microspheres in the pulmonary region, respectfully. Determining accurate clearance rates for the pulmonary cells this hyperlipidemic mouse model is extremely useful when ultimately interrogating whether an inhaled toxic substance can adequately trigger downstream immune responses.

1139 Chronic $PM_{2.5}$ Exposure-Mediated Recruitment of Bone Marrow-Derived Macrophages: Impact on Pulmonary Immune Homeostasis and Inflammation

R. Singh[1], V. Vinaychandran[1], P. Rengasamy[1], R. Chan[1], B. Park[1], L. Das[1], E. A. Cara[1], R. Diamond-Zaluski[1], A. Cha[1], C. Asase[1], A. Maiseyeu[1], J. Zhong[1], S. Biswal[2], W. Mitzner[2], and S. Rajagopalan[1]. *[1]Case Western Reserve University, Cleveland, OH; and [2]Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.*

Chronic exposure to particulate matter air pollution <2.5µ ($PM_{2.5}$) has been linked to chronic cardiopulmonary disease. The impact of $PM_{2.5}$ on proliferation and maintenance of tissue-resident macrophages (MΦ) in the lung and the contribution of bone marrow-derived monocytes is poorly understood. Chimeric mice were developed by lethal irradiation (1,000 cGy) of chest shielded recipient (CD45.2) mice (to protect resident cells in lung) followed by Busulfan (i.p., 30mg/kg) and bone marrow (BM) transplantation from donor (CD45.1) mice. Following recovery (8 weeks), mice were exposed to concentrated ambient $PM_{2.5}$ (CAP) or filtered air (FA) 6-8 hours/day, 5 days/week using a *Versatile Aerosol Concentrator and Exposure System* for 4 and 32 weeks. Multi-color flow cytometry (10 color panel) was used to quantitate the myeloid cell subsets in the lungs and monocyte subsets in blood/spleen/BM and proliferation/apoptosis of alveolar MΦ (AMΦ, Siglec $F^{hi}CD11c^{hi}$). Flow sorted lung AMΦ (of CD45.2 & CD45.1 origin) and monocytes were used for RNA-seq analysis. Four weeks of $PM_{2.5}$ exposure resulted in higher CD45.1 $Ly6c^{hi}$ proinflammatory monocytes (2.5-fold, $p<0.05$) in the CD45.2 lungs of $PM_{2.5}$ compared to FA exposed mice. The source of Ly6chi monocytes in lung appeared to be from a hematopoietic source (likely bone marrow) as evidenced by more Ly6chi monocytes in blood and a corresponding decrease in the bone marrow (blood, 3.2-fold increase $p<0.05$ and bone marrow, 1.2-fold decrease, PM2.5 *vs* FA). AMΦ ($CD64^{+}CD11c^{hi}CD11b^{lo}$) in both $PM_{2.5}$ and FA mice were primarily CD45.2 at 4 weeks with no evidence of hematopoietic contribution. In contrast at 32 weeks, CD45.1 cells constituted 43.9±18.2% of AMΦ with evidence of enhanced apoptosis (Annexin V^{+}) and decreased proliferation ($BrdU^{+}$) in CD45.2 AMΦ. RNA-seq analysis of CD45.1 inflammatory AMΦ in the $PM_{2.5}$ exposed mice was consistent with a unique inflammatory transcriptomic signature signifying a $PM_{2.5}$ effect. $PM_{2.5}$ entrains a systemic bone marrow-derived CD45.1 response that together with enhanced apoptosis of tissue-resident CD45.2 AMΦ likely contributes to disrupted pulmonary immune homeostasis and perpetuation of chronic inflammation.

1140 Diesel Exhaust Particles Induce Autophagy in Bronchial Epithelial Cells

E. D. Román-Pagán, K. M. Casillas, and L. B. Mendez. *Universidad Ana G. Méndez Carolina, Carolina, PR.*

Exposure to diesel exhaust particles (DEP) can exacerbate asthma by inducing oxidative stress, inflammation, and cellular injury in the lung. Recent studies have reported increased levels of autophagy markers in asthmatic individuals. In addition, polymorphisms in autophagy-related genes have been associated with a reduced lung function in individuals with moderate to severe asthma. Since autophagy can be induced by oxidative stress, we hypothesize that DEP alters autophagy in human bronchial epithelial cells. To determine DEP effects in the autophagy process, primary bronchial epithelial cells derived from asthmatic (DHBE) and non-asthmatic (NHBE) individuals were exposed to physiologically relevant concentrations of DEP (5-50 µg/mL). The amount of autophagic vacuoles were determined using a fluorescent dye and time-response experiments were conducted to assess autophagy flux. Preliminary results showed that in DHBE cells, DEP induced autophagy in a dose-dependent manner. Meanwhile, in NHBE cells an increase was only observed at the highest concentration (50µg/mL). The increase in autophagic vacuoles was not due to inhibition of the autophagy flux as DEP did not have an effect in p62 degradation rate. Further experiments will be conducted to evaluate if DEP induces the phagophore formation. Our results suggest that DEP can alter the autophagy process in bronchial epithelial cells. In addition, that asthmatic cells can be up to 10 times more susceptible to DEP when compared with normal bronchial epithelial cells.

1141 Beyond the Barrier: Transepithelial Exposures Reveal Novel Roles for Oxidative Stress and Proinflammation within the Airway Microenvironment

S. C. Faber[1], N. McNabb[2], E. Aungst[2], and S. D. McCullough[2]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

Oxidative stress and the release of pro-inflammatory mediators are well established events following inhaled chemical exposure; however, our understanding of the cellular/molecular pathways involved in inhalation toxicity within the airway microenvironment (AME) remain limited due to studies centered around a single airway cell type (*i.e.,* epithelial cells), and lack of physiologically-relevant studies on cell types beyond the epithelial barrier. Utilizing an organotypic model that recapitulates the "trans-epithelial" nature of analogous exposures on *in vivo*, we investigated the effect of diesel exhaust particulates (DEP) on human bronchial epithelial cell (HBEC) and human lung fibroblast (HLF) signaling within the AME. We hypothesized that trans-epithelial DEP (TE-DEP) exposure mediates oxidative stress/pro-inflammatory response through an imbalance in oxidant/antioxidant gene expression and alterations in key cellular stress-responsive pathways. Live-cell imaging with a redox-sensitive fluorescent biosensor (pLV-roGFP-HyPer Red) defined the dynamics of glutathione oxidation and H_2O_2 signaling in HLF, which peaked at 6 hours following TE-DEP exposure. Likewise, the oxidative stress-responsive gene, HMOX-1, peaked at 6 hours in both HBEC and HLF, while the pro-inflammatory gene, IL-8, peaked at 4 hours in HBEC and 10 hours in HLF, by which time HMOX-1 returned to baseline. Oxidative stress arrays identified additional genes (*i.e.,* NQO1, PTGS2, and GCLM1) induced following TE-DEP exposure. Pretreatment of HLF with free radical scavengers reduced DEP-dependent HMOX-1 and IL-8 expression in HLF and adjacent HBEC. Temporal analysis of stress-responsive MAPK, NF-kB, and NRF2 pathways confirmed DEP-mediated and time-dependent phosphorylation of key cellular targets, and pretreatment with MAPK inhibitors attenuated DEP-dependent HMOX-1 and IL-8 expression. Further, neutrophil chemotaxis increased following exposure to TE-DEP conditioned medium indicating DEP-mediated changes in recruitment. This study is the first to characterize the dynamics of oxidative stress/pro-inflammatory signaling following trans-epithelial chemical exposure, providing novel insight for the development of therapeutic interventions to reduce adverse effects of inhaled chemical exposure. *Does not reflect Agency policy.*

1142 Rodent and Human TRPA1, V1, and V3 Exhibit Different Responses to Prototypical and Particulate Matter Agonists

J. G. Lamb, C. E. Deering-Rice, and C. A. Reilly. *University of Utah, Salt Lake City, UT.*

People are exposed to numerous forms of particulate matter (PM) in the course of daily activities. Exposures can contain coal fly ash (CFA), diesel exhaust particles (DEP), cigarette smoke PM (CSPM), calcium oxide (CaO), wood smoke (WSPM), and more. In the lung, activation of transient receptor potential (TRP) channels are one mechanism by which PM can trigger adverse effects. Human TRPA1 is activated by CFA, DEP and WSPM, as well as the soluble agonist allyl isothiocyanate (AITC). Human TRPV1 is activated by the soluble agonist nonivamide and CFA and TRPV3 is activated by the soluble agonist drofenine and WSPM. We have observed that responses of TRP channels to particles differ across species, particularly rodents and humans. This variability could have implications for studies attempting to translate results from mice to humans and vice versa. Alignment of human and mouse TRPA1, V1 and V3 amino acid sequences highlight differences in the pore-loop regions of these TRP channels which may partially explain species differences in the response to various PM. Mouse and human TRPA1, V1 and V3 plasmids and mutants thereof, were transiently transfected into GcAMP6-over-expressing HEK-293 reporter cells and calcium flux assays were performed to examine the basis for species-specific differences in responses to PM and known soluble agonists. For mouse TrpV3 the response to WSPM was decreased compared to human and this decrease involved the amino acids P612 and N616 in the pore-loop region. Mouse TrpV1 also had reduced responses to CFA and CaO compared to human TRPV1. Key amino acids were D605, S609 and P619 in the pore-loop region while S609 and P619 dictated the response to CaO. However, mouse TrpA1 exhibited an increased response to DEP, CSPM, WSPM, and CFA when compared to human TRPA1. Studies are ongoing to ascertain if pore-loop residues of TRPA1 underlie this effect. Identification of specific PM-sensing sites on TRP channels furthers our knowledge of the mechanisms by which TRPs are activated by PM and reveal potential limitations in animal models to study TRP channel contributions to particle toxicities in humans. *Support: ES017431, ES027015.*

1143 Interactions among the Particulate Matter (PM) Components for Cytotoxicity

Y. Wang, J. V. Puthussery, H. Yu, and V. Verma. *University of Illinois at Urbana-Champaign, Urbana, IL.* Sponsor: Y. Wang, Society of Environmental Toxicology and Chemistry

Several studies have shown the associations of ambient particulate matter (PM) concentrations with many adverse health effects. The toxic effect of PM is related to its chemical composition, and many hazardous components in PM have been spotted. However, the toxicity contribution from their interaction can not be neglected. To understand the interaction, in this study, we have chosen three metals (Cu, Fe, and Mn) and four quinones (9,10-phenanthraquinone, 1,2-naphthoquinone, 1,4-naphthoquinone, and 5- hydroxy-1,4-naphthoquinone), that are most abundant in PM, in addition to the ambient humic-like substances (HULIS) from the real PM samples. We exposed the Chinese hamster ovary (CHO) cells to the mixtures of these components for 72 hours to assess the cytotoxicity and obtained the lethal concentration that causes 50% inhibition (LC50). Mixture toxicity index (MTI) method was used to determine the interaction. The MTI result indicates that Fe is synergistic with most quinones and HULIS in cytotoxicity. The interactions among quinones are mostly additive. Our results reveal that metals and organic compounds in the environmentally relevant ratio are not simply additive; they are probably synergistic in most circumstances.

1144 Single Cell RNA Sequencing Reveals a Unique Monocyte Population in Bronchoalveolar Lavage Cells of Mice Challenged with Afghanistan Particulate Matter and Allergen

R. L. Berman[1], E. Min[1], J. Huang[1], K. W. Kopf[1], G. P. Downey[1], K. Riemondy[2], H. A. Smith[2], H. Chu[1], and B. J. Day[1]. *[1]National Jewish Health, Denver, CO; and [2]University of Colorado, Aurora, CO.*

Upon returning from deployment to Afghanistan, increasing numbers of service personnel are reporting symptoms consistent with an asthma-like airways disease including coughing, wheezing, and airway hyperresponsiveness. It is thought that prolonged inhalation of toxic desert silicate-containing particulate matter (PM) may contribute to this deployment-related lung disease (DRLD). Furthermore, symptoms of DLRD persist in the post deployment setting, where soldiers are exposed to aeroallergens such as house dust mite. The goal of this study was to define the transcriptomic responses of each type of leukocyte found in the airway lumen and airspace after inhalation of Afghanistan desert particulate matter (APM) and subsequent challenge to house dust mite (HDM) in mice. C57BL/6 mice (n=15/group) were exposed to filtered air or aerosolized APM for 6 hours per day, 12 consecutive days using a whole body exposure system, followed by intranasal PBS or HDM allergen challenges to mimic asthma. One day after the last allergen challenge, mice were euthanized to collect bronchoalveolar lavage cells for assessment of inflammation and single cell RNA sequencing (scRNAseq) using the 10x Genomics Platform. The flexiVent small animal respiratory physiology system was used to measure airway hyperresponsiveness (AHR) using total respiratory system resistance (Rrs). APM exposure followed by allergen challenge trended to increase AHR compared to filtered air controls (average Max(Rrs) 1.4 or 2.9 cmH2O.s/mL, respectively). In mice exposed to APM, allergen challenge significantly increased inflammation (total leukocyte count: p=0.01, absolute eosinophil numbers: p=0.01). Unsupervised clustering of BAL cell scRNAseq data revealed a unique monocyte population induced only by both APM and allergen treatments. This population of monocytes is characterized by a gene expression signature of 606 genes, many of which belong to pathways involved in worsening of asthma-like airways diseases, such as Alox15, which is involved in airway obstruction; Itgam, which mediates inflammation via regulating leukocyte adhesion/migration; and Ccl24, which induces recruitment of eosinophils. These results demonstrate that exposure to APM while on deployment to Afghanistan can prime airways to be more responsive to allergen exposure after deployment, and that the underlying mechanisms may involve induction of a unique lung monocyte population that has the ability to regulate AHR and inflammation. *Funding by DOD grant (W81XWH-16-2-0018).*

1145 Ambient Particulate Matter-Induced Cardiotoxicity and Pulmonotoxicity in C57/B6 Mouse

L. Cui[1], Q. Jiang[1], L. Shi[1], N. Lv[2], A. Ji[1], M. Gao[1], F. Chen[1], Y. Zhang[1], and Y. Zheng[1]. *[1]Qingdao University School of Public Health, Qingdao, China; and [2]Qingdao University School of Pharmacy, Qingdao, China.*

Ambient particulate matter exposure is associated with elevated cardiovascular risk in general population. To evaluate the potential cardiotoxicity following particulate matter (PM) exposure, an individual ventilated cage (IVC) system is utilized to expose C57/B6 mouse to either ambient air with particulate matter pollution (From 2018-2019 winter, Shijiazhuang, China), or filtered clean air for 21 or 42 days. To explore the potential molecular mechanism, WY 14,643 and GW6471, agonist and antagonist for peroxisome proliferator-activated receptor alpha (PPARa), were co-administered to the animals. At desired time points, the heart and lung tissues were collected, and potential morphological and functional changes following the PM exposure were assessed with histopathology and echocardiography, respectively. Additionally, immunohistochemistry for alpha-smooth muscle actin (SMA) was used to assess the fibrotic changes and cardiopulmonary effects in the lungs. The results indicated that right ventricular wall thickness was increased and the heart rate was elevated following PM exposure, while increased fibrotic changes were indicated by Masson trichrome staining and alpha-SMA immunohistochemistry. Alpha-SMA immunohistochemistry also indicated that the smooth muscle layer of small pulmonary arteries thickened following PM exposure, suggesting that the changes in right ventricle is secondary to the small pulmonary arteries. Interestingly, co-treatment with PPARa agonist WY 14,643 alleviated such changes, while GW6471 either had little effects or exacerbated such changes, suggesting that interference with PPARa signaling and fatty acid metabolism is contributing to the endpoints observed in this study. In summary, exposure to ambient PM resulted in morphological and functional changes in the hearts, fibrotic changes and thickened smooth muscle layer in small pulmonary arteries in the lung of C57/B6 mouse, in which interference with PPARa signaling is involved. *This work was supported by National Natural Science Foundation of China (Grant No.81872591, 91643203, 81502835).*

1146 Exposure to Airborne Fine Particulate Matter Is Associated with Impaired Endothelial Function and Biomarkers of Oxidative Stress and Inflammation

T. O'Toole, D. W. Riggs, N. Zafar, S. Krishnasamy, R. Yeager, S. N. Rai, and A. Bhatnagar. *University of Louisville, Louisville, KY.*

Epidemiological evidence suggests that exposure to air pollution is associated with cardiovascular disease (CVD). While ambient air pollution is a complex mixture of particulate matter (PM), gases and metals, the association between PM exposure and CVD is particularly strong. However, the pathophysiologic mechanisms underlying this association are not completely understood. Thus, we conducted a cross-sectional study of 100 participants, recruited from the University of Louisville Hospital Clinics. Peripheral endothelial function in these participants was assessed by calculating a reactive hyperemia index (RHI). Urine samples were used to measure isoprostanes, while plasma levels of cytokines, adhesion molecules, and proteases were measured using a Luminex-based assay. Ambient levels of fine PM ($PM_{2.5}$) were obtained by calculating the daily average of all regional EPA-validated monitoring stations in the Louisville, KY region. Adjusted associations between $PM_{2.5}$ levels and measured outcomes were tested using generalized linear models. We found that there was a 12.4% decrease in RHI with every 10μg/m^3 $PM_{2.5}$ increase (95% CI: -21.0, -2.7). F-2 isoprostane metabolite, a measure of oxidative stress, showed a positive association of 28.4% per 10μg/m^3 $PM_{2.5}$ (95% CI: 2.7, 60.3). We also observed positive associations with angiopoietin 1 (17.4%; 95% CI: 2.8, 33.8), vascular endothelial growth factor (10.4%; 95% CI: 0.6, 21.0), placental growth factor (31.7%; 95% CI: 12.2, 54.5), intracellular adhesion molecule-1 (24.6%; 95% CI: 1.6, 52.8), and matrix metalloproteinase-9 (30.3%; 95% CI: 8.0, 57.5) per 10μg/m^3 increase in $PM_{2.5}$. Additionally, we observed a negative association between $PM_{2.5}$ and vascular cell adhesion molecule-1 of -15.9% per 10μg/m^3 increase (95% CI: -28.3, -1.3). Thus, exposure to $PM_{2.5}$ was associated with impaired vascular function, which may result from oxidative stress and inflammation, thereby leading to a pro-atherogenic state.

1147 Cytotoxicity of Low Concentrations of Ultrafine Diesel Exhaust Particles on Endothelial and Microglial Cell Monocultures and Mixed Co-cultures

G. V. Aquino. *Baylor University, Waco, TX.*

Diesel exhaust particles (DEPs) are a recognized risk factor for several health conditions including neurodegenerative diseases. However, information regarding the toxicity of low concentrations of ultrafine (UF) DEPs in the brain is limited. While *in vitro* studies of cerebral capillary endothelial cell (CEC) monocultures provide insight into the cellular mechanisms by which particulate matter (PM) cause toxicity, they do not account for mitigating or aggravating effects of cell-cell interactions on PM toxicity. The goals of this study were to evaluate the cytotoxicity of low concentrations of UF DEPs and to investigate if cell-cell interactions mitigate or aggravate the effects of UF DEP exposure. Rat brain microvascular endothelial cells (BMVECs) were used as a simple blood-brain-barrier (BBB) model, and rat microglia (primary and Highly Aggressive Proliferating Immortalized) as model immune cells of the brain. To determine cytotoxicity of UF-DEP and investigate the effect of cell-cell interactions, this study measured LDH leakage, cell metabolic activity (CMA), and ROS production in five different *in vitro* cell culture systems: endothelial (E), microglial (M), and HAPI (H) monocultures, and endothelial-microglial (EM) and endothelial-HAPI (EH) mixed co-cultures. The cells were exposed to 2 ng/ml, 1 µg/ml, and 20 µg/ml UF DEPs in 96-well plates for 24 hours before assaying. Results indicated that low concentrations of UF DEPs significantly decreased cell viability (i.e. increased LDH leakage and decreased cell metabolic activity) and increased ROS production in a dose-dependent manner in most cell culture systems but differentially across systems. Additionally, while the co-cultures responded differently from one another, cell-cell interactions in the EM co-culture slightly but significantly aggravated the LDH leakage and ROS production, but did not decrease CMA, compared to the E monoculture. This study demonstrated that exposure to low concentrations of UFDEPs can disrupt the function of CECs and microglia, and that cell-cell interactions can influence the degree of cytotoxic effects from exposure to environmental toxicants. Therefore, better models that recapitulate the complete neurovascular unit and its complex intercellular interactions *in vitro* should be employed when studying toxicity and environmental exposures in the BBB.

1148 AMPK Activation Attenuates Inflammatory Response to Reduce Ambient $PM_{2.5}$-Induced Metabolic Disorders in Healthy and Diabetic Mice

K. Pan[1], S. Jiang[1], X. Du[1], L. Song[1], H. Kan[1], Y. Xie[1], Q. Sun[2], and J. Zhao[1]. *[1]Fudan University, Shanghai, China; and [2]Ohio State University, Columbus, OH.*

Epidemiological and experimental studies have indicated that ambient fine particulate matter ($PM_{2.5}$) exposure is associated with the occurrence and development of metabolic disorders such as obesity and type 2 diabetesmellitus (T2DM). However, the mechanism is not clear yet, and there are few studies to explore the possible prevention measure. In this study, C57BL/6 and db/db mice were exposed to concentrated $PM_{2.5}$ or filtered air using Shanghai-METAS for 12 weeks. From week 11, some of the mice were assigned to receive a subcutaneous injection of AMPK activator (AICAR).The results showed that $PM_{2.5}$ exposure induced the impairments of glucose tolerance, insulin resistance, lipid metabolism disorders and disturbances of energy metabolism in both C57BL/6 and db/db mice. These impairments might be consistent with the increased respiratory, circulating and visceral adipose tissue (VAT) inflammatory response, which was characterized by the release of IL-6 and TNF-α in lung, serum and VAT. More importantly, AICAR administration led to the significant enhancement of energy metabolism, elevation of AMPK as well as the decreased IL-6 and TNF-α in VAT of $PM_{2.5}$-exposed mice, which suggesting that AMPK activation might attenuate the inflammatory responses in VAT via the inhibition of MAPKs and NFκB. The study indicated that exposure to ambient $PM_{2.5}$ under the concentration which is often seen in some developing countries could induce the occurrence of metabolic disorders in normal healthy mice and exacerbate metabolic disorders in diabetic mice. The adverse impacts of $PM_{2.5}$ on insulin sensitivity, energy homeostasis, lipid metabolism and inflammatory response were associated with AMPK inhibition. AMPK activation might inhibit $PM_{2.5}$-induced metabolic disorders via inhibition of inflammatory cytokines release. These findings suggested that AMPK activation is a potential therapy to prevent some of the metabolic disorders attributable to air pollution exposure.

1149 Metabolomics Approaches to Identify Plasmatic Factors Responsible for Fine Particulate Matter ($PM_{2.5}$)-Induced Vascular Insulin Resistance and Inflammation

B. R. Rood, J. Clark, B. Hill, and P. Haberzettl. *University of Louisville, Louisville, KY.*

Exposure to fine particulate matter ($PM_{2.5}$) increases the risk of developing cardiovascular disease (CVD). Our previous studies demonstrated that exposure to concentrated $PM_{2.5}$ (CAP) induces vascular inflammation and insulin resistance in mice, which is, at least in part, dependent on pulmonary oxidative stress. Although we could attribute the vascular effects to pulmonary oxidative stress, it is unclear how oxidative stress is transmitted from the lung to blood vessels. Because research suggests that plasmatic factors that diffuse from the lung trigger exposure-induced injury in peripheral tissues, we tested whether *ex vivo* treatment of naïve aortas with plasma isolated from mice exposed for 9 days to CAP induces insulin resistance. We found that plasma from CAP-exposed mice induces insulin resistance in the isolated blood vessel, indicating that a plasmatic factor could be responsible for $PM_{2.5}$-induced vascular defects. To identify putative plasmatic factors, we investigated whether $PM_{2.5}$ exposure affects the plasma metabolome and whether the metabolite changes are dependent on pulmonary oxidative stress. For this, we exposed mice overexpressing lung-specific extracellular superoxide dismutase (ecSOD-Tg) and their wild-type (WT) littermates to CAP or HEPA-filtered air and analyzed metabolite abundances in plasma using ultra-performance liquid chromatography mass spectrometry (UPLC-MS). Metabolomics showed that CAP exposure impacted the level of 93 metabolites ($p \leq 0.05$, out of 724 compounds) in WT mice while in ecSOD-Tg mice only 24 metabolites changed significantly. Metabolites that increased in plasma of CAP-exposed WT mice were saturated and unsaturated fatty acids as well as inflammatory mono- and di-hydroxy fatty acids. In additional studies, we found that fatty acids such as palmitate are sufficient to induce inflammation in naïve aortas and HUVEC cells. Additionally, we found that CAP exposure decreased circulating phosphatidylcholines and phosphatidylethanolamines and increased circulating glycerol in WT mice. Our findings suggest that pulmonary oxidative stress caused by $PM_{2.5}$ exposure increases circulating fatty acids, which trigger vascular insulin resistance and inflammation that could contribute to an increased risk for developing CVD.

1150 The Cardiovascular Effects of Ovarian Hormone Removal in apoE-/- Mice Chronically Exposed to Concentrated Ambient $PM_{2.5}$

D. A. Herman[1], V. Tanwar[2], R. M. Arechavala[1], S. R. Rensuch[1], I. Hasen[1], N. Schwietermann[2], L. E. Wold[2], U. Luderer[1], and M. T. Kleinman[1]. *[1]University of California Irvine, Irvine, CA; and [2]Ohio State University, Columbus, OH.*

Post-menopausal women and women with reduced ovarian function are at elevated risk of cardiovascular disease. Particulate matter (PM) air pollution has been associated with increased incidences of cardiovascular disease leading to increased daily mortality and hospital admissions. Fine PM (Dp < 2.5 µm) contains a mixture of metallic elements, road dust, and includes ultrafine PM (Dp< 0.1 µm) encompassing vehicle emissions which, due to their large surface area/unit mass, allows for greater adsorption of reactive organic molecules and increased availability for interaction with potential cellular targets. The objective of this study was to determine whether ovariectomized (OVX), apoE-/- mice are more susceptible to the cardiovascular effects of concentrated ambient $PM_{2.5}$ (CAPs) exposure than apoE-/- mice with intact ovaries. Groups of animals were exposed to either purified air (PA) or to concentrated ambient $PM_{2.5}$ (CAPs). Mice were exposed 5 hours/day, 4 days/week for 12 weeks at the University of California, Irvine, about 1600m southwest of a major freeway. Blood pressure was measured weekly while implanted cardiac transducers continuously monitored ECGs from the mice. ECGs were analyzed at specific post-exposure times to detect change from the baseline measurements at numerous waveform parameters. OVX mice exposed to CAPs exhibited immediate shortened P-wave duration compared to intact mice exposed to CAPs which may indicate a decreased rate of electrical conduction through the atria. These OVX animals also showed a non-significant trend toward PR-interval elongation which may indicate the presence of atrioventricular blockages in the heart. The most pronounced changes to baseline ECG measurements were observed in the ST-segment. Exposed OVX animals had decreased ST-segment levels compared to the intact exposed animals. These OVX animals also exhibited a more pronounced T-wave, as measured by increased T-wave area and T-wave amplitude. An initial decrease in diastolic blood pressure in exposed OVX mice compared to controls was observed. The exposed mice also exhibited a non-significant trend towards decreased breathing rates possibly indicating that the inhaled PM is resulting in short, shallow breaths. Hypotension can result from conditions such as heart

disease and bradycardia while S-T segment changes are common measures of myocardial dysfunction in humans which possibly lead to life-threatening cardiac events. Further investigation into the observed changes need be performed to explicate the sex-specific mechanisms corresponding to changes resulting from CAPs exposures.

1151 Identifying the Molecular Mechanisms of Air Pollution-Induced Thrombosis

E. Vitucci[1], and S. McCullough[2]. [1]*University of North Carolina at Chapel Hill, Chapel Hill, NC; and* [2]*US EPA, Research Triangle Park, NC.*

An estimated 3.5-million people die annually from air pollution-induced cardiovascular disease (API-CVD). API-thrombosis (API-T) is a main contributor to these mortalities and morbidities; however, the molecular mechanisms driving API-T are unclear. To identify the mechanisms driving API-T, we developed a tri-culture *in vitro* model that represents the interface of the respiratory and cardiovascular system, the alveolar capillary region (ACR). This organotypic model includes human alveolar-like epithelial cells (H441), human lung fibroblasts, and human lung microvascular endothelial cells (HULEC). We hypothesized that air pollutant exposure of the H441 cells would induce endothelial dysfunction in the HULEC, initiating the onset of pro-thrombotic/pro-coagulative state. To test this, we exposed confluent monolayers of H441 cells to the ubiquitous air pollutant, diesel exhaust particulates (DEP), and investigated the effect of this trans-epithelial exposure (TE-DEP) on the underlying HULEC. Upon TE-DEP exposure we identified induction of anti-oxidants such as heme oxygenase 1 (HMOX-1) and NAD(P)H dehydrogenase [quinone] 1 (NQO1) in the HULEC. Increased nuclear factor erythoid-2 related factor (NRF2) protein and reduced glutathione redox potential were also identified in the HULEC. Concurrently, we observed decreased expression of the endothelial fibrinolytic and anti-coagulant genes, tissue-type plasminogen activator (PLAT), plasminogen activator, urokinase (PLAU), and thrombomodulin (THBD) in the HULEC, and increased expression of the procoagulant gene, coagulation factor III (F3). Increased fibrin clot formation was also observed on the HULEC post TE-DEP exposure. Lastly, F3 expression increased in primary human aortic endothelial cells upon treatment with conditioned media from the TE-DEP exposed HULEC. Collectively, these data suggest that TE-DEP exposure induces redox dysfunction and endothelial pro-thrombotic/pro-coagulative activation in the ACR, and suggest that ACR-secreted factors may initiate a systemic pro-thrombotic/pro-coagulative state upon TE-DEP exposure. We conclude that redox dysfunction and pro-thrombotic/pro-coagulative activation in the capillary beds of the ACR may be critical initiation steps in the onset of API-T. Ultimately, data from this model can be used to develop intervention strategies and identify exposure biomarkers to help prevent the onset of API-T and API-CVD.

1152 Air Pollution ($PM_{2.5}$) Triggers Insulin Resistance in Mice: Implication of Impaired Transcriptional Level of Circadian Gene and Glucose Metabolism in Brown Adipose Tissue

P. Rengasamy, S. Ravi, E. Ann Ebreo Cara, R. D. Zaluski, R. S. Gangwar, L. Das, and S. Rajagopalan. *Case Western Reserve University, Cleveland, OH.*
Sponsor: D. Conklin

Air pollution exposure is associated with an increased risk of acute and chronic metabolic distress often leading to cardiovascular mortality. Our previous research demonstrated that $PM_{2.5}$ causes insulin resistance (IR) with onset of type 2 diabetes in a mouse model of chronic ambient air pollution exposure. However, the mechanism of $PM_{2.5}$ mediated disruption of metabolic homeostasis remains unknown. An unbiased transcriptomic analysis of $PM_{2.5}$ exposed mice revealed differential regulation of circadian genes in peripheral tissues compared to control mice exposed to filtered air (FA). Our goal is to study $PM_{2.5}$ modulation of circadian rhythm genes in brown adipose tissue that is associated with IR and cardiovascular events. We evaluated increased glucose tolerance ($p<0.0004$) and reduced energy expenditure ($p<0.001$) in $PM_{2.5}$ mice compared to FA. $PM_{2.5}$ mice exhibited increased plasma corticosterone (2258±140 vs 3795±286, $p<0.002$) and urine corticosterone levels (14.15±0.73 vs 18.26± 1.1, $P<0.01$), suggesting dysregulation of the hypothalamus-pituitary-adrenal system leading to insulin resistance. These results corroborated with reduced FDG uptake in the brown adipose tissue due to the reduced prdm16 and UCP 1 mRNA expression. Interestingly, the same tissues exhibited a reduced expression of circadian genes Bmal1, Clock, Cry1 and Cry2 in $PM_{2.5}$ mice as validated by qPCR. Our study suggests a previously unrecognized role for $PM_{2.5}$ as a circadian rhythm disruptor that may act as a critical regulator of glucose homeostasis in the pathogenesis of insulin resistance.

1153 Air Pollution Exposure as a Circadian Disruptor: Implications for Insulin Resistance and Type 2 Diabetes

P. Rengasamy, E. Ann Ebreo Cara, S. Ravi, A. Cha, R. D. Zaluski, R. S. Gangwar, L. Das, V. Vinayachandran, and S. Rajagopalan. *Case Western Reserve University, Cleveland, OH.*

Environmental stressors like air pollution represent an increasingly recognized cause of non-communicable disease with recent estimates implicating 9.1 million deaths globally. Particulate matter <2.5 μm ($PM_{2.5}$) induced insulin resistance (IR) and type 2 diabetes, may represent a proximate mechanism, but common integrative mechanisms are currently lacking. In an initial unbiased transcriptomic analysis on the livers of $PM_{2.5}$ exposed mice, circadian genes were the most common gene ontology (GO) terms in response to exposure. C57BL6 male mice were exposed to 24-weeks of FA/$PM_{2.5}$ and simultaneously exposed to dim light at night (LAN) or dark at night (DAN). Metabolic cage experiments showed that compared with DAN FA, $PM_{2.5}$ exposed mice had significantly reduced energy expenditure, respiratory quotient, and VO_2 consumption, indicative of metabolic dysfunction. LAN exposure mimicked IR and glucose intolerance phenotype observed with $PM_{2.5}$. Validation of transcriptomic data by qPCR analyses revealed that $PM_{2.5}$ and LAN mice regulated expression of BMAL1, CLOCK, Per1, Per 2, Cry1 and Cry2. When compared with FA/DAN mice, the oscillatory phase and amplitude of circadian genes were altered by $PM_{2.5}$ and comparable to LAN exposure. Chronic $PM_{2.5}$ exposure and LAN, instigates insulin resistance and dysregulation of core components of liver circadian genes, raising the possibility that $PM_{2.5}$-induced IR is mediated by circadian disruption of core clock genes in liver. The role of other peripheral and central circadian genes in the pathogenesis of $PM_{2.5}$-mediated IR and its causal pathways deserve further investigation.

1154 Fine Particulate Matter ($PM_{2.5}$) Exposure Induces Vascular Circadian Misalignment without Affecting the Central Clock

P. Haberzettl, A. Ribble, D. J. Conklin, L. G. Haberzettl, and A. Bhatnagar. *University of Louisville, Louisville, KY.*

Exposure to fine particulate matter ($PM_{2.5}$) increase the risk for cardiovascular disease and diabetes. In mice, exposure to concentrated $PM_{2.5}$ (CAP) exacerbates diet-induced systemic insulin resistance, and diet-independently induces vascular inflammation and insulin resistance. However, it remains unclear how $PM_{2.5}$ triggers inflammation and suppresses insulin signaling in the blood vessel. Because inflammation and insulin resistance are associated with the disruption of peripheral circadian clocks in the vasculature we examined the effects of $PM_{2.5}$ on the circadian oscillation of vascular core clock genes. For this, mice maintained under controlled light conditions [12h light (>200 lux), 12h dark (<10 lux)] were exposed for 30 days (6h/d) to CAP or HEPA-filtered air. Aortas were collected at Zeitgeber times (ZT) 3, 7, 11, 15, 19, and 23 to analyze the 24h circadian gene expression by *RT*-PCR. To examine central effects, functional circadian pattern (e.g., activity) were measured using metabolic cages. Circadian pattern of the expression of core clock (e.g., *circadian-locomotor-output-cycle-kaput, clock* and *cryptochrome2, cry2*), antioxidant defense (e.g., *extracellular superoxide dismutase*, *sod3* and *nuclear factor (erythroid-derived 2)-like 2, nrf2*) and proinflammatory (e.g., *interleukin1β*, *il-1β*) genes were analyzed using the cosinor method that follows changes in acrophase, amplitude, and estimating statistic of rhythm (MESOR). We found that while aortic expression of *clock* and *sod3* show significant rhythmicity (*clock*: p=0.02, *sod3*: p= 0.01, n=5) in air-exposed mice, no rhythmicity (*clock*: p=0.91, *sod3*: p= 0.37, n=5) was found in CAP-exposed mice indicating the loss of 24 h circadian rhythmicity of the peripheral circadian clock due to CAP exposure. CAP exposure also changed amplitude (*cry2*) and period (*il-1β*) or induced a shift in phase (*nrf2*). While $PM_{2.5}$ exposure disrupts vascular circadian expression of core clock, antioxidant and inflammatory genes, no CAP-induced central changes (e.g., activity) or effects on insulin resistance and obesity were observed. Our data suggest that $PM_{2.5}$ exposure disrupts peripheral vascular clocks without affecting central clock regulation. CAP-induced vascular circadian misalignment could trigger vascular inflammation and insulin resistance that may be an important mechanism underlying $PM_{2.5}$-induced vascular injury that could accelerate progression to systemic insulin resistance.

1155 Exposure to $PM_{2.5}$ from Kaohusing, Taiwan, Induces Prenatal Oxidative Stress and Fetal Brain Developmental Alternation in the Sprague-Dawley Rat Model

M. Chao, C. Wu, M. Lee, and C. Tseng. *Chung Yuan Christian University, Taoyuan, Taiwan.*

Epidemiologies suggest that an increase of $PM_{2.5}$ in ambient air corresponds to an increase in lung and cardiovascular diseases. Recent studies show that $PM_{2.5}$ travels down the respiratory tract, into the lungs, enters systemic blood circulation, and increases the incidence of respiratory diseases among newborn infants which might cause chronic inflammation in pregnant women and retard fetal development. Our study indicated that intratracheally exposed prenatal rats to $PM_{2.5}$ collected from Kaohusing, Taiwan might cause dose-independently decrease both of pregnancy rate and birth rate, and induce cytokines and free radicals release in the amniotic fluid of the pregnant. On E15~E17, pregnant SD rats were injected with Bromodeoxyuridine (BrdU) (s.c.) to detect proliferating cells, and the rats were euthanized on E18 an hour after the last $PM_{2.5}$ exposure. Blood and tissue samples were collected, the results showed no significant damage of $PM_{2.5}$ to the maternal organs. Nevertheless, the maternal body weight of rats exposed to $PM_{2.5}$ experienced a constant decline, with increasing white blood cell count and an elevated inflammatory cytokine in the blood. Furthermore, pregnant rats exposed to $PM_{2.5}$ had a noticeable higher level of ROS in the amniotic fluid as well as a higher number of stillbirths. In the fetal brain, results have shown that the total amount of glutathione (GSH) were significantly lower, with an increase level of inflammatory cytokine. On the other hand, the fetal cerebral cortex on E18 were collected, and we found that laminar positioning of early born cortical cells expressing SATB2 and CTIP2 were disturbed, with a scattering distribution. Thus, we demonstrated that exposure of $PM_{2.5}$ to pregnant rats might lead to an increased inflammatory response and integrate into pre-existing neuronal circuits.

1156 Differential Effects of Ultrafine, Fine, and Coarse PM from Imperial Valley, California

S. M. Mack, E. Laing, K. Bein, and K. E. Pinkerton. *University of California Davis, Davis, CA.*

Particulate matter (PM) in Imperial Valley, California comes from a variety of sources including, but not limited to: agriculture, feedlots, vehicles at the border crossing, the megacity of Mexicali, and the dry lakebed of the evaporating Salton Sea. To determine if there are differences in the composition and biological response to Imperial County PM by size, ambient PM samples were collected from a sampling unit stationed just south of the Salton Sea. Ultrafine ($PM_{0.1}$), fine ($PM_{2.5}$) and coarse (PM_{10}) samples were collected and extracted separately. Analyses of the chemical compositions were performed using Inductively Coupled Plasma-Mass Spectrometry (ICP-MS) and high-resolution time-of-flight aerosol mass spectrometry (HRAMS). Endotoxin and ß-glucan levels were also quantified using *Limulus* Amebocyte Lysate (LAL) pathway assays. An aliquot of each sample was heated overnight to remove any bioaerosols present. Biological response was measured by exposing a cell line of macrophages (U937) to PM for 24-hours and quantifying the response with quantitative real-time Reverse Transcription-Polymerase Chain Reaction (qPCR). The analyses of the chemical characterizations by ICP-MS and HRAMS did not demonstrate observable differences between particle sizes. More analysis on the organic compounds present in each sample is required. Biological measurements demonstrate that PM_{10} induces an inflammatory response in macrophages, with significant increases in the gene expression of *IL-6, IL-8, COX-2* and *CXCL1*. $PM_{0.1}$ demonstrates a significant increase in expression of *CYP1a1*. Heat-treatment of PM samples significantly lowered the levels of endotoxin and ß -glucans in $PM_{0.1}$ and $PM_{2.5}$, but not in PM_{10}. However, the biological response to PM_{10} significantly changed before and after heat-treatment, suggesting an additional chemical change unrelated to endotoxin or ß -glucan activity. This difference in response was not observed in heat-treated $PM_{0.1}$ or $PM_{2.5}$. Residents in Imperial Valley have access to 24-hour air quality data from 50 different monitors that give real-time levels of $PM_{2.5}$ and PM_{10} and also provide a recommendation on healthy practices dependent on the current AQI (air quality index). While these results are useful for daily considerations, there is no information on the composition or toxicity of ambient PM. In contrast, the cell-screening methodology described can provide definitive information on the toxicity of PM and further inform community members on the quality of local air.

1157 Cache Valley $PM_{2.5}$ Activates Akt, Inflammatory Pathways, and Induces Genetic Damage in Human Lung Cells

A. T. Nguyen, J. Weston, N. Grooms, M. Eggleston, R. S. Martin, and R. Coulombe. *Utah State University, Logan, UT.*

Northern Utah's Cache Valley frequently has some of the nation's highest concentrations of $PM_{2.5}$ particulate air pollution (CVPM). Exposure to $PM_{2.5}$ is associated with increased all-cause mortality, cardiovascular and cardiopulmonary diseases, heart attack, stroke, COPD, Alzheimer's disease, and lung cancer. The purpose of this study was to determine the cellular responses of human lung cells (BEAS-2B) exposed to CVPM (1 and 12 µg/ml; 24 hr) collected onto stainless steel plates using a Tisch impactor to minimize particle extraction artifacts associated with filter-based collection. Parallel experiments were conducted with diesel exhaust particles (DEP) as a positive control. Exposure to CVPM resulted in genetic damage as assessed by the Comet Assay, with potency equivalent to that of DEP, and a significant increase in the number of actively-dividing cells compared to control as assessed by flow cytometry ($p < 0.05$). Whole-genome microarray (Affymetrix Human 2.0) identified affected genes principally related to the inflammatory and immune pathways, as well as activated serine/threonine Akt (*aka* protein kinase B or PKB)-dependent pathways, among others. Subsequent qRT-PCR showed that CVPM exposure significantly increased expression of inflammatory markers including IL-6, CD40LG, and PLAG27 as well as cytochrome P450 (CYP) 1A1. Immunoblotting confirmed activation of Akt by phosphorylation of Thr308 in both CVPM and DEP exposed cells. This data from experiments where ambient CVPM was collected onto a solid substrate agrees in with prior findings that CVPM upregulates inflammatory pathways as well as activates Akt with potency similar to that seen with DEP. In total, our data supports the hypothesis that CVPM toxicology involves pro-inflammatory and carcinogenic pathways. *This research is supported by the Marriner S. Eccles Charitable Foundation and by Utah State University.*

1158 Characterization of the Inorganic Compounds Found in Airborne $PM_{2.5}$ in Two Sites from Puerto Rico (Urban and Rural)

H. Jirau-Colón[1,2], J. Layuno[2], A. Gioda[3], and B. D. Jiménez-Vélez[1,2]. *[1]Universidad de Puerto Rico Recinto de Ciencias Médicas, San Juan, PR; [2]Center for Environment and Toxicological Research, San Juan, PR; and [3]Pontifícia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil.*

The exposure to the chemical constituents of airborne particulate matter (PM) is an important factor when considering their potential health effects. Transition metals, capable of redox cycling, are known to contribute significantly to the exacerbation of respiratory ailments. These transition metals are enriched in airborne PM from polluted urban and industrial sites. Exposure to these constituents result in the induction of oxidative stress in the bronchial epithelium and furthermore, promote the secretion of inflammatory mediators. Therefore, it is important to know the contributions of $PM_{2.5}$ constituents from both rural, and urban (more exposed to industrial activity) sites in order to investigate their relationships to toxic responses due to atmospheric exposure. $PM_{2.5}$ samples from a Rural (Humacao) and an Urban site (Bayamon) in Puerto Rico were analyzed for inorganic constituents. Samples from both locations were subjected to a Microwave-Assisted digestion and the resulting extracts characterized for their inorganic constituents by means of Induced Coupled Plasma Mass Spectrometry (ICP-MS). Approximately 59 trace elements were evaluated, of which 8 are considered with the greatest toxic potential. Higher $PM_{2.5}$ concentrations were found at the urban the site (5.12 ug/m^3) compared to the rural site (4.33 ug/m^3). During summer, African Dust Events are common, reaching into the rural site and contributing to its $PM_{2.5}$ concentration. The concentration at the rural site was found to be higher during these months compared to the urban site. Average Copper and Lead concentrations were three and two-fold higher at the urban site (0.71 ng/m^3 and 0.05 ng/m^3 respectively) compared to the rural site (0.19 ng/m^3 and 0.02 ng/m^3). Of the eight potential toxic metals considered, only Iron was found to be higher at the rural site (19.88ng/m^3 compared to 21.19 ng/m^3 in the urban). These results become key elements for future $PM_{2.5}$ extract comparisons between sites after Hurricane Maria by employing cytotoxic response using bronchial epithelium as cell model of respiratory distress due to exposure.

1159 $PM_{2.5}$ from a Marcellus Shale Drilling Operation Induces Cardiovascular Toxicity

T. Knuckles, and M. Kemp. *West Virginia University, Morgantown, WV.*

Unconventional natural gas well development (UNGD) of the Marcellus Shale geological formation has continued to be a burgeoning energy driver in the US. Thus, rural communities and regions are experiencing increased industrial activities and air pollutant exposures. Our laboratory has identified increased concentrations of particulate matter (PM) in the fine (<2.5 μm, $PM_{2.5}$) and ultrafine (<0.1 μm, $PM_{0.1}$) size ranges near UNGD areas. Furthermore, negative consequences of gas well emissions on health outcomes have been reported in the epidemiological literature. We collected high-volume $PM_{2.5}$ samples onto PTFE filters over 1 week during fracture stimulation at a Marcellus Shale gas well site. Additional samples were taken upwind, and downwind from the well pad during the same time-frame. The samples were liberated from the filters into ultrapure water and dried via lyophilization. Previous *in vitro* data has shown significant cytotoxicity based on distance downwind from the well pad. Young Sprague Dawley rats were exposed to 100 or 300 μg/rat $PM_{2.5}$ from the drill site via intratracheal instillation. $PM_{2.5}$ significantly increased heart rate (HR, Sham 317±8 BPM vs. $PM_{2.5}$ 342±8 BPM). However, separately 100 or 300 μg/rat did not significantly alter HR. *In vivo*, arteriolar responses to metabolic vasodilation, endogenous neurotransmitter vasoconstriction, and endothelial vasodilators were negative. In isolated mesenteric arterioles, there was significant enhancement of phenylephrine-induced vasoconstriction 1 nM (% Max Constriction Sham 2.5±1.0%, $PM_{2.5}$ 8.8±2.6%). Taken together, these data suggest that exposure can significantly increase heart rate, and induce arteriolar vasoconstriction, though the mechanisms are unknown. *Funding: NIEHS R15ES028005.*

1160 Temporal Differences in Oxidative Potential and Chemical Composition of $PM_{2.5}$

A. T. Vinson, B. Black, and C. Roper. *University of Mississippi School of Pharmacy, Oxford, MS.*

Exposure to fine particulate matter ($PM_{2.5}$) has well-established systemic human health effects. Oxidative stress is a hypothesized mechanism for the health effects associated with $PM_{2.5}$ exposures. Oxidative potential (OP) is the measure of a substance's capacity to oxidize a target molecule. The OP of $PM_{2.5}$ has recently been suggested as a measure that is more indicative of human health effects than the routinely measured $PM_{2.5}$ concentration. The purpose of this experiment is to analyze the OP of $PM_{2.5}$ collected on air filters and determine if there differences in the OP of $PM_{2.5}$ collected from the same location on different days. $PM_{2.5}$ was collected onto PTFE-coated filters from a monitor placed in a public park in Eugene, OR on different days in the Winter. $PM_{2.5}$ will be extracted from each filter via sonication in methanol. An aliquot of the extraction solution will be used to measure OP using the dithiothreitol (DTT) assay. An additional aliquot will undergo analysis via inductively coupled plasma - mass spectrometry (ICP-MS) to quantify elements (n=30). Correlations between OP, $PM_{2.5}$ mass, and chemical composition will be made. Initial testing of a subset of the filters shows significant differences in elements based on the day that $PM_{2.5}$ was collected, including: Cd, Ce, and Pb ($p \leq 0.05$, one-way ANOVA). The DTT assay has been optimized and calibration curves for the assay are reproducible with no significant difference observed between replicates and with an r^2 value consistently above 0.99. $PM_{2.5}$ from the park location collected on different days has shown up to a 2-fold difference in OP for a subset of samples (range of 8.3 to 4.2 nM DTT consumed/μg $PM_{2.5}$ for three filters). We anticipate to see differences in OP for $PM_{2.5}$ collected on different days due to the chemical composition, particularly if redox active elements are in higher concentrations. Correlations will help us identify components of $PM_{2.5}$ that may be impacting the OP more so than the total mass. This research will add to the growing evidence and justification for investigating the OP of $PM_{2.5}$.

1161 Effect of a High-Fat Diet and Occupational Exposure in Different Rat Strains on Lung and Systemic Responses: Development of an Animal Model to Examine the Exposome

J. M. Antonini, V. Kodali, M. Shoeb, M. Kashon, K. A. Roach, G. Boyce, T. Meighan, S. Stone, W. McKinney, T. Boots, J. R. Roberts, P. C. Zeidler-Erdely, and A. Erdely. *NIOSH, Morgantown, WV.*

The exposome is the measure of all exposures of an individual in a lifetime and how those exposures relate to health. Important components of the exposome include lifestyle (diet), environmental and occupational exposures, and individual genetic predisposition. Mapping of the exposome could improve the understanding of disease and aid in prevention strategies and possible cures of many diseases. The goal was to develop an experimental model of the exposome by collecting biological samples during critical life stages of an exposed animal that are applicable to worker populations. Genetic contributions were assessed using strains of male rats with different genetic backgrounds [Fischer-344 (F344), Sprague-Dawley (SD), Brown-Norway (BN)] maintained on a regular (REG) or high fat (HF) diet for 24 wk. At wk 7 during diet maintenance, groups of rats from each strain were exposed to welding fume (WF; 20 mg/m^3 x 3 hr/d x 4 d/wk x 5 wk) or filtered air until wk 12, at which time some animals were euthanized. A separate set of rats from each strain were allowed to recover from WF exposure until the end of the 24 wk period. Bronchoalveolar lavage fluid and serum were collected at 7, 12, and 24 wk to assess general health indices. Exposure to WF during maintenance on a HF diet caused specific adverse health outcomes directly after exposure as well as after a 12-wk recovery phase. Depending on the animal strain, there was evidence that WF exposure and HF diet together worsened lung toxicity and kidney function as well as altered different serum enzymes and proteins. The exposomal factors of diet, exposure, and strain were all important, depending on the health outcome measured. Exposure had the most significant influence on the pulmonary responses, whereas strain and diet were the most significant contributors regarding parameters related to extrapulmonary responses. Principal component analysis further confirmed the influence of strain on the responses measured, indicating the importance of genetic predisposition as an exposomal factor. In summary, this study showed that an animal model can be useful in the assessment of the exposome as external lifetime exposures can be easily controlled and adverse health outcomes measured.

1162 Differential Responses of Murine Alveolar Macrophages to Elongated Mineral Particles of Asbestiform versus Non-Asbestiform Varieties

T. O. Khaliullin[1,2], E. R. Kisin[2], N. Yanamala[2], and A. A. Shvedova[2,1]. *[1]West Virginia University, Morgantown, WV; and [2]NIOSH, Morgantown, WV.*

Occupational exposures to asbestiform elongated mineral particles (EMP) may lead to diffuse fibrosis, lung cancer, malignant mesothelioma and autoimmune diseases. Cleavage fragments (CF) are chemically identical to asbestiform varieties of mineral, but there is no consensus on whether to treat them as asbestos from the toxicological and regulatory standpoint. Alveolar macrophages (AM) are the first-responders to inhaled particulates, participating in clearance and activating the other resident and recruited immunocompetent cells, which has an impact on the long-term outcomes. In the current study we are addressing the question of how differences in EMP crystal growth habit (asbestiform vs. non-asbestiform) affect AM responses. MPI cells, a non-transformed line that closely mimics AM phenotype, were treated with mass-, surface area- (s.a.), and particle number- (p.n.) equivalent doses of respirable asbestiform and non-asbestiform riebeckite/tremolite EMP (median lengths 4.5-5.5 μm) for 24 h with or without LPS (5 ng/ml). We assessed viability and apoptotic response, lactate dehydrogenase (LDH) and cytokines in cell supernatants. Riebeckite/tremolite asbestos and CF were taken up and induced similar LDH leakage and decrease in viability at the s.a. equivalent doses. At the equal mass, asbestiform EMPs were clearly more cytotoxic. When treated with equal p.n., CF had more pronounced cytotoxic effects. Apoptosis induction was more pronounced in asbestos-treated cells, compared to CF in all comparisons (mass/s.a./p.n.). There was an increase in chemokines and elevated pro-inflammatory cytokine secretion compared to control. Principal component analysis of the cytokine/chemokine secretion showed close clustering for the s.a. and p.n. equivalent treatments. LPS stimulation shifted the cytokine profiles towards inflammation compared to non-LPS-stimulated cells, with more IL-1β and TNF-alpha secretion in asbestos-treated cells compared to CF. In conclusion, murine AM initial responses to respirable EMP of similar lengths, but different growth habit depend on the s.a. metric rather than the mass or the p.n. The study also confirms that asbestiform habit itself is an important determinant of some signaling pathways, i.e. apoptosis. Finding out what metric is critical for the mineral fiber toxicity is a complex task and the *in vivo* study with the same EMP is underway to further address the issue.

1163 Multimodal Mass Spectromtry Analysis following Repeated Intratracheal Instillation of Dispersed Silver Nanoparticles in Rats

G. R. Boyce, J. Antonini, A. B. Stefaniak, M. Kashon, S. Friend, and J. R. Roberts. *NIOSH, Morgantown, WV.*

Silver nanoparticles are among the most widely manufactured nanomaterials and have been incorporated into a wide variety of consumer products such as textiles, detergents, medical devices, drug delivery products, anti-microbial

sprays, personal care products, paints/coatings, and water purification. This has led to the potential increase in risk of worker exposure to these particles. We have previously conducted an *in vivo* study to characterize pulmonary and systemic effects following repeated exposure where rats were intratracheally instilled once a week for eight weeks with 9.35 µg or 112 µg of dispersed silver nanoparticles (Nano-Ag) or dispersion medium (DM) as a vehicle control. Lung histopathology, and analyses of bronchoalveolar lavage fluid (BALF) and serum were performed at 7, 28, and 84 days after the last exposure. Lung injury was characterized by alveolar and interstitial inflammation, as well as oxidative stress. In the current study, a metabolomic approach was employed to characterized changes in the BALF and serum to further examine mechanisms of toxicity and establish a potential panel of biomarkers of exposure and effect. Metabolite characterization was conducted with matrix assisted laser desorption ionization (MALDI) and liquid chromatography mass spectrometry (LC-MS). The metabolomics analysis revealed a significant increase in 44 metabolites in BALF, including 1,2-Dipalmitoyl-sn-glycero-3-phosphoglycerol (DPPG) and cholesterol in the rats exposed to 112 µg at the 7- and 28-day time points. Rats exposed to the high dose had a significant increase in ~60 serum metabolites, with the greatest degree of change in the alanine biosynthesis pathway intermediates in the serum, which have been shown to be indicators of liver toxicity. There was a >2.0-fold increase in alanine, valine, and glutamate in the 112 µg exposed animals at the 7- and 28-day time points. The results of this study show that pulmonary exposure to nanosilver particles leads to changes in the BALF lipidome, which may be related to the pathway of lung injury and oxidative stress. In addition, increased levels of circulating metabolites indicative of liver toxicity agree with numerous *in vivo* studies by other investigators. Further analysis of these molecules and lipids will be conducted to establish a potential biomarker panel for nanosilver exposure and effect.

1164 Single Cell RNA Sequencing and Mouse Transcriptome Analysis Show Amelioration of SEB-Induced Acute Lung Injury via Altering Metabolic Profile of THC-Treated Mice

A. K. Mohammed, H. Alghetaa, K. Wilson, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina, Columbia, SC.*

Inhalation of Staphylococcal Enterotoxin B (SEB) is known to induce acute lung injury (ALI) and studies from our laboratory have shown that THC, a psychoactive ingredient found in *Cannabis sativa,* can induce anti-inflammatory cells such as T regs. Lysine is an essential amino acid that plays several important roles by decreasing IFNg cytokine, inhibition of ERK1/2 and NF-κB signaling pathway, antimicrobial activity against Gram positive bacteria and production of carnitine, which is key in fatty acid metabolism and used as nutritional supplement. In the current study, we investigated the metabolic profile in ALI with or without THC treatment. Lung microbiota was collected and 16S rRNA sequencing was performed. 16S rRNA metagenomic data were generated and functional profiles predicted using PICRUST. Methionine and lysine biosynthesis were increased significantly in THC treated group while lysine degradation was upregulated significantly in vehicle group. Furthermore, we analyzed the metabolomic profile in serum by mass-spectrometry analysis and we found that lysine and carnitine concentrations were increased significantly in THC treated group. Moreover, we found by single cell RNA sequencing of whole lung tissue that solute carrier (Slc25a3 and Slc25a39) genes, which are carnitine transporters, were increased statistically in THC group in CD4+ and CD8+ T cells as well as MDSCs. In addition, carnitine palmitoyltransferase 1 (CPT1), a mitochondrial enzyme responsible for the formation of acyl carnitine which is transported from cytosol to mitochondrial matrix was also increased in CD4+ T cells and alveolar macrophages following THC treatment. Furthermore, we confirmed the results by transcriptome analysis that the solute carrier family was increased significantly in lung infiltrating mononuclear cells of THC treated group. Moreover, our studies on fuel source use showed that SEB-activated T cells treated with THC are glucose-independent while vehicle group is glucose-dependent. Together, THC modulates metabolic functions of lung microbiota and T cells which may affect their signaling, differentiation and toxicity which led to improve homeostasis in lungs. *Supported by NIH grants P01AT003961, R01AI123947, R01AI129788, R01ES019313, and P20GM103641.*

1165 Anti-TNFα Antibody Mitigates Sulfur Mustard-Induced Lung Injury in Rats

T. Seymore[1], C. Jiang[2], H. Abramova[2], R. Malaviya[2], J. Laskin[2], and D. Laskin[2]. *[1]Pennsylvania State University, University Park, PA; and [2]Rutgers, The State University of New Jersey, Piscataway, NJ.*

Sulfur mustard (SM) is a vesicating chemical warfare agent that causes severe lung injury when inhaled. Acute sulfur mustard-induced toxicity is due, in part, to persistent accumulation of macrophages in the lung and the release of inflammatory mediators including cytokines, chemokines, eicosanoids and growth factors. The proinflammatory cytokine, tumor necrosis alpha (TNFα), is released from activated macrophages; it has been shown to contribute to lung injury by promoting inflammatory cell accumulation in tissues and stimulating the release of other inflammatory mediators. This leads to oxidative stress, airway hyperresponsiveness, and tissue remodeling. In these studies, we tested the hypothesis that anti-TNFα antibody treatment would mitigate mustard induced acute lung inflammation and injury. Male Wistar rats were exposed to SM vapors (0.4 mg/kg) or air control and treated with either monoclonal anti-TNFα antibody (15 mg/kg) or vehicle 15-30 min later. Animals were euthanized 3 days after exposure, bronchoalveolar lavage fluid (BAL) and lung tissue collected. Treatment of rats with SM resulted in lung injury and inflammation as measured by increases in bronchoalveolar lavage fluid (BAL) cell and protein content. SM exposure also resulted in increased numbers of lung macrophages expressing tumor necrosis factor (TNF) α and heme oxygenase (HO)-1 indicating inflammation and oxidative stress. Treatment of rats with anti-TNFα antibody (15 mg/kg, i.v.) 15-30 min after SM inhalation reduced lung injury and inflammation, SM-induced levels of HO-1 and TNFα were also suppressed by anti-TNFα antibody treatment. These data demonstrate that inhibiting TNFα may be an effective approach to mitigating acute lung injury induced by vesicants. *Supported by NIH Grants U54AR055073, R01ES004738, and P30ES005022.*

1166 Comparison of Overlooked yet Prevalent Polycyclic Aromatic Hydrocarbon Mixtures on Adverse Effects in Lung Cells

M. N. Melton[1], D. Romo[1], K. Velmurugan[1], B. L. Upham[2], and A. K. Bauer[1]. *[1]University of Colorado Anschutz Medical Center, Aurora, CO; and [2]Michigan State University, East Lansing, MI.*

Polycyclic aromatic hydrocarbon (PAH)s are major components of firsthand and secondhand smoke (cigarette and marijuana) and air pollution, among other sources, and thus far, research has almost exclusively focused on the higher molecular weight (HMW; >5 rings) PAHs for all health effects (e.g., asthma, inflammation and cancer). However, the low molecular weight PAHs (2-4 rings) are in higher prevalence than HMW PAHs in all exposure settings and our previous studies implicate these LMW PAHs in altering critical signaling pathways in lung cells. Specifically, we previously demonstrated that two of these LMW PAHs, 1-methylanthracene (1-MeA) and fluoranthene (Flthn), inhibit gap junctions, decrease connexin 43 (Cx43; primary connexin in lung) expression, activate MAP kinases, and induce inflammatory mediators, such as tumor necrosis factor alpha (TNF). Gap junctional intercellular communication (GJIC) is involved in lung tissue homeostasis and is reduced in early stage lung carcinogenesis. Our hypothesis is that adverse effects of PAH mixtures will differ depending on the PAHs tested. We used MTS assays for cytotoxicity, scalpel-loaded/dye transfer assays to measure GJIC, connexin (Cx)43 immunoblots, as well as quantitative RT-PCR in a mouse alveolar type II pneumocyte cell line (C10 cells) in the absence or presence of equimolar ratios of these mixtures (1-MeA:Flthn) or (1-MeA:Flthn:Phenanthrene (Phe)) at several time points. Additional studies validated findings in a human lung cell line (BEAS2B). Cytotoxicity was observed at doses >60 µM in C10 cells with both 2 and 3PAH mixtures, however, was higher in 3PAH mixtures. The 30 min dose response for GJIC showed that both PAH mixtures had more GJIC dysregulation than the individual PAHs, however, the dose response for the 3PAHs was shifted left compared to 2PAHs; similar findings were observed in the BEAS2B cells. Cx43 expression was reduced in response to either PAH mixture after 24 h. Lastly, we observed significant differences between pro-inflammatory cytokines in response to 3PAHs versus 2 PAHs. Collectively we provide evidence that a relevant environmental exposure to LMW PAHs can elicit adverse effects in lung cells and are dependent on the specific PAHs. Future studies will investigate the combination of both HMW and LMW PAHs in these responses. *Funded by R15ES024893-01 (AKB)/FAMRI CIA (AKB).*

1167 Epidemiological and Experimental Studies on a New Incident of Lung Diseases in Japanese Workers Handling Cross-Linked Water-Soluble Acrylic Acid Polymer (CWAAP) Powders

M. Suka[1], T. Kido[1], T. Yamauchi[1], Y. Morimoto[2], S. Mochizuki[3], M. Murata[4], W. Yoshioka[1], and H. Yanagisawa[1]. *[1]Jikei University School of Medicine, Tokyo, Japan; [2]University of Occupational and Environmental Health, Fukuoka, Japan; [3]University of Kitakyushu, Fukuoka, Japan; and [4]Waseda University, Tokyo, Japan.*

Many workers handling CWAAP powders came down with lung diseases in a Japanese company. Since there have been no case reports on pulmonary toxicity of CWAAP, we conducted epidemiological and experimental studies to verify whether occupational inhalation exposure to CWAAP powders cause lung diseases. [Epidemiological study] The incidence of abnormal lung shadows on chest x-ray in 30 male workers (age 19-55 years) handling CWAAP powders (between September 2009 and May 2017) was compared with that of Japanese male office workers (current smokers aged 30-34 years). [Experimental study] Male Fisher 344 rats received a single intratracheal instillation (0.05-0.5 mg/rat) and a 5-day (6 hours/day) inhalation of CWAAP powders. Histopathological changes in lung tissues were examined at 3 days, 1 week, 1 month, 2 months, and 3 months. [Epidemiological study] The 3-year cumulative incidence of abnormal lung shadows was significantly higher in workers handling CWAAP powders (0.213 vs. 0.032, $p<0.001$). Chest CT scan disclosed intestinal shadows around the bronchioles predominantly in the upper fields of both lungs in all cases. [Experimental study] Infiltration of polymorphonuclear neutrophils and foamy macrophages in alveolar spaces was persistently observed at 3 days, 1 week, and 1 month in a dose-dependent manner. Interstitial collagen deposition was observed using Masson trichrome staining and immunohistochemistry for collagen type 1 at 3 months. The findings from epidemiological and experimental studies revealed that occupational inhalation exposure to high levels of CWAAP powders can induce lung fibrosis. Further studies are needed to evaluate the carcinogenetic potential of inhaled CWAAP powders. *Acknowledgement: This study was supported by the Industrial Disease Clinical Research Grant (MHLW).*

1168 Cardiopulmonary Effects of Phosphine Poisoning: A Preliminary Evaluation of Milrinone

W. Y. Tuet, S. A. Pierce, M. C. Racine, S. Stone, E. Pueblo, A. Dukes, J. Tressler, L. Jennings, B. J. McCranor, and B. Wong. *US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.*

Phosphine gas (PH_3) is a widely used grain fumigant and common reagent in chemical synthesis. Despite commercial uses, PH_3 poses a serious threat to human health, through accidental or intentional exposure, as it is both highly toxic and easily attainable. PH_3 poisoning affects all major organ systems and is thought to specifically target oxidative respiration; nevertheless, the exact mechanism of PH_3-induced toxicity remains largely unknown. Previous studies indicate that cardiac failure and circulatory compromise may be central to PH_3-induced mortality. Here, we investigate milrinone (MLR), a phosphodiesterase-3 (PDE-3) inhibitor used to treat cardiac failure, as a potential countermeasure for PH_3 poisoning. Telemetrized female rats were exposed to PH_3 at a concentration-time product of 21450 ppm×min using a custom whole-body inhalation exposure system with integrated real-time physiological monitoring capabilities. Rats were divided into cohorts and treated prophylactically with one of three doses of MLR (40, 200, or 600 µg/kg) or water. Respiratory dynamics and cardiac parameters were recorded before, during, and after PH_3 exposure. Prophylactic administration of high dose MLR (600 µg/kg) nominally improved survivability compared to water-treated animals. However, normalized time of death did not differ substantially between different treatment groups, suggesting that MLR did not extend the treatment window for PH_3 poisoning despite reducing mortality. In terms of respiratory function, MLR did not alleviate changes in respiration and PH_3 exposure induced an increased respiratory drive regardless of treatment regimen, with observed minute volume elevations of 150 - 200%. Conversely, MLR treatment appeared to improve aspects of cardiac function affected by PH_3 exposure. In the absence of treatment, cardiac contractility (+dP/dt) increased by approximately 50% as a result of PH_3 exposure; rats administered MLR exhibited higher +dP/dt increases with slight dose dependent effects. Similarly, mean arterial pressure (MAP) increased following PH_3 exposure, however MLR treatment reduced MAP with slight dose dependent effects. These expected dose-dependent responses and increased survivability illustrate the viability of MLR as a potential countermeasure for PH_3 exposure when administered prophylactically.

1169 Single Cell RNA Sequencing Reveals Metabolic Reprogramming in Inflammatory Cells in SEB-Induced Acute Lung Injury following Treatment with Resveratrol via AhR-miR-100-Axis

H. F. Alghetaa, A. Mohammed, K. Wilson, M. Nagarkatti, and P. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

Resveratrol, (RES), a phytoalexin, is well-known for its anti-inflammatory and anti-oxidant properties. SEB, a superantigen, is known to trigger acute lung injury (ALI) and cause mortality. In the current study, we tested the effect of RES in a dual-dose model of SEB exposure that triggers ALI and causes 100% mortality in C3H/HeJ-mice. The data revealed RES attenuated SEB-induced ALI and prevented mortality. Lung-infiltrating mononuclear cells were obtained from mice that were pre-treated with RES or vehicle followed by SEB exposure for 48hrs. The microRNA expression profile was determined to examine the epigenetic regulation and dysregulated genes were studied by scRNA-Seq analysis. scRNA-Seq analysis showed significant reduction in the expression as well as the number of cells expressing of mTOR and associated genes, RAC1, AKT, and Rictor, in various inflammatory cells in lungs of RES-treated when compared to vehicle-treated group. In contrast, Ppar-γ, Tgfβ-1 and Sirt2 gene expression as well as autophagy-related genes, ATG-13 and ULK1 were significantly higher in RES-treated group. miRNA array showed upregulation of miR-100 in T-cells treated with SEB+RES *in vivo* as well as *in vitro*. CD3+ T cells from lungs of T cell-specific AhR cKO or wild type mice treated with SEB+RES showed that miR-100-5p expression is AhR-dependent. Further, RES inhibited T-cell proliferation *in vitro* by blocking mTOR signaling and inducing β-oxidation in mitochondria instead of utilizing glucose as the main source of fuel which may be due to suppression of RAC1 mRNA controlling transport of glucose by glucose transporter 4 (GLUT4) vesicle. In addition, live-cell metabolic assay showed that bioenergetic profile utilized glucose-independent pathway and diminished glycolysis rate in RES-treated T-cells. We conclude that RES treatment ameliorated the ALI epigenetically either directly by metabolic reprogramming of activated T-cells by enhancing autophagy/apoptosis or indirectly by increasing anti-inflammatory cells. *Supported by NIH grants P01AT003961, R01AT006888, R01ES019313, R01MH094755, P20GM103641.*

1170 Role of Airway Club Cell Cytochrome P450-Mediated Bioactivation in Lung Epithelial Injury Induced by Naphthalene Inhalation

N. Kovalchuk[1], Q. Zhang[1], L. Van Winkle[2], and X. Ding[1]. *[1]University of Arizona, Tucson, AZ; and [2]University of California Davis, Davis, CA.*

Prior studies have clearly established that cytochrome P450 (CYP) enzymes in both lung and liver can bioactivate naphthalene (NA), a possible human carcinogen. In this study we examined the specific contribution of pulmonary CYPs in Club cells to the airway toxicity caused by inhaled NA. We used a lung-*Cpr*-null mouse model, which undergoes doxycycline-induced, Cre-mediated deletion of the *Cpr* (a redox partner of all microsomal CYPs) gene specifically in airway Club cells. In 2-month-old lung-*Cpr*-null mice, *Cpr* deletion occurred in 66% of Club cells in the proximal airways and 86% of Club cells in the distal airways, as indicated by the results of dual immunofluorescence staining of lung tissue sections for the Club cell marker CCSP (Club cell secretory protein) and CPR expression. Post-exposure toxicokinetic profiles of plasma NA and NA-GSH (a biomarker of NA bioactivation) were similar between lung-*Cpr*-null mice and their control littermates with normal CPR expression, following a single 4-h, nose-only, 10-ppm NA inhalation exposure. Total protein concentration and lactate dehydrogenase (LDH) activity in bronchioalveolar lavage fluid (BALF) collected 20-h after termination of active NA inhalation exposure were, respectively, 37% and 39% lower in lung-*Cpr*-null mice than in control littermates. The extent of incorporation of 5-bromo-2′-deoxyuridine (BrdU labeling index), which was significantly increased in both proximal and distal airways of all NA-exposed mice at 2 days post-exposure (by 4-13 fold, compared to filtered air-exposed, genotype-matched control groups), was 2-3 fold lower in lung-*Cpr*-null mice compared to control littermates. Similarly, genotype-related differences in sensitivity to NA-induced airway damage were also observed in mice after intraperitoneal administration of a single bolus dose of NA at 200 mg/kg. These results confirm that CYPs specifically localized to airway Club cells play a major role in NA-induced airway epithelial damage *in vivo* at an environmentally relevant NA concentration. *Supported in part by NIH grant ES020867.*

1171 Comparative Assessment of *In Vitro* Toxicity Induced by Crystalline Silica and Multiwalled Carbon Nanotubes in Human and Mouse Macrophages

G. M. Mustafa. *NIOSH, Morgantown, WV.*

Pulmonary exposure to particles like crystalline silica (CS) and multi-walled carbon nanotubes (MWCNTs) are known occupational hazards. Once in the lung, these particles activate alveolar macrophages (AM), a first step in the complicated inflammatory cascade and development of diseases. To study the mechanisms involved in particle induced inflammation at the cellular level, human (THP-1) and mouse (RAW 264.7) macrophages were used as *in vitro* models and toxicity of CS and MWCNTs was tested. Cytotoxic dose-responses of each particle were determined at final concentrations of 0.9, 1.8, 3.7, 7.5, 15, 30, 60, 120, 240 and 480 μg/cm^2 for 24-hrs. Both particles caused a dose-dependent reduction in cell viability. Four concentrations pertaining to 0%, 10%, 30% and 60% toxicity for each cell and particle type were chosen for cytokine analysis: 41 markers in THP-1 and 32 markers in RAW 264.7 were measured. Activation of inflammasome cascade (IL18), pro-inflammatory markers (TNF-α), dysregulation (IL6) and fibrotic markers like growth factors, some of which play an important role in fibrosis, were observed. Cytokines involved in inflammation (IL1-B, IL18) and cell recruitment (MCP-1, MIP) were found to be elevated. Based on TH1/TH2 (IL18/IL4) ratio, there was a concentration-dependent polarization to TH1 response. Overall, THP-1 cells produced a greater inflammatory response to particle exposure than RAW 264.7 cells and MWCNTs were more potent than CS. Data clustering showed MWCNTs and CS treated THP-1 and RAW cells had 24 and 7 common cytokines, respectively, and 11 cytokines were found to be common between both cell lines and particle types. Principle component Analysis showed that the response, at same doses can be easily distinguished between particle type and was more apparent in THP-1 than RAW cells. In conclusion, both particle exposures resulted in significant cytotoxicity as well as production of inflammatory mediator in a concentration-dependent manner. However, THP -1 cells were more responsive than RAW cells and the potency of MWCNTs observed was much higher compared to silica at equal mass in both cell types, possibly due to difference in particle size and also due to difference in ASC inflammasome/casp1 activation cascade between two cell types. Ongoing transcriptomic studies may further differentiate the mechanisms of particle toxicity in different types of macrophages.

1172 *In Vitro* Toxicity Comparison of Surrogate Metal Oxides Found in Welding Fumes

P. C. Zeidler-Erdely, T. Trainor, S. S. Leonard, A. B. Stefaniak, L. Bowers, R. N. Andrews, M. J. Keane, J. M. Antonini, A. Erdely, and V. Kodali. *NIOSH, Morgantown, WV.*

Welding fumes were classified as a Group 1 carcinogen (*carcinogenic to humans*) in 2017 by the International Agency for Research on Cancer based on sufficient epidemiological evidence and limited evidence in experimental animals. Toxic metals commonly found in the fumes are chromium (Cr), iron (Fe), and nickel (Ni). Copper (Cu)-based welding consumables are currently being investigated as a less toxic alternative. The objective of this study was to evaluate the acute toxicological potency of a new Cu-Ni welding fume in human bronchial epithelial cells (BEAS-2B) over a wide dose range (0, 1.56, 3.13, 6.25, 12.5, 25, 50 and 100 μg/ml). The primary components of the welding fume were also assayed to determine their relative potencies and included nickel (II) oxide (NiO; <10 μm and <50 nm sizes), copper (II) oxide (CuO; <10 μm and <50 nm sizes), and iron (III) oxide (Fe_2O_3; <5 μm). Physicochemical properties including dissolution were determined for the welding fume and its components. Membrane damage and cell proliferation/viability were quantified by measuring lactate dehydrogenase (LDH) release and conversion of the tetrazolium salt, WST-1, respectively after 24 h of exposure. The acellular oxidative potential of the welding fume and its component metals was determined by electron paramagnetic resonance. Cellular oxidative stress was measured via flow cytometry using change in CellROX. Experiments were run in a randomized complete block design (n=3 independent blocks) with a one-way layout of treatment combinations. The data showed that CuO (<50 nm) and Cu-Ni fume were the most toxic, and significantly increased LDH levels and decreased cell proliferation/viability with increasing concentrations *in vitro*. NiO (<50nm) was of intermediate toxicity primarily decreasing cell proliferation/viability at the higher doses with no significant effect on LDH levels. At equal mass, the nanocomponents were more toxic compared to their micron-sized components. No significant effects for damage and proliferation/viability were found for the other metal oxides tested. CuO (<10 μm and <50 nm sizes) and the Cu-Ni fume resulted in significant acellular and cellular levels of oxidative stress while the other metal oxides had no significant effect. These results suggest that the Cu-Ni fume has the potential to be inflammatory and toxic *in vivo*, and this effect may be primarily driven by the Cu component.

1173 *In Vitro* Toxicity Assessment of Respirable Solid Surface Composite Sawing Particles

W. K. Mandler[1], S. Kang[2], M. Farcas[1], C. Qi[2], S. A. Friend[1], and Y. Qian[1]. *[1]NIOSH, Morgantown, WV; and [2]NIOSH, Cincinnati, OH.*

Solid surface composites (SSC) are a class of popular construction materials composed of aluminum trihydrate (ATH) and acrylic polymers. Previous investigations have demonstrated that sawing SSC releases substantial airborne dusts ranging size from 6 nm to 19.8 μm, with a geometric mean diameter of 1.05 μm. In mice, aspiration exposure to airborne SSC dusts induced symptoms of pulmonary inflammation at 24 h post-exposure: neutrophilic influx, alveolitis, and increased lactate dehydrogenase (LDH) and proinflammatory cytokine levels in lavage fluid. The particles appeared to be poorly-cleared, with 81% remaining at 14 days post-exposure. The objective of this study was to determine the toxicity of specifically respirable-sized particles on a model of human alveolar macrophages (THP-1). The relative toxicities of sub-fractions (0.07, 0.66, 1.58, 5.0, and 13.42 μm diameter) of the airborne particles were also determined. THP-1 macrophages were exposed for 24 h to respirable particles from sawing SSC (0, 12.5, 25, 50, or 100 μg/ml), or size-specific fractions (25, 50, and 100 μg/ml). Respirable particles decreased viability by 15% and 19% after exposure to 50 μg/ml and 100 μg/ml SSC, respectively, which correlated with increased cell culture supernatant LDH activity by 40% and 70% when compared to control. Reactive oxygen species (ROS) production were increased by 64% and 106% after exposure to 50 μg/ml and 100 μg/ml, and the glutathione peroxidase activity was increased by 22%, 18%, and 20% at the 12.5, 25, and 50 μg/mL exposure levels, respectively. IL-1β, IL-2, IL-4, IL-10, IL-12p70, IL-13, IFNγ, and TNFα were all increased in a dose-dependent manner. In the cells exposed to sub-fractions of SSC particles, at 50 μg/ml, the 0.07μm particles killed 23% of cells. At 100 μg/ml, 0.07 and 1.58 μm particles killed 36%, and 22% of cells, respectively. While each of these described fractions elicited a significant LDH response from control, they were not statistically different from each other. These results indicate a potential for cytotoxicity of respirable SSC particles and a relationship between particle size and toxicity.

1174 Identification of IL-17 Pathway as a Plausible Target for Pulmonary Effects following Acrolein Exposure Studies on Inbred Mouse Strains and Human Primary Bronchial Epithelial Cells at Air-Liquid Interface

L. Ernstgård[1], A. Dwivedi[1], L. Palmberg[1], K. Ganguly[1], L. Chen[2], T. Gordon[2], G. Johanson[1], and S. Upadhyay[1]. *[1]Karolinska Institutet, Stockholm, Sweden; and [2]New York University School of Medicine, New York, NY.*

Acrolein is an important constituent of e.g. cigarette and biomass smoke. Chronic inhalation exposure has been associated with lung diseases like asthma and chronic obstructive pulmonary disease. Inter-strain variability in inflammatory response and oxidative stress was evaluated in seven inbred mice strains (129S1/SvImJ, A/J, BALB/cByJ, C3H/HeJ, C57BL/6J, DBA/2J, and FVB/NJ, females 12-14 weeks old) exposed to 0 or 1 ppm acrolein for 11 weeks (6 h/d, 5 d/wk). The *in vivo* experiments were followed up by acute exposure *in vitro* (0, 0.1 and 0.2 ppm acrolein, 30 min) using human primary bronchial epithelial cells (PBEC) cultured at air-liquid-interface (ALI). *In vivo*, total cell numbers in broncho-alveolar lavage and protein concentrations was unaffected by acrolein in all mouse strains. BALB/cByJ, C57BL/6J, and 129S1/SvImJ were the most affected strains with significantly increased expression of oxidative stress, pro-inflammatory and/or tissue injury markers. Both *Mmp9* and *Timp1* were significantly upregulated in the strains DBA/2J, C3H/HeJ and FVB/NJ indicating a change in protease-anti-protease balance. Upregulation of *Il17b* in the susceptible strains mice led us to investigate the pro-inflammatory IL-17 pathway genes in the PBEC-ALI model. *In vitro*, significantly increased expression of *IL17A, C and D*; *IL1β, IL22*, and *RORA* was detected in the PBEC-ALI following exposure to 0.1 and 0.2 ppm acrolein. The inter-strain differences in response to sub-chronic exposure to acrolein suggest that genetics may play a role in the pulmonary response to acrolein. Additionally, acrolein exposure mediated alteration of key IL-17 pathway genes in the PBEC-ALI model, which identifies IL-17 as a plausible candidate pathway warranting further mechanistic studies.

1175 Comparison of Vapor and Liquid Phase Acrolein Exposures to Air-Liquid Interface (ALI) Cell Cultures

D. H. Brandwein, F. A. Bettmann, M. P. DeLorme, A. T. Eveland, and L. M. Milchak. *3M, Saint Paul, MN.*

The 3M Strategic Toxicology Laboratory (STL) is an internal corporate resource that emphasizes the use of *in vitro* methodology when providing support to 3M businesses. The STL is investigating vapor and liquid phase exposure to cell cultures at the air-liquid interface (ALI) as an animal alternative assay to help assess respiratory toxicity. This study describes the use of acrolein, a potent respiratory toxicant, as a model test substance. Vapor atmospheres were generated using a Vitrocell® 12/12 system. A549 cells were seeded into Transwell® inserts, grown submerged for 1 week then raised to the ALI for an additional 7-14 days, creating cultures robust to the clean-air negative control conditions of the Vitrocell apparatus. EpiAirway™ tissues were purchased from MatTek. All exposures were carried out for three hours and viability assessed immediately or 20 - 24 hours post exposure. At the vapor phase, A549 cell viability was reduced to 58% (14.6 ppm) and 91% (4.6 ppm) compared with the Vitrocell clean-air control group, with a further decrease in each case of approximately 20% following the post-exposure period. Cell viability was not affected at the 1.46 ppm level. In the liquid phase, EpiAirway cultures were exposed to acrolein in corn oil ranging from 0.01 - 3,000 ug/mL. Viability decreased at all concentrations greater than 10 ug/mL. At 1,000 ug/mL, viability was reduced to 48% immediately and 4% 20 hours post exposure. A549 cultures were also exposed to acrolein dilutions in DPBS in the same range as EpiAirway and followed a similar viability profile. Both modes of exposure, vapor and liquid, demonstrated dose dependent effects on viability. However, the concentrations of acrolein required to decrease viability were much lower with vapor exposure than with direct liquid exposure. The liquid exposure level (1000 ug/ml) which produced approximately 50% reduction in viability (EC_{50}) converts to over 400,000 ppm in air, whereas 14.6 ppm vapor exposure reduced viability to approximately 58%. Further experiments are required to better understand the discrepancy in the liquid phase and vapor phase levels required to achieve the EC_{50} and to identify the most appropriate comparison method, such as concentration or mass/surface area. Understanding these differences will be critical to achieve the best utilization of these *in vitro* methods as a tool for respiratory toxicity assessment.

1176 Effect of Tyloxapol Treatment on % Active Cilia, Cilia Beating Frequency, and Mucociliary Clarance in MucilAir-Cystic Fibrosis Tissues

C. S. Roper, S. Eleanor, H. Paulo, and J. Wallace. *Charles River, Edinburgh, United Kingdom.* Sponsor: R. Stachlewitz

The lungs are cleared of particles and kept sterile by cilia beating the mucus resulting in mucociliary clearance (MCC) of these materials. In cystic fibrosis (CF) patients, the mucus produced is thicker and, therefore, the MCC system does not function effectively. MucilAir™-Cystic Fibrosis tissues (MCF) are a functional model of the human airway epithelium derived from CF patients' cells cultured at the air-liquid interface resulting in a similar morphology to the patient, with functioning cilia, but defective MCC. The aim of the study was to measure the effects of the surfactant drug, Tyloxapol (TP), β-lactose (negative control) both in saline, and saline on the critical end-points for CF drug efficacy testing; % active cilia, cilia beating frequency (CBF) and MCC. Triplicate MCF were exposed to TP in saline at 0.0005 and 0.1% (v/v) over a 24 h time course alongside saline and β-lactose controls for 24 h only. Membrane integrity was measured pre and postdose by transepithelial electrical resistance (TEER). Displacement, a measure of MCC, was assessed by applying microbeads to the apical tissue surface, then movement tracked by video, with images analysed using TrackMate plugin on ImageJ software (NIH). CBF images were transferred to Epithelix CiliaX software to calculate % active cilia (>3.5 Hz) and CBF in all areas. Since % active cilia, CBF and MCC showed similar trends, only MCC, the final endpoint for measurement of drug treatments for CF, is discussed. All values are given as mean ± SD. The undosed displacement was 3.45 ± 7.04 µm. At 24 h, displacement increased for saline (52.9 ± 40.7 µm), β-lactose (36.2 ± 20.8 µm), low TP (62.1 ± 31.9 µm) and high TP (7.3 ± 7.4 µm). For the low dose timecourse, displacement increased to 20.8 ± 26.3 µm at 1 min and remained at this level until 1 h before increasing to 61.9 ± 34.0 µm at 2 h. For the high dose, displacement increased to 15.1 ± 11.5 µm at 1 min increasing to 35.0 ± 23.1 µm at 1 h before increasing to 68.3 ± 54.1 µm at 2 h. Toxicity in the high dose samples was observed as reduced TEER from 30 min post dose. Efficacy was partly due to the mucus thinning effect of saline used for all treatments, although the surfactant properties of TP increased this further. In conclusion, this study demonstrated that % active cilia, CBF and MCC can be measured and changes observed in M-CF. Therefore, it is proposed to use these endpoints in this test system to identify improved and novel treatments for MCC in CF.

1177 Gasoline Testing in VITROCELL 24/48 *In Vitro* Inhalation Exposure System as Alternative Method for *In Vivo* Inhalation Toxicity Studies

S. Verstraelen, A. Jacobs, K. Hollanders, J. Van Laer, D. Bertels, M. Van Deun, S. Remy, L. Geerts, H. Witters, L. Deferme, and E. Frijns. *VITO, Mol, Belgium.* Sponsor: M. Popovech

There is an increasing demand to implement *in vitro* alternatives to *in vivo* experimentation in different research areas to comply with the 3R concept. As the inhalation route is one of the most relevant routes of exposure, alternatives approaches would need realistic lung cell models (*e.g.* 3D), realistic inhalation exposure systems (*i.e.* air-liquid interface (ALI)), and proper dosimetry techniques to increase the predictive ability of *in vitro* cell models and therefore accelerate the shift from *in vivo* towards *in vitro* testing. The ultimate goal of the 'PETRALI' project is to develop an alternative method for *in vivo* inhalation testing of petroleum-based substances. This work on gasoline testing was preceded by (i) development and validation of a generation facility to volatilize single compounds (*e.g.* ethylbenzene (EB)) and complex substances (*e.g.* gasoline); (ii) successful optimization and validation of VITROCELL® 24/48 exposure system for negative control (clean air ,CA), positive control (nitrogen dioxide, NO_2), and EB testing. Based on the pilot results using EB, an experimental set-up of 4 hour (h) gasoline aerosolization and deposition at ALI, followed by post-exposure incubation under ALI conditions (up to 24 h) has been established. The *in vitro* administered aerosol concentration of about 45.000 mg/m³ (converted LC50 rat for gasoline from *in vivo* to *in vitro*) could not be generated due to condensation of the gasoline vapour to 37°C needed for cell viability. So, A549 cells were exposed to a concentration-range of about 5000, 7500, and 10000 mg/m³ in 3 independent experimental runs. For each gasoline concentration two rows of 6 positions each were exposed. The flow per insert was 1.5 mlpm and trumpet height 2 mm. One row was exposed to CA and one row to NO_2 (about 20 ppm). Generation up to a maximum of 10000 mg/m³ gasoline gave no effect on A549 cell viability (MTT). Additional endpoints, such as inflammation and oxidative stress were measured. Exposure of A549 cells to 10000 mg/m³ gasoline induced an increase of pro-inflammatory markers *IL6* (log2 fold change (FC) = 1.94, p = 7.28E-3), *IL8* (log2 FC = 1.98, p = 2.18E-3), and *CCL2* (log2 FC = 1.13, p = 3.08E-3) as compared to CA, which was statistically significant for all markers. The oxidative stress marker *SOD2* was statistically significant increased for 10000 mg/m³ (log2 FC of ~ 0.56, borderline result). Administered dose could not be determined due to a combination of low deposition efficiency of the ALI system and detection limits off headspace GC-MS analysis for this complex mixture. Detailed results of the *in vitro* gasoline ALI exposure study and it's challenges/solutions for characterization will be highlighted. *The VITROCELL® 24/48* in vitro *inhalation exposure system was awarded to VITO by the PETA International Science Consortium.*

1178 Primary Human 3D Airway-Macrophage Culture Platform to Assess Toxicity of Suspended versus Aerosolized ZnO Nanoparticles

C. Branco[1], P. Weindl[2], T. Krebs[2], S. Huang[1], E. Sage[3], B. Boda[1], and S. Constant[1]. *[1]Epithelix, Plan-les-Ouates, Switzerland; [2]Vitrocell Systems GmbH, Waldkirch, Germany; and [3]Hôpital Foch, Paris, France.*

The increasing use of nano-sized particles require an evaluation of their occupational exposure limit. Several studies demonstrated cytotoxicity and inflammation caused by metal nanoparticles, among them ZnO, which may increase the risk of pulmonary and also cardiovascular diseases. To enable a relevant *in vitro* prediction, complex primary human tissue models and realistic exposure methods are needed. We report an *in vitro* immunocompetent model based on air-liquid interface 3D fully differentiated human epithelia from upper (MucilAir™) or lower (SmallAir™) airway, co-cultured with human fibroblasts and surrogates of airway macrophages to evaluate inhalation toxicity of ZnO nanoparticles. The co-culture systems including basal, ciliated, goblet or club cells, fibroblasts and M0-like macrophages were successfully maintained and functional in a serum free culture medium (ImmunoAir™) for two weeks. The aim of the study was to compare the effects of aerosol and suspension exposure of ZnO nanoparticles on primary epithelial cells derived from human upper and lower airway with fibroblasts and macrophages using multi-endpoints analysis. Apical aerosol exposure of 1 µg/cm² ZnO (10-30 nm) was performed using a novel Vitrocell vial injector device using tetrafluoro-ethane as propellant, allowing uniform and real-time dose-controlled deposition. Dry exposure was compared to 1 and 10 µg/cm² apical suspension exposure in saline solution. Repeated 24 hours exposure were investigated during 3 days. Epithelial tissue integrity was well preserved in all conditions with a low cytotoxicity only on small airway model. Mucociliary dynamics was reduced and basal H_2O_2 production, Il-6 release were increased only on upper airway model. Dose dependent increase of Il-8 was observed

for both airway models. Amphiregulin, a growth factor implicated in epithelial tissue remodeling, was increased for both type of epithelia. Altogether, ZnO nanoparticles induces more robust changes via aerosol, than suspension exposure, and upper airway responds by multiple parameters, but without cytotoxicity, while small airway epithelia shows more cytotoxicity. These data suggest that this new generation of immunocompetent human airway models combined with aerosolized exposure may be useful for inhalation toxicity evaluation of airborne substances.

1179 Ciliopathic and Inflammatory Effect of Poly(I:C) on *In Vitro* 3D Human Airway Epithelium

R. Bonfante[1], B. Boda[1], E. Sage[2], L. Wiszniewski[1], S. Huang[1], I. Najera[3], and S. Constant[1]. *[1]Epithelix, Plan-les-Ouates, Switzerland; [2]Hôpital Foch, Paris, France; and [3]Virion Biotherapeutics, London, United Kingdom.*

As first line of defense against airborne pathogens, the airway epithelium reacts through effective mucociliary clearance and secretion of inflammatory mediators. Poly (I:C), a mimetic of respiratory viruses, is capable of activating Toll-like receptor such as TLR3 on the airway epithelial cells. In this study, we would like to better understand the effect of Poly (I:C) on airway epithelial function using a multi-endpoint approach. An *in vitro* human airway model based on a pool of nasal cells from 14 donors (MucilAir™) was used to assess acute as well as repeated dose effect of Poly (I:C). The epithelial model is fully differentiated and tight, exhibiting efficient mucociliary clearance function (MCC). The tissues were exposed either to 9; 30 and 90 µg/cm^2 of Poly (I:C) apically during 96h, or to 30 µg/cm^2 of poly (I:C) every day during one week. Trans-epithelial electric resistance (TEER), cytotoxicity, and MCC were assessed simultaneously. Although no cytotoxicity was observed at all tested conditions, poly (I:C) induces a dose- dependent (i) decrease of TEER and (ii) reduction of MCC, correlated with a decrease of cilia beating frequency. The Inflammatory mediators such as Il-8, IL-6, IL-1β; RANTES and Interferon-λ are all reversibly upregulated in the context of single exposure, and also in case of one week repeated dose treatment. Altogether, Poly (I:C) induce a potent and typical inflammatory response with progressive loss of tissue integrity and mucociliary clearance function. Therefore, Poly (I:C) could be used as positive control to benchmark the effect of airborne substances on airway epithelium.

1180 Inter-Laboratory Ring Trial of the GARD Air Assay for Assessment of Respiratory Sensitizers—Results of Predictive Performance and Reproducibility

R. Gradin[1], A. Johansson[1], A. Forreryd[1], A. Edwards[2], V. Zuckerstätter[3], and H. Johansson[1]. *[1]SenzaGen AB, Lund, Sweden; [2]Burleson Research Technologies, Morrisville, NC; and [3]Eurofins BioPharma Product Testing Munich GmbH, Planegg, Germany.* Sponsor: J. Schmidt

Chemical sensitization is a disease state induced by the human immune system in response to chemical sensitizers, the proactive identification of which remains a central part of hazard and risk assessment of chemicals. Due to legislation, public opinion, concern for human environmental health and economic interests, there is an urgent need to develop animal-free methods for assessment of chemical sensitizers. While several assays for assessment of skin sensitizers have been proposed, the demand for an assay that accurately and specifically predicts and classifies chemical respiratory sensitizers remains unfulfilled. To this end, the novel assay GARD™air was developed, designed as an independent application of the GARD™ - Genomic Allergen Rapid Detection - technology platform. The GARD™ platform evaluates the transcriptional patterns of endpoint-specific genomic biomarker signatures in a human dendritic-like cell line following exposure, in order to provide machine learning-assisted classifications of tested substances. Specifically, the GARD™air prediction model is based on a set of genomic predictors related to the bridging of innate and adaptive immune functions and skewing towards Th2 type immune responses and has been previously been demonstrated to be functionally relevant, able to accurately classify respiratory sensitizers and differentiate them from skin sensitizers. Here, we present data from a recently performed inter-laboratory ring trial, aiming to estimate the within- and between-laboratory reproducibility (WLR and BLR), as well as the predictive performance (PP) of GARD™air. In summary, WLR ranged between 52-72%, while BLR was 79%. The PP was defined by an accumulated accuracy of 74% across the three different laboratories, with notable and consistent peak performances within subsets of the chemical space. Of further note, a specificity of 95% indicated that GARD™air is a potent screening tool for safety assessment of respiratory sensitization, providing a broad spectrum of industries with an affordable and more accurate alternative to current in-house (non-validated) animal-based methods.

1181 *In Vitro* Approach for Assessing Respiratory Toxicity in Human Lung Cells

M. Sharma[1], S. Verstraelen[2], E. Frijns[3], F. Maes[3], and A. J. Clippinger[1]. *[1]PETA International Science Consortium, London, United Kingdom; [2]VITO, Flemish Institute for Technological Research, Mol, Belgium; and [3]VITO, Mol, Belgium.*

Approaches to efficiently and effectively assess the toxicity of chemicals on the human respiratory tract using *in vitro* systems would provide useful information to inform product development and risk management decisions. Presented here is an approach to help better understand the appropriate *in vitro* system to use and the biological markers to monitor based on the test chemical under evaluation. In this study, BEAS-2B cells (a human bronchial epithelial cell line) were exposed to various concentrations (0.72ppm, 25ppm, and 85ppm) of triethoxysilane vapor at the air-liquid interface using a capillary dosage unit coupled to a VITROCELL 6/4 exposure module. Triethoxysilane is an industrial chemical classified as a GHS category 2 inhalation toxicant based on rat acute inhalation toxicity testing. A significant concentration-dependent decrease in cell viability (resazurin-based assay) and increase in cytotoxicity (lactate dehydrogenase assay) was observed after exposure to the triethoxysilane (test chemical) and nitrogen dioxide (positive control) as compared to clean air (negative control). A significant increase in expression of inflammatory markers [interleukin (IL)-1β, IL-2, IL-4, IL-6, IL-8, IL-10, IL-12p70, IL-13, interferon-gamma (IFN-γ), and tumor necrosis factor-alpha (TNF-α)], determined by Meso Scale Discovery technology (https://www.mesoscale.com/en), was observed at 25ppm. Additional work is underway to test other silanes that vary only in their carbon length to determine if this *in vitro* system can detect the decrease in toxicity that correlates with increasing carbon-chain length and to determine the advantages of using a 2D cell line (BEAS-2B cell) versus a 3D human reconstructed tissue model. Overall, these results will evaluate the utility of an *in vitro* system to predict the likelihood of a chemical to cause portal-of-entry effects on the human respiratory tract and could be a useful approach to rank chemical toxicity.

1182 Improving Respiratory Toxicity RD_{50} Prediction for Structurally Similar Chemicals

M. H. Rubens, and M. H. Whittaker. *ToxServices, Washington, DC.*

The RD_{50} is the nominal air concentration leading to a 50% reduction in respiratory rate and has been used to establish airborne levels that are likely to provoke sensory irritation. Alarie (1981) defined the term sensory irritation to describe adverse health effects caused by compounds interacting with peripheral nerve fibers. Historically, the RD_{50} was experimentally determined *in vivo* where the chemical's potency as an acute respiratory irritant was measured through its ability to decrease respiratory frequency in laboratory mice following a short-term exposure. The *in silico* method for establishing a RD_{50} value for sensory irritation has remained largely unchanged over the past 25 years. As efforts to establish robust alternatives to animal testing for various endpoints progress, it is imperative that *in silico* predictions for respiratory toxicity continue to improve. In this present study, we build upon a previous calculation derived by the European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) using the octanol-water partition coefficient (K_{ow}) and the air-water partition coefficient (K_{aw}) to predict a RD_{50} for data poor chemicals. ECETOC observed that the accuracy of any given predicted RD_{50} using the generalized equation for all chemicals may be improved upon if statistical analyses were completed among a series of homologous chemicals. Thus, using a multiple linear regression approach, equations for predicting the RD_{50} for two structurally related groups of chemicals were generated. This group categorization enhanced the ability of K_{ow} and K_{aw} to predict the RD_{50} for aldehydes, ketones, and alcohols by 6.2% and for hydrocarbons by 2.1% when compared to ECETOC's generalized RD_{50} equation for all chemicals. This improvement of an *in silico* method for predicting sensory irritation will contribute to advances in alternative methods to animal testing and build upon our understanding of structure-related activity to fill data gaps for a predominately uncharacterized health endpoint.

1183 Inhalation of Acrolein Affects the Regulation of Mitochondrial Metabolism in the Airways

C. B. Tulen[1], S. J. Snow[2,3], P. A. Leermakers[1], U. P. Kodavanti[2,4], F. J. van Schooten[1], A. Opperhuizen[1,5], and A. H. Remels[1]. *[1]Maastricht University Medical Center+, Maastricht, Netherlands; [2]US EPA, Research Triangle Park, NC; [3]ICF International Inc., Durham, NC; [4]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [5]Netherlands Food and Consumer Product Safety Authority, Utrecht, Netherlands.*

Exposure of the airways to cigarette smoke is a known risk factor for developing several lung diseases including Chronic Obstructive Pulmonary Disease (COPD). Although cigarette smoke is a complex mixture of over 6000 chemicals, acrolein, a αβ1-unsaturated aldehyde generated during the pyrolysis and combustion of tobacco, is thought to be responsible for a large proportion of the non-cancer disease risk associated with smoking. Recently, cigarette smoke-induced mitochondrial dysfunction in airway epithelial cells has been implicated in the pathogenesis of COPD. While *in vitro* studies suggest that acrolein can impair mitochondrial function, whether or not inhalation of acrolein *in vivo* affects mitochondrial content or the pathways controlling this (mitochondrial biogenesis *vs* mitophagy) in cells of the airways is unknown. Therefore, in the present study, rats were exposed to acrolein inhalation (nose-only; 0-4 ppm), 4 hours/day for 1 or 2 consecutive days (n=6/group) and the activity and abundance of key constituents of mitochondrial metabolic pathways as well as expression of key proteins controlling mitochondrial biogenesis and mitophagy were investigated. Acrolein, dose- and time-dependently, affected the activity of enzymes involved in metabolic pathways, increased mtDNA copy number and decreased protein and transcript abundance of several subunits of complexes involved in the electron transport chain. Furthermore, protein and mRNA levels of key regulators of mitochondrial biogenesis were decreased in rat lung following exposure to the highest dose of acrolein. Protein and mRNA expression of components of the mitophagy machinery were unaltered in response to acrolein exposure. Collectively, these results demonstrate that acute acrolein exposure disrupts the molecular regulation of mitochondrial metabolism in rat lung. *Does not reflect the US EPA policy.*

1184 An Inexpensive Open-Source *In Vitro* Exposure System for Uniform Sedimentation of Liquid Aerosols Generated by New and Emerging Tobacco Products

P. W. Clapp, C. T. Jadelis, K. L. Zeman, J. Wu, J. T. Minges, I. Jaspers, and W. D. Bennett. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Multi-well *in vitro* aerosol exposure systems are necessary for investigating the toxicity of new and emerging tobacco products (NETPs). Most commercially available exposure systems rely on impaction, stagnation flow, or electrostatic manipulation of diluted aerosol to achieve particle deposition at cell culture surfaces. However, reported particle sizes of NETP emissions suggest these methods may not produce adequate deposition for toxicity testing. To address this, we developed and validated an inexpensive gravimetric sedimentation exposure system for puff-actuated NETPs. Our NETP Aerosol Settling Chamber, which can be housed within a standard cell culture incubator, uses microcontroller-based automation to deliver aerosols to a small (16cm x 9cm x 7cm) chamber containing a single multi-well plate. To quantify particle deposition, fiberglass filters were placed into 6.5mm Transwells and filter weights were recorded before and after a JUUL e-cigarette vape session (40, 5-second, puffs and 9-minute inter-puff settling time). A direct comparison was made with a Vitrocell VC10 stagnation flow system using the same experiment design and JUUL vape protocol. Sedimentation of JUUL aerosols in our system resulted in uniform particle deposition of 253µg ± 9µg onto each of 24, 6.5mm Transwells. The Vitrocell VC10 achieved 36µg ± 21µg deposition; significantly less than the deposition achieved by sedimentation and with greater inter-well variability. Based on these data, we believe our exposure system may provide an effective and inexpensive means for *in vitro* toxicity testing of NETP aerosols. Our intent is to publish a digital blueprint of this system, assembly instructions, parts list, and software code in an open-source format. Ultimately, we hope that this novel NETP Aerosol Settling Chamber will provide an improved and affordable approach for testing the toxicity of tobacco smoke, aerosols, and specific constituents in NETPs.

1185 A Proposed Framework to Assess the Respiratory Sensitization Potential of Isocyanate-Based Prepolymers

S. Krieger[1], S. Arnold[1], A. Chappelle[2], M. Spence[2], B. West[2], W. Irwin[3], M. Phillips[3], and T. Stedeford[3]. *[1]Dow, Midland, MI; [2]International Isocyanate Institute, Boonton, NJ; and [3]US EPA, Washington, DC.*

The prediction of chemical respiratory sensitizers presents a challenge due to the lack of validated test guidelines and formally recognized *in vitro* or animal assays for this endpoint. Tiered weight of scientific evidence (WoE) approaches where skin sensitization data are evaluated as a first tier have been suggested and are routinely utilized. Using existing approaches, low molecular weight chemicals with a negative skin sensitization result are also considered negative for the potential to cause respiratory sensitization and further exploration of respiratory sensitization potential is considered only where positive skin sensitization results are observed or the substance is an isocyanate. Isocyanate-based polyurethane prepolymers, formed by combining an excess of diisocyanate (DII) monomer with polyol, exhibit properties (*i.e.*, higher molecular weight (MW) and viscosity, lower isocyanate content (%NCO) and vapor pressure) that decrease exposure relative to DII monomer. Local Lymph Node Assays (LLNA) conducted with low residual monomer toluene diisocyanate (TDI)-based prepolymers indicate that while lower MW prepolymers (950 and 1800 g/mole) exhibit evidence of sensitization potential (EC_3 0.11 and 7%, respectively), their potency is approximately 100-fold below that of TDI monomer (EC_3 ~0.02%) and a TDI-based prepolymer with a MW of 2950 g/mole was not interpreted to possess dermal sensitization potential based on comparison to mice treated with a similar concentration of residual TDI monomer. These results indicate that sensitizing activity is not solely related to %NCO and key physical and chemical parameters may influence sensitization potential. To evaluate the respiratory sensitization potential of isocyanate-based prepolymers, we propose a framework that is unique in its inclusion of further evaluation following a negative skin sensitization result in order to assess the potential for absorption in the lung. In our proposed framework, a negative skin sensitization result indicates that the prepolymer is neither a dermal sensitizer nor a respiratory sensitizer *via* the dermal route and triggers assessment of bioavailability, reactivity, biological/immunological WoE, and exposure to determine the potential risk. The proposed framework incorporates *in silico*, *in chemico* and *in vitro* methods and will facilitate an evaluation of the relationship between physical-chemical properties and respiratory sensitization potential.

1186 Toward the Replacement of Fetal Bovine Serum in Cell Culture Application: The Example of A549 Cells

A. Chary[1], S. Contal[1], C. Stoffels[1], A. J. Clippinger[2], and A. C. Gutleb[1]. *[1]Luxembourg Institute of Science and Technology, Esch-sur-alzette, Luxembourg; and [2]PETA International Science Consortium Ltd., London, United Kingdom.*

Foetal bovine serum (FBS), used as a supplement for cell culture media, presents significant scientific and animal-welfare concerns. The aim of this study is the complete replacement of animal derived components for cell culture application in the alveolar epithelial type II A549 cell line, which is commonly used in respiratory toxicology testing. A549 cells were transitioned to four different commercially available FBS free media: XerumFree™ XF212 (TNC BIO), HL-1™ (Lonza), X-VIVO™ 10 (Lonza), and CNT-PRA (CELLnTEC). After a successful transition into FBS free medium, different strategies were used to freeze cells (i.e. using 20% FBS + 10% DMSO, 10% DMSO only, DMSO + ProFreeze™ (Lonza), or CNT-CRYO-50 (CELLnTEC) freezing media). In parallel, TrypLE™ (Gibco) and TrypZean® (Lonza) were used as alternatives to trypsin to detached cells during cell maintenance. A549 cells did not survive the direct replacement of FBS; however, a gradual replacement (according to the suppliers' instructions) was successful for HL-1, X-VIVO 10 and CNT-PRA media. After several passages in FBS free conditions, A549 cells displayed different cell morphology depending on the media. Freezing cells in ProFreeze freezing medium showed results most similar to freezing the cells in FBS-containing media. The growth and functionality of the cells were compared between the alternative media and the control with 10% FBS. Following optimization of conditions, different strategies are possible for the replacement of animal derived components in the culture of A549 cells and that could be applied to many other cell lines. Use of chemically defined media represents a considerable advancement in cell culture that could overcome the reproducibility issues that result from different lots of FBS.

1187 A Model for Evaluating Synergistic Opioid-Induced Respiratory Depression

R. Borders, J. Shaffer, Y. Lu, K. Kearney, and B. Roche. *Charles River, Ashland, OH.*

Drug overdose is one of the leading cause of injury-related death in the United States with almost 68% of reported cases in 2017 involving a prescription or illicit opioid. Opioid overdose or combining opioids with other sedative medication causes respiratory depression leading to mortality. With the recent emergence of the opioid abuse crisis, it has become increasingly important to understand the potential interactive effects on respiratory parameters of new chemical entities (NCEs) that may be taken with opioids. For such assessments, positive and negative assay controls are useful to demonstrate proper evaluation. In this regard, respiratory function of male Sprague Dawley rats was assessed by plethysmography following administration of an intravenous (IV) morphine challenge (3 mg/kg) and/or oral baclofen (20 mg/kg). The conditions tested included oral vehicle (negative control), oral vehicle with IV saline (negative control), oral vehicle with IV morphine (positive control), oral baclofen alone (positive control), and oral baclofen concomitant with IV morphine (double positive control). In this model we demonstrate that administering morphine together with baclofen resulted in synergistic decreases in respiratory frequency (RF) and substantial decreases in minute volume (V) of 66% and 62% from baseline, compared to administering morphine (RF:17%; V:55%) or baclofen (RF: 38%; V: 48%) independently. Hence, baclofen with a morphine challenge model can be effectively used as a comparator to assess potential interactive effects of NCEs with opioids.

1188 Development of a Thermal Spray Coating Generator and Exposure System for Toxicology Studies

A. Afshari, E. G. Lee, W. G. McKinney, and J. M. Antonini. *NIOSH, Morgantown, WV.*

Thermal spray coating is a surface treatment process that enables different types of materials to be deposited on various substrates- metal, metal alloys, ceramics, and plastics. The process involves spraying a metal coating product which is melted by high temperatures and then sprayed under pressure onto a surface. Applications for thermal spray processes have a broad range across all industrial sectors. This technique is widely used in repairing bridges, water towers, wind turbines, pipelines, and ship tankers as well as in the automobile and aircrafts industries. During the process, large quantities of aerosols composed of fine and ultrafine metal particles are generated. Little is known about the physical (e.g., particle size and morphology) and chemical (e.g., metal composition, solubility, surface chemistry, metallurgy) properties of the particles formed during the process. The goals of this research were to construct a thermal spray coating generator and exposure system for toxicology studies and to characterize the properties of the formed aerosols during different spray coating processes in a laboratory setting. Initial studies have evaluated twin-wire arc thermal spray coating using P-MET 730 stainless steel consumable wire. In twin-wire arc thermal spraying coating, two consumable metal wires are fed independently into the spray gun. The wires are charged, forming an arc between them. The heat from the arc melts the wires generating metal particles which are entrained in an air jet from a spray gun. The entrained molten metal is then deposited onto a rotary substrate via compressed air. Count median electric mobility diameter was measured to be 196 nm with a geometric standard deviation of 1.5, using a scanning mobility particle sizer (SMPS). Importantly, a significant portion of the primary particles were observed via scanning electron microscopy (SEM) to be in the ultrafine size range with diameters <100 nm. The particles were primarily composed of iron, chromium, nickel, and manganese. With the development of this system, it is possible to investigate the pulmonary and systemic health effects associated with the inhalation of aerosols generated from different thermal spray coating processes in an animal model.

1189 Effect of Polyhexamethylene Guanidine Phosphate on Epithelial Barrier Function in Human Bronchial Epithelial Cells

S. Jin, G. Lee, and H. Jeong. *Chungnam National University, Daejeon, Korea, Republic of.*

Polyhexamethylene guanidine phosphate (PHMG-p) has been used as a disinfectant and biocide, and was reported to involve in lung diseases, such as pulmonary fibrosis. However, the effect of PHMG-p on the barrier function of the bronchial epithelium is unknown yet. Tight junctions (TJs), which comprise the interacting proteins, such as occludin, zona occludens-1 and claudins maintain epithelial barrier function. The damage of TJ is the major cause of epithelial barrier breakdown during lung inflammation. In this study, we investigated whether PHMG-p modulates the protein expression of TJ in human bronchial epithelial BEAS-2B cells. PHMG-p decreased the TJs and the other proteins including E-cadherin and β-catenin, which also maintain in barrier function in the epithelium. In addition, PHMG-p impaired the cellular F-actin architectures, involved in the maintenance of TJ structure and barrier function. Furthermore, PHMG-p increased the active calpain1, calcium-dependent protease, which is known to breakdown TJs. In addition, PHMG-p increased in the intracellular calcium levels via extracellular space. Interestingly, addition of calpain1 inhibitor, ALLN, and removal of calcium source in extracellular space significantly reversed the impairment of TJs and F-actin architectures induced by PHMG-p. These results suggest that epithelial barrier dysfunction is one of the symptoms to lead pulmonary diseases by PHMG-p via calpain1 activation.

1190 Early De-Risking Approaches for Identification of Anti-Fibrotics for Idiopathic Pulmonary Fibrosis (IPF) Treatment

M. Wagstaff[1], A. Young[2], C. Roper[3], M. McElroy[3], J. Aarbiou[4], and A. Zuurmond[4]. *[1]Charles River, Wilmington, MA; [2]Charles River, Saffron Walden, United Kingdom; [3]Charles River, Edinburgh, United Kingdom; and [4]Charles River, Leiden, Netherlands.* Sponsor: S. Bulera

Idiopathic Pulmonary Fibrosis (IPF) is a chronic progressing lung disease with a progressive and irreversible decline in lung function. It has a poor prognosis (3-5 yr survival from diagnosis) and increasing global prevalence (20 people per 100,000 population). To date, only Nintedanib (NINT) and Pirfenidone have been licensed to treat IPF, therefore there is increased effort to discover new therapies. NINT, a tyrosine kinase inhibitor was profiled in a fibroblast to myofibroblast human IPF lung assay to determine both efficacy and cytotoxicity using high content imaging. Myofibroblast formation is strongly associated with fibrotic lesions. NINT inhibited the generation of α smooth muscle actin formation (a marker of the transition to a myofibroblast phenotype) at doses of 30 nM and above, with an IC50 of 370 nM. Cytotoxicity (measured as changes in nuclei number, >50% reduction) was observed at >10 uM concentrations. In a bleomycin-induced lung fibrosis rat model, NINT dosed orally at 60 mg/kg BID inhibited lung fibrosis at lung concentrations of ca 100 nM (Median Modified Ashcroft Score reduced from 3 to 2, P<0.001, and hydroxyproline (collagen) levels in the lung were reduced by 30%, P<0.001). At these exposures mild side effects were observed, including reduced food consumption, lessened activity and body weight loss. These effects increased in severity with increasing dose and were seen in mouse as well as rat models. Hence, it may be possible to link early *in vitro* assessments of efficacy and cytotoxicity with *in vivo* pharmacokinetics and exposure estimates to help optimize the testing of compounds *in vivo* and de-risk compounds.

1191 The Role of Matrix Metalloproteinases in Multiwalled Carbon Nanotube (MWCNT)-Induced Inflammation in C57BL/6 Mice

T. L. Young[1], G. Herbert[1], S. Lucas[1], A. K. Ottens[2], A. D. Erdely[3], T. Wang[4], and M. J. Campen[1]. *[1]University of New Mexico, Albuquerque, NM; [2]Virginia Commonwealth University, Richmond, VA; [3]NIOSH, Morgantown, WV; and [4]University of Arizona, Phoenix, AZ.*

Matrix metalloproteinases (MMPs) are ubiquitously expressed extracellular matrix (ECM) proteases that are activated in inflammation and injury and play varied roles in cellular homeostasis, adaptation, tissue remodeling and immunity. We previously demonstrated that acute MWCNT exposure led to impaired vascular reactivity that was dependent on MMP-9 activation and CD36 signaling. We hypothesized that MWCNT inhalation exposure alters broad spectrum MMP activity, leading to serum-borne factors that enhance vascular permeability and activate inflammatory pathways. To test this hypothesis, male C57BL/6 mice (6-8 weeks) were given 10 mg/kg of the broad-spectrum MMP inhibitor, Marimastat, and then dosed with 0 (dispersion media; DM), 10 or 40 µg MWCNT via oropharyngeal aspiration 1 hour after Marimastat dosing. Pulmonary inflammation was evaluated 24 hrs following MWCNT exposure, in terms of cell and protein quantification of bronchoalveolar lavage fluid (BALF). Serum bioactivity was determined in mouse brain endothelial cells (MBEC) via serum cumulative inflammatory potential (SCIP) assay. Vascular integrity was evaluated via electric cell-substrate impedance sensing (ECIS) assay, and confocal assessment of intracellular gap formation. Neutrophil infiltration and total BALF protein significantly increased in 40 µg-dosed mice (n=6/group; p<0.01) and was not altered by MMP blockade. MBECs treated with serum from MWCNT-treated mice exhibited a ~75% reduction in barrier integrity compared to DM controls. A ~50% of DM recovery in barrier integrity was observed with MMP blockade. Additionally, MMP blockade diminished

MWCNT serum-enhanced thrombin-mediated loss of barrier integrity and enhanced sphingosine 1-phosphate-induced barrier stability in MBEC. Actin immunostaining of MBEC confirmed that MWCNT serum exposure disrupted cell-cell junctions in a MMP-dependent manner. A thrombospondin type-1 domain-containing peptide reduced regrowth of MBECs in a dose-dependent manner ($p<0.0001$). Thus, while MMP blockade did not alter lung inflammation resulting from MWCNT exposure, subsequent pathologic serum bioactivity arising from MWCNT treatment was dependent on pulmonary MMP activity.

1192 Use of Cell Media Nicotine Concentration as a Marker to Predict Cell Surface Deposited Nicotine in Transwells after Fresh Smoke/ Aerosol Exposure

R. Wieczorek[1], E. Trelles Sticken[1], L. M. Bode[1], and L. Simms[2].
[1]IB-Reemtsma, Hamburg, Germany; and [2]Imperial Brands, Bristol, United Kingdom.

Exposure of organotypic 3D lung models at the air liquid interface (ALI) to fresh whole smoke/aerosol provides a more human relevant exposure assessment of combustible cigarettes and e-vapour products. The aim of this study is to present a method for determination of nicotine deposition at the 3D MucilAir™ tissue surface, in transwells of 24 MWP after repeated exposure to 30, 60 or 90 puffs of tobacco cigarette (3R4F, 1:17 dilution) or undiluted *my*blu™ e-vapour aerosol over 4 weeks. Exact measurement of nicotine deposited at the cell surface is difficult due to absorption of nicotine in to the cells. The nicotine serves as a general marker of exposure. We wanted to determine if cell media nicotine concentration was correlated with cell surface deposition. To measure this, the deposition efficiency onto a glass plate inserted directly into the transwell was determined and was compared to glass discs with cells grown on the surface (BEAS-2B, V79). During the four weeks of repeated exposure of MucilAir™ tissues at ALI to 3R4F smoke and *my*blu™ aerosol, basal culture media were collected for nicotine quantification. Additionally nicotine deposition on to glass discs representing the cell surface area was measured. Toxicological effects observed over the exposure time in comparison to the puff numbers were compared on nicotine basis. With regard to increasing puff numbers, dilution factors, and the surface area of glass plates nicotine deposition on glass discs in the transwells correlated well with the deposited nicotine in the cell media (measured using LC MS/MS). However the correlation coefficients obtained with the different products regarding nicotine deposition and nicotine concentration in the cell media deviated from each other due to the different physical characteristics of 3R4F smoke and myblu™ aerosol.

1193 DNA Damage from Regional Metal-Enriched Particulate Matter in a549 Lung Epithelial Cells

R. P. Hunter, A. Bolt, A. Brearley, J. Cerrato, C. Velasco, J. Weaver, D. McChesney, P. Muttil, G. Herbert, M. Campen, and K. Zychowski.
University of New Mexico, Albuquerque, NM.

Inhalation of particulate matter (PM) promotes the development of pulmonary diseases and cancer. Exposure to heavy metal-containing PM induces genotoxicity as mediated through the initiation of an inflammatory and oxidative response. However, the initial biochemical and physical interaction between PM and pulmonary epithelial cells that drives DNA damage is incompletely understood. This study therefore sought to develop an *in vitro* model to examine the genotoxic effect of PM on lung epithelial cells. PM was derived from 1) sediments from the Jackpile and St. Anthony uranium mines in NM; 2) from a church attic in Paguate, NM; and 3) tungsten carbide PM. All samples were resuspended in air and collected in a next-generation cascade impactor to ensure PM was respirable. Cells were labeled with a viability stain and a monoclonal antibody specific to the pH2AX histone variant, then imaged through the Cellinsight High-Content-Screening platform. H2AX fluorescence appeared greater in cells exposed to PM from the Jackpile mine, and dusts from the nearby church sample. Findings suggest that physical/chemical interaction with PM produce genotoxic effects on lung endothelium in the absence of inflammation. Further research is needed to elucidate underlying cellular mechanisms and putative physicochemical drivers of PM-induced genotoxicity.

1194 Effect of PHMG-p on Increasing of TRAIL-Related Death Receptors in Human Bronchial Epithelial Cells and Animal Model

H. Jeong[1], J. Choi[1], S. Jin[1], M. Song[2], and K. Lee[2]. *[1]Chungnam National University, Daejeon, Korea, Republic of; and [2]Korea Institute of Toxicology, Jeonbuk, Korea, Republic of.*

PHMG-p was used as the main component of the humidifier disinfectant to clean the humidifier and eliminate the growth of microorganisms. Epidemiological and toxicological studies have indicated that PHMG-p induces pulmonary inflammation and fibrosis caused by PHMG-p inhalation, but the toxicological mechanism of PHMG-p is still unknown. This study investigated whether PHMG-p-mediated upregulation of TNF-related apoptosis-inducing ligands (TRAIL) death receptors was associated with increased cell death. PHMG-p enhanced TRAIL-associated apoptosis, which correlated with upregulation of both TRAIL and TRAIL death receptor (DR) 4/5 expression through the induction of CHOP. PHMG-p enhanced the apoptosis-associated with extrinsic target protein (Fas and FADD) and intrinsic target protein (caspase-3, capase-8, and PARP). Also, PHMG-p promoted the pro-apoptotic (Bax) and reduced the anti-apoptotic (Bcl-2 and Bcl-xL) protein expression via upregulation of DNA damage associated proteins (H2AX and p53). Finally, PHMG-p increased Bid-activated cytochrome c release. Furthermore, the same symptoms as cells were seen in the PHMG-p-inhaled animal model. PHMG-p enhanced the apoptosis-associated with extrinsic and intrinsic protein target in mice. These results demonstrated the view that PHMG-p induces TRAIL-associated the cell death via the assembly of a death-induced signal complex (DISC) by TARIL-mediated DR4/5, FADD and caspase-8 activation in the early stages.

1195 The SILIFE Project: Production, Toxicity Screening, and Industrial Application of Quartz Species with Reduced Lung Toxicity

C. Ziemann[1], E. Monfort[2], M. J. Ibáñez[2], A. López Lilao[2], G. Bonvicini[3], and O. Creutzenberg[1]. *[1]Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; [2]Instituto de Tecnología Cerámica, Universitat Jaume I, Castellón, Spain; and [3]Centro Ceramico di Bologna, Bologna, Italy.* Sponsor: C. Dasenbrock

In 1997 the IARC classified respirable crystalline silicas (RCS) as human carcinogens (category 1), strongly affecting work places in silica-dependent industries. IARC acknowledged differences among RCS species, based on source, chemical, thermal and mechanical history. As abundance, density and heterogeneity of surface silanol groups/radicals seem to be involved in RCS-mediated lung toxicity, adverse RCS lung effects might be reduced by coatings, covalently blocking these groups. Persistent problems with silicosis and the diversity of quartz applications stimulated issuance of the EU-project SILIFE, aiming at developing a dry surface-coating technology to abate RCS toxicity on industrial scale. The development process included choice of feasible, cost-effective coating additives (i.e. organosilanes and catalysts), definition of treatment parameters (technology, reaction time, dosage, application), proof of coating effectiveness and toxicity-reducing functionality by physico-chemical (e.g. ζ potential) and predictive *in vitro* and *in vivo* toxicity tests, with final implementation of coated RCS into industrial processes. Primary rat alveolar macrophages (4 h of incubation, 75 µg/cm^2 of pristine/coated quartzes) served as sensitive *in vitro* toxicity screening model with membrane (LDH-release) and DNA damage (Comet assay) as relevant endpoints. The very promising *in vitro* results were validated in a 28-/90-days intratracheal instillation study in male Wistar rats (pristine v. coated industrial quartz species; 2 mg/lung; positive control: quartz DQ12, 1 mg/lung). In bronchoalveolar lavage fluid both latency and variable, quartz species-dependent adverse reactivity of three industrial quartz samples was noted, using classical inflammatory parameters (differential cell count, LDH, ß-glucuronidase, total protein) and pro-inflammatory mediators (CINC-1, TXB_2) as meaningful readouts. But, more importantly, the study clearly demonstrated that some covalent RCS-coatings were indeed able to effectively block RCS lung toxicity in the rat for up to 90 days, without markedly compromising the technical process quality. Thus, covalent surface-coating of biologically reactive RCS species represents a promising strategy to render RCS handling safer. *Funding: LIFE 2014: project no. LIFE14 ENV/ES/00238.*

1196 Responses of Human Monocyte-Derived Macrophages and Differentiated THP-1 Cells Exposed to Silica Particles

J. Lichter, K. Hertz, M. S. Schellenberger, A. Buth, K. Kotulski, U. Bock, and B. Blömeke. *Universität Trier, Trier, Germany.*

Macrophages, as professional phagocytes, represent a crucial cell component that surveys against injury and immune responses. *In vivo* they act as first line of defense and are involved in removal and clearance of (nano)particles but also their toxic effects e.g., by triggering reactive oxygen species production and inflammation. Here we evaluated the responses of human monocyte-derived macrophages (MDM) exposed to silica particles (DQ12, 2.1 µm) and compared with responses of the human cell line THP-1, which were differentiated into adherent macrophage-like cells (THP-1M) by phorbol-12-myristate-13-acetate (PMA). As endpoints we measured cellular ATP content, amounts of lactate dehydrogenase (LDH), tumor necrosis factor alpha (TNF-α), interleukin (IL-) -1α, IL-1β, and IL-8 in cell culture supernatants. MDM (12 donors) generated from blood monocytes by addition of granulocyte-macrophage colony-stimulating factor were exposed (24h) to increasing amounts of DQ12 (10-160 µg/cm^2) and separately to lipopolysaccharide (LPS, from *E. coli* strain O55:B5) as positive control using exposure media with or without 10% fetal calf serum (FCS). ATP contents decreased (paralleled by increased LDH) with increasing particles amounts, namely at 40 µg/cm^2 to 50%, 25% after addition 80 µg/cm^2, and 2% in the presence of 160 µg/cm^2. Amounts of TNF-α reached 500 pg/mL TNF-α (range 2-15 fold of control) in both culture media after treatment with 80 µg/cm^2 DQ12. For comparison, LPS (0.3 to 3,000 EU/mL) increased TNF-α up to 20 ng/mL using medium with FCS. Increased amounts of IL-1α (up to 108 pg/mL, range 13-37 fold of control) were found after treatment with DQ12. In contrast, increased IL-1β amounts were only detected when cells were using FCS containing medium (up to 180 pg/mL, 2-9 fold), while IL-8 levels were not enhanced. THP-1M were exposed directly after their generation (without resting) and after 2 days of cultivation in PMA-free medium (with resting). DQ12 did not result in enhanced TNF-α amounts, while IL-1α was comparable with responses of MDM. Amounts of IL-1β in supernatants of THP-1M without resting were comparable to MDM, but were reduced after resting. Exposing THP-1M to high amounts of LPS found significant lower amounts of TNF-α compared to MDM, with THP-1M without resting being more comparable to MDM. Comparing responses to the model particle DQ12 and separately LPS, we conclude that THP-1M without resting may be a suitable model for studying macrophage functions and IL-1 α/ß responses. However, it is also necessary to point out that they have rather limited capacities to release TNF-α.

1197 Alternative Testing of Inhalable Aerosols: A Complementary *In Vitro/Ex Vivo* Model for Acute Inhalation Toxicity

D. Ritter, T. Hansen, J. Knebel, S. Wilde, and K. Schwarz. *Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany.*
Sponsor: A. Bitsch

An *in vitro* model consisting of a human alveolar lung cell line (A549) in an air-lifted interface (ALI) culture situation and exposure using the P.R.I.T. ExpoCube device was combined in an experimental strategy with an *ex vivo* model consisting of an isolated perfused lung model (IPL) from the rat to achieve a testing strategy using only low amounts of testing materials (< 1 g), short testing periods and a high relevance of results as documented by correlation to literature data from acute inhalation toxicity *in vivo* animal testing. Test items for model validation included 5 commercial crop substances (Chlorothalonil, Captan, Mancozeb, Fosetyl-AL, Ethiprol) and two additional control items (sodium dodecyl sulfate (SDS) and n-dodecane). Test items were applied in a short-term / high concentration exposure design in both models. Acute inhalation toxicity was estimated from effects on cellular viability (*in vitro*) and on tidal volume and lung weight (*ex vivo*). Moreover, effects on the breathing mechanics could be explored using the *ex vivo* IPL approach. Dosimetry considerations were carried out on the basis of the specific particle deposition characteristics of the ExpoCube expose device (*in vitro*) respectively the multiple-path particle dosimetry model (MPPD, *ex vivo*) to estimate surface loads *in vitro* (µg/cm^2) or lung loads (µg/lung) *ex vivo*. Comparison to *in vivo* literature data indicated highly correlated estimations of the acute toxicity *in vitro* in a nearly quantitative way without interference by test item solubilities also including the range of surface-load values *in vitro* and *in vivo* in the range of 1 to 100 µg/cm^2. *Ex vivo* results clearly enabled detection of harmful substances and, moreover, also enabled detection of test items exhibiting adverse effects on the mechanical breathing behavior, possibly by affecting the surfactant system of the lung (Fosetyl-AL, SDS, dodecane). In conclusion, it is proposed to apply the test system in a tiered approach (*in vitro*/*ex vivo*/*in vivo*) to achieve a relevant acute inhalation toxicity testing using only small amount of test substances and short testing periods in the sense of the "3R-principle" for replacing, refinement and reduction of animal experimentation.

1198 A Novel *In Vitro* Model to Assess Inhalation Toxicokinetics in a Multi-Organ Plate

J. A. Willoughby Sr., M. Helmus, N. Hibbard, and J. M. McKim. *IONTOX, Kalamazoo, MI.*

Aerosol generators have been used for years to assess respiratory toxicity of chemicals and nanoparticles *in vitro*. They allow for an *in vivo* like delivery of material to the lung tissue. Here we present the first characterization of an aerosol generator linked to a multi-organ platform (HuDMOP™) in order to model the systemic toxicokinetics of an inhaled material. The HuDMOP™ system is an integrated meso-scale, multiple organ *in vitro* system with simulated blood flow capable of modeling human systemic toxicity. Nicotine, was used for the characterization of this aerosol-to-multi-organ platform. First, wells containing only media were dosed with aerosolized nicotine either once (487 µg dose), or in a repeated dose format (three or six doses for 1460 µg and 2920 µg total dose, respectively) with each dose a minute apart. Media was sampled and analyzed by LC/MS to determine concentration of nicotine in the media and allow for percent (%) recovery calculations. The % recovery in the media was ~6.4% for all three exposure regimens. This was repeated with the aerosol generator closer to the media, which resulted in less recovery (~4.2%), suggesting the greater distance (4.3 cm) was optimal for maximal exposure. Finally, MucilAir™ tissues were linked to HepG2 cells in the HuDMOP™ system, creating a human lung-to-liver two organ system. The aerosol generator was connected and the MucilAir™ tissues were exposed to a single 487 µg dose of nicotine. The basolateral lung media, simulated blood, and liver media were sampled 1, 2, 3 and 6 hr after exposure, and analyzed by LC/MS. In addition, a blank (no lung tissue or liver cells) was run in order to assess the kinetics of nicotine without metabolism. In the presence of tissues/cells, nicotine peaked at 1 hr post-exposure (2157 ng/mL) in the basolateral lung compartment, then came to equilibrium at ~1100 ng/mL. In the liver compartment, nicotine increased slowly during the course of the 6 hr exposure, to a maximum of 63 ng/mL at 6 hr. In the simulated blood nicotine increased rapidly over the first 1 hr (169 ng/mL), after which the rate of increase slowed with a maximum accumulated concentration of 218 ng/mL at 3 hr. After 3 hr nicotine in the simulated blood decreased to 163 ng/mL at 6 hr. The kinetics of nicotine distribution were similar in the absence of cells, however, the overall levels of nicotine were higher, likely due to lack of metabolism. These results suggest that HuDMOP™ system linked to an aerosol generator can model systemic toxicokinetics of inhaled materials *in vitro*.

1199 Next Generation Risk Assessment Approach for Inhalation Exposures: Polymer Case Studies

I. Muller[1], H. Behrsing[2], A. Bowden[1], S. Cable[1], S. Constant[3], M. Theiventhran[1], J. Wallace[4], S. Windebank[1], and M. Baltazar[1]. *[1]Unilever, Sharnbrook, United Kingdom; [2]Institute for In Vitro Sciences Inc., Gaithersburg, MD; [3]Epithelix, Geneva, Switzerland; and [4]Charles River, Edinburgh, United Kingdom.*

Next Generation Risk Assessment (NGRA) is an exposure-led, hypothesis-driven approach that integrates new approach methodologies (NAMs) to assure human safety without animal data. We are currently evaluating a NGRA approach for inhalation exposures using hypothetical case studies of a film-forming polymer in personal care products (e.g. antiperspirants) and a silane in cleaning products. Impairment of mucociliary clearance, lung fibrosis and lung surfactant inhibition were identified as the relevant endpoints for the most common consumer exposure scenarios (e.g. daily use of an antiperspirant). To investigate these endpoints, two cell models were selected for *in vitro* testing: the MucilAir™-HF cell model (Epithelix) a system which shows ciliated as well as mucous producing cells typical for the bronchial region and the EpiAlveolar™ cell model (MatTek) a coculture system out of AT1 and AT2 (surfactant producing) cells, fibroblasts and THP1 cell representing the most common cells of the alveolar tract. In addition to the two case study chemicals another 16 benchmark substances were selected either due to their well-known effects in the specific areas of the lung, history of safe use and/or due to chemical or physical similarities to the case study chemicals. Linking the *in vitro* point of departures to the relevant *in vivo* consumer exposure level is essential to evaluate the usefulness of the *in vitro* test systems. Therefore, consumer habits and practises were used to derive an airborne concentration (mg/m^3) for each chemical and exposure scenario, which was then transformed into deposited mass in the bronchial and alveolar region (µg/cm^2) using MPPDv2.8. Cells were exposed daily for up to 12 days *in vitro* and different endpoints measured every other day. Preliminary results indi-

cate that the alveolar model was more sensitive to some of the pro-inflammatory benchmark substances tested. Polyhexamethylene guanidine phosphate for example induces a mild inflammatory response in the MucilAir™-HF system over the 12 days' treatment while inducing significant cytotoxicity in the EpiAlveolar™ cell model after only 4 days of exposure. Results on mucocilliary clearance are inconclusive since Benzalkonium chloride showed no significant effects.

1200 Prevention of Naphthalene Toxicity by Ergothioneine in Mice

V. J. Brown[1], L. Ding[2], L. Yin[2], P. Edwards[1], X. Ding[2], and L. Van Winkle[1].
[1]University of California Davis, Davis, CA; and [2]University of Arizona, Tucson, AZ.

Naphthalene (NA), the simplest polycyclic aromatic hydrocarbon (PAH), is commonly found in mothballs, vehicle exhaust, wildfire and cigarette smoke. The effects of NA are site- and species-specific, with well-defined, dose-dependent Club cell toxicity in the mouse conducting airway epithelium, regardless of exposure route. Despite widespread exposure, few studies have examined efficacies of putative chemoprotective agents to limit the toxic effects of NA. Ergothioneine (ET), a thiol-thione found in mushrooms, has been reported to function as a cytoprotectant against oxidative stress in several systems. A specific ET transporter, known as the organic cation transporter novel type-1 (OCTN1) and encoded by the gene Slc22a4, has been identified as the main regulator for the uptake of cellular ET. This study aims to test the cytoprotective ability of dietary ET in the adult mouse lungs following NA exposure. C57BL/6J adult (2-3 months old) mice were exposed to an ET-free diet throughout the gestation and postnatal periods. They were then treated with an oral dosage of 70 mg/kg of ET, or saline, daily for 5 days. At 2-3 days following the ET treatment, the mice were given a single dose of NA (150 mg/kg) in corn oil, or corn oil alone, i.p. At 24 hours post NA injection, the lungs were processed for immunohistochemistry, high resolution histology, gene expression analysis, and metabolite analysis. The levels of ET were compared between saline (vehicle)- and ET-treated mice on the ET-free diet, to ascertain ET-treatment associated increases in circulating and lung tissue ET levels. Histology analysis at 24 hours post-NA treatment showed that ET-treated male mice were partially protected from NA-induced Club cell toxicity, compared to saline- and NA-treated mice. Levels of reduced glutathione (GSH) in the lung and liver at 24 hours post NA treatment were greater in ET-pretreated mice than in saline-pretreated mice, a result supporting the protective function of ET against NA-induced oxidant stress in the lungs. Additionally, gene expression of Slc22a4 in the lung was greater in ET-treated mice exposed to NA than in those exposed to corn oil. Furthermore, immunohistochemical analysis showed an apparent increase in OCTN1 immunoreactivity in the large airways and terminal bronchioles of NA-treated mice, compared to corn oil-treated mice, which may serve to facilitate cellular uptake of ET upon exposure to NA. *Supported in part by NIH grant ES020867 and T32 ES007059.*

1201 Physiochemical Characterization and Toxicological Assessment of Regional Particulates Adjacent Abandoned Uranium Mines within Native American Communities

J. Begay[1], Y. Ordonez[1], S. Lucas[1], B. Sanchez[1], A. Wheeler[1], F. Baldwin, Jr.[1], G. Herbert[1], C. Shuey[1], J. Harkema[2], J. Wagner[2], M. Morishita[3], B. Bleske[1], K. Zychowski[1], and M. Campen[1]. *[1]University of New Mexico, Albuquerque, NM; [2]Michigan State University, East Lansing, MI; and [3]University of Michigan, Ann Arbor, MI.*

Particulate matter (PM) inhalation has adverse effects on the respiratory and cardiovascular systems. In sediments of abandoned uranium mines (AUMs), we found PM sized less than 2.5µm (small enough to enter the deep lung), in Northern Arizona (Claim 28) and Western New Mexico. Here, we determine the amount of the metal-rich PM in the ambient air at these locations, as well as the prevailing wind speed/direction with respect to surrounding communities, and immunological and physiological responses of mice after concentrated PM exposures. This will be the foundation to determine the relative toxicity of the ambient PM and its potential long-term health impacts. C57BL/6 and ApoE-deficient ($ApoE^{-/-}$; a vascular inflammation model) mice were exposed to concentrated ambient PM in a mobile laboratory located approximately 1 km southwest from the AUM, for 1 or 28 days for 4 hours/day to approximately 80 µg/m^3 PM. Lungs and aortas were collected for mRNA markers of inflammatory disease, followed by qPCR to gauge the possible inflammatory responses with inflammatory-specific probes. Bronchoalveolar lavage (BAL) was conducted to examine influx of macrophages and neutrophils into the lungs. Inflammatory response was also confirmed by mesoscale data analysis. No changes in BAL cellularity were noted and other indices of toxicity were modest. 1-day exposure qPCR showed increase in lung TNF-alpha and TGF-beta transcript levels in the PM group compared to filtered air (FA) mice. 28-day PM-exposed mice showed reduced CXCL1, TNF-alpha, and TGF-beta mRNA levels compared to FA mice. ICP-MS metals analysis of $PM_{2.5}$ in these exposures revealed a pattern of metallic species consistent with a crustal background (ie, no overt contamination from the mine sites). Wind stations placed above the mobile laboratory and mine sites showed a general wind direction from the southwest to northeast, which is generally away from the community near Claim 28. Currents effects seen are consistent with previous work of pulmonary inflammation related to PM exposure. Completion of exposures at contrasting mine sites give insight on the toxic potency of mine site-derived dusts and its prevalence in tribal communities.

1202 Accurate Identification of Estrogen Receptor in Mesothelioma Cell Lines Using High-Resolution Mass Spectrometry

G. Zhang, S. Wang, L. Weng, C. Mesaros, I. A. Blair, and T. M. Penning.
University of Pennsylvania, Philadelphia, PA.

Asbestos is a carcinogen that causes mesothelioma a rare cancer that arises from the mesothelial lining of the pleura. Malignant pleural mesothelioma is an aggressive tumor that is resistant to conventional treatment including chemotherapy, surgery or radiation. Epidemiological observations show that for non-occupational exposure the incidence of mesothelioma is higher in women than men. However, women diagnosed with malignant pleural mesothelioma respond better to treatment and have a better prognosis than men. A recent study revealed that activation of estrogen receptor (ER)β decreased the growth of malignant mesothelioma (REN) cell xenografts. In contrary to this finding, our qPCR showed that three different malignant mesothelioma cell lines (MSTO-211H, REN, and IST) expressed ERα and ERβ at very low levels and this was supported by immunoblot analysis. However, the validity of ERα and ERβ antibodies has been an issue of concern. Herein, we developed an immunoprecipitation in gel-digestion liquid chromatography tandem mass spectrometric (IP-LC/MS/MS) proteomics method to detect ERα and ERβ in MCF-7 cells, and mesothelioma cell lysates. The presence of ER proteins was verified using accurate mass detection of tryptic peptides and MS/MS fragmentation patterns using a mass spectral library search in Skylines. Using this method, we successfully identified ERα and ERβ in HEK293 transfection cell lines. In MCF-7 cells we only detected ERα. However, there were no ERα or ERβ peptide fragments detected in mesothelioma cell lines. This finding indicated mesothelioma cell growth is not mediated by expression of ERα and ERβ. In the future, we aim to measure the expression of GPR30, a membrane-bound estrogen receptor protein, in malignant mesothelioma cells with our IP-based LC-MS/MS proteomics method. *Supported by P30-ES013508 from NIEHS.*

1203 Toxicological Effects of Soot Nanoparticles on the BALF of Alzheimer's Disease Model Mice

P. A. Vartiainen, L. Saveleva, M. Kortelainen, I. Belaia, S. Chew, H. Konttinen, V. Sitnikova, H. Hakkarainen, T. Ihantola, M. Martikainen, K. Kanninen, and P. Jalava. *University of Eastern Finland, Kuopio, Finland.*
Sponsor: M. Viluksela

Black carbon is a nanoscale anthropogenic air pollutant and is usually present in the form of soot that is formed in incomplete combustion processes. In addition to climate forcing effects, sooty aerosol is associated with exacerbation of several diseases, such as cardiovascular diseases, respiratory diseases, and neurodegenerative diseases like Alzheimer's disease (AD). The purpose of this study was to study adverse effects of nanoscale particulate matter in AD mice. In this study, we exposed 30 to 33 weeks old female transgenic (TG) 5xFAD mice and their wild-type (WT) female litter mates (n=12) to cast burner generated soot aerosol (GS) (32 nm mean diameter) or to clean air as a control. In this part of the study, we investigated the effects of particle exposure in the lungs, since the route of effects seen in the brain is unclear. With later analyses in the brain and other organs, including behavioral tests, we will have an overview of which exposure routes and biological mechanisms are the most important for brain health in aerosol exposure. From collected bronchoalveolar lavage fluid (BALF), total cell count, cell differential count, comet assay, and cytokine analysis (IFNγ, IL-10, IL-12p70, IL-1b, IL-2, IL-4, IL-5, IL-6, TNFα, and KC) were made. In addition to BALF, brains, intestine, and liver were collected and extensive analysis were made (not shown here). Genotoxicity in BALF cells shows slight variation between GS and clean air. In BALF cytokine concentrations (IFNγ, IL-10, IL-12p70, IL-1b, IL-2, IL-4, IL-5, IL-6, TNFα, and KC) some differences between exposure groups were seen. Engulfed soot agglomerates inside BALF macrophages were seen in GS group, which is an indicator for successful exposure.

1204 The Role of Long Non-Coding RNA, MALAT1, in Regulation of Oxidative Stress and Inflammation in a Mouse Model of Infant Respiratory Syncytial Virus Infection

R. A. Shore. *Texas A&M University, College Station, TX.*

Human respiratory syncytial virus (hRSV) is a mucosal pathogen that affects virtually all infants by the age of 2 years and is responsible for 99% of childhood deaths that occur in developing countries. The global burden of hRSV in 2015 was estimated that 33.1 million children were infected, 3.2 million were admitted to hospitals, and 60,000 (<5 years) succumbed to illness. Currently, treatments for hRSV are limited and no vaccine is available, thus a greater understanding of hRSV pathogenesis is needed to target novel pathways to alleviate infection-associated sequelae. The long non-coding RNA metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) has recently been suggested to act as a negative modulator of the Nrf2 transcription factor. MALAT1-defecient mice show significant upregulation of Nrf2-regulated antioxidant genes. Since the Nrf2 antioxidant response is critical to suppressing RSV pathogenesis, we sought to elucidate the role of MALAT1 in RSV infection using our neonatal mouse model that mimics infant infection. Five-day-old pups with *Malat1*$^{+/+}$, *Malat1*$^{+/-}$, or *Malat1*$^{-/-}$ backgrounds were infected with a chimeric RSV strain (rA2-19F). At 3 days post-infection pups were euthanized, and lungs were harvested in order to quantify pulmonary viral load. Pups were also sacrificed 9 days post-infection to characterize bronchoalveolar lavage fluid (BALF) cellularity and cytokine levels, lung and nasal epithelium histopathology, and pulmonary T cell profiles. Furthermore, there was no difference in total nucleated cell count collected from BALF, or body weights between groups. Work is ongoing to characterize the pathophysiological parameters post-infection.

1205 Endotoxin-Induced Mucous Cell Metaplasia in Mouse Pulmonary Airways Is Dependent on Innate Lymphoid Cells

J. G. Wagner, L. Heine, S. Shareef, A. Tindle, R. P. Lewandowski, and J. R. Harkema. *Michigan State University, East Lansing, MI.*

Inhalation exposure to gaseous and particulate environmental pollutants, including bacterial endotoxin (lipopolysaccharide; LPS), can cause an overproduction and hypersecretion of mucus that contributes to the severity of airway inflammatory diseases such as rhinitis and bronchiolitis. Airway responses to LPS include accumulation of neutrophils, mucin gene expression, and airway wall remodeling that ultimately results in a hypersecretory epithelium. We have recently discovered the requirement for innate lymphoid cells (ILCs) in ozone-induced mucous cell metaplasia in the nasal epithelium. In the present study we compared responses in lymphoid cell-sufficient C57BL/6 mice, ILC-sufficient Rag2-/- mice (devoid of T- and B-cells), and ILC-deficient Rag2-/-Il2rg-/- mice (devoid of all lymphoid cells) to test the hypothesis that the pathogenesis of LPS-induced mucous cell metaplasia (MCM) is dependent on ILCs. Mice were intranasally instilled with 0 or 10 µg of *E. coli*-derived LPS for 9 consecutive weekdays. Twenty-four hours after the last instillation, bronchoalveolar lavage fluid (BALF) was collected to determine inflammatory cell infiltration. Lungs tissues were collected gene expression analysis, and for morphometric determination of neutrophil density, and intraepithelial accumulations of mucosubstances and Club Cell Secretory Protein (CCSP). Airway exposure to LPS caused significant MCM in the lungs of ILC-sufficient mice (i.e., C57BL/6 and Rag2-/- mice) but not in ILC-deficient mice (Rag2-/-Il2rg-/- mice). In all mouse strains, LPS exposure was associated with a decrease in epithelial CCSP, and increases of neutrophils in BALF and airway tissues. Genes for mucin-associated proteins Muc5AC and ClCa3/GOB5, and for pro-inflammatory TNFα and IFNγ, were induced only in ILC-sufficient mice exposed to LPS. These results demonstrate that LPS-induced epithelial responses and mucus overproduction in mouse airways is dependent on ILCs. Further studies are needed to determine the subtype of innate lymphocytes (ILC-1, -2 or -3) that contributes to airway wall remodeling.

1206 Pharmacological CFTR Modulation Decreases Glycolytic Flux and Mitochondrial Respiration in Bronchial Epithelial Cells

D. G. Brown, C. C. Anderson, J. R. Roede, and V. V. Phelan. *University of Colorado at Denver, Aurora, CO.*

Cystic Fibrosis (CF) results from a mutation in the gene for the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR). The CFTR is a chloride channel that is necessary for proper ion transport across epithelial surfaces, but also has indirect effects on a number of cellular processes including apoptosis, oxidative stress, and metabolism. CF patients suffer from a broad array of complications, including chronic bacterial infections and inflammation, leading to frequent pulmonary exacerbations and premature death. Additionally, individuals with CF possess dysfunctional mitochondria and display elevated markers of oxidative stress. Mitochondrial dysfunction has been identified across many pathologies and can often lead to apoptosis in high-energy cell types. The purpose of this study was to analyze energy metabolism in CF human bronchial epithelial cells (CFBE41o-; CFTR$^{\Delta F508}$) utilizing the Seahorse extracellular flux platform. This investigation revealed increased glycolytic flux and mitochondrial respiration, with significant increases in basal respiration, maximal respiration, proton leak, ATP production, non-glycolytic acidification rate, basal glycolysis, and glycolytic reserve in CFBE41o$^-$ cells compared to CFBE41o$^-$-corrected cells (CFTR^{WT}). To validate the role of mutant CFTR$^{\Delta F508}$ in the observed differences in energy metabolism, we exposed CFBE41o$^-$ cells to CFTR modulators Tezacaftor and Ivacaftor for 24 hrs. CFTR modulators are an important part of CF therapy and have provided significant improvement in lung function as measured by forced expiratory volume (FEV1). Combination Tezacaftor/Ivacaftor (Symdeko) was approved for use in CF in 2018 and is used to help correct the position of the CFTR in the apical membrane and improve chloride transport, respectively. Treatment of CFTR$^{\Delta F508}$ bronchial epithelial cells with the CFTR corrector or potentiator in mono- or combination treatment showed a general trend of reduced glycolytic flux and mitochondrial respiration. Additionally, we observed a significant reduction in ATP production and glycolytic reserve percentage with all treatments and significantly reduced basal mitochondrial respiration and coupling efficiency in cells treated with drugs in combination. Together these data show a synergistic effect of CFTR potentiation/modulation in lowering glycolytic flux and mitochondrial respiration in CF and the indirect role of the CFTR in energy metabolism.

1207 Real-Time Monitoring of the Adaptive Response to Oxidative Stress in Human Airway Epithelial Cells Exposed to an Environmental Peroxide

E. R. Pennington[1], S. Masood[2], Z. Zhang[2], A. Gold[2], W. Wu[3], Y. Yang[4], and J. M. Samet[5]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Xinxiang Medical University, Xinxiang, China; [4]Chinese Academy of Sciences, Shanghai, China; and [5]US EPA, Chapel Hill, NC.*

Isoprene hydroxy hydroperoxide (ISOPOOH) is a major component of secondary organic aerosol formed by the photochemical oxidation of isoprene, the most abundant non-methane organic compound emitted into the troposphere. While previous studies have shown that ISOPOOH is a potent oxidant stressor of human airway epithelial cells (HAEC), the mechanisms involved are poorly understood. Intracellular redox homeostasis is supported by a high ratio of reduced to oxidized glutathione (GSH and GSSG, respectively) that is maintained at the expense of NADPH. In the present study, we used the genetically-encoded ratiometric sensor roGFP, which reports on the intracellular redox potential (E_{GSH} = RT/F log(2GSH/GSSH)) and iNAP1, which senses changes in NADPH, to monitor redox changes in HAEC undergoing controlled exposure to ISOPOOH in real time. Exposure of HAEC to ISOPOOH induced a pronounced oxidation of intracellular glutathione, that was temporally associated with a transient decrease in NADPH. The recovery of E_{GSH} and NADPH responses to baseline was initially complete but became impaired with repeated exposure to ISOPOOH, suggesting irreversible changes induced by sustained oxidative stress. Glucose deprivation of HAEC markedly potentiated E_{GSH} and NADPH responses induced by subsequent ISOPOOH exposures. Strikingly, the addition of 1 mM glucose following ISOPOOH challenge induced rapid and complete restoration of baseline NADPH and E_{GSH}. These findings reveal mechanisms involved in the cellular response to ISOPOOH and provide an unprecedented live view of the dynamic control of redox homeostasis in human lung cells exposed to environmental oxidative stress. *This abstract of a proposed presentation does not necessarily reflect US EPA policy.*

1208 Dynamic Expression of TRPV3 and Modulation of Wound Repair by Human Lung Bronchial Epithelial Cells

K. L. Burrell, N. D. Nguyen, T. A. Memon, C. E. Deering-Rice, and C. A. Reilly. *University of Utah, Salt Lake City, UT.*

Transient receptor potential vanilloid-3 (TRPV3) is a Ca^{2+} channel expressed by human lung epithelial cells. TRPV3 is activated by wood smoke particulate matter (WSPM) and it was proposed that TRPV3 may play roles in WSPM-induced cytotoxicity and damage repair based on the observation that mice treated sub-acutely with WSPM displayed bronchial hypersensitivity and

areas of epithelial hyperplasia, which were blocked by a TRPV3 antagonist. This study shows that TRPV3 expression is rapidly induced by HBEC3-KT and BEAS-2B human bronchial epithelial cells following monolayer disruption by trypsin-, scratch-, or WSPM treatment, further indicating a possible role for TRPV3 in coordinating early stages of the wound repair process. Using an *in vitro* scratch assay, it was found that TRPV3 antagonists "locked" cells into a non-migratory phenotype and prevented cell adhesion, presumably by blocking initiation of adhesion, migration, and other fundamental elements necessary for the wound repair process. Interestingly, over-expressing TRPV3 in BEAS-2B cells as well as TRPV3 agonists also attenuated wound repair. Transcriptomic profiling of BEAS-2B and BEAS-2B TRPV3-overexpressing cells revealed marked differences in the expression of epithelial-mesenchymal transition (EMT)-specific genes, and a downregulation of epidermal growth factor receptor (EGFR) receptors and growth factors. Supplementation of BEAS-2B TRPV3-overexpressing cells with the EGFR ligands HB-EGF and amphiregulin partially rescued this slow-repairing phenotype. Additionally, inhibition of EGFR and the kinase GSK3β attenuated TRPV3 expression following injury and slowed scratch repair. Finally, modulation of TRPV3 activity using agonists and antagonists influenced these and other EMT biomarkers including vimentin and E-cadherin. These results suggest a high degree of integration between TRPV3 and the canonical EGFR/EMT signaling networks during wound repair, which provide insights into how TRPV3 may influence lung epithelial repair after injury. These finding have both toxicological and therapeutic significance. *Support: ES017431 and ES027015.*

PS 1209 Assessment of Respiratory Health Symptoms and Asthma in Children Near a Drying Saline Lake

M. H. Razafy, S. F. Farzan, and J. Johnston. *University of Southern California, Los Angeles, CA.* Sponsor: M. Gribble

Residents of the Imperial Valley, a rural, agricultural border region in California, have raised concerns over high rates of pediatric asthma symptoms. There is an urgent need to understand the influences and predictors of children's respiratory health in Imperial Valley. We assessed the impacts of sociodemographic, lifestyle, and household factors on children's respiratory health and asthma prevalence by administering a survey to parents of elementary school children (n = 357) in northern Imperial Valley. We observed an overall asthma prevalence of 22.4% and respiratory symptoms and allergies were widely reported, including wheezing (35.3%), allergies (36.1%), bronchitic symptoms (28.6%), and dry cough (33.3%). Asthmatics were significantly more likely to report respiratory symptoms, but high rates of wheezing, allergies, and dry cough were observed among non-asthmatics, suggesting the possibility for underdiagnosis of respiratory impairment in our school-age population. Having an asthmatic mother and exposure to environmental tobacco smoke were also associated with greater odds of asthma. Our findings provide evidence to support community concerns about children's respiratory health, while also suggesting that household and demographic characteristics have limited explanatory power for assessing asthma in this population. This work provides critical baseline data with which to evaluate local environmental factors and their influence on asthma and respiratory symptoms.

PS 1210 Immune Alteration in Neonatal Mice Born from Dams Intratracheally Exposed to Microplastics from Pregnant Day 9 to Neonatal Day 7

Y. Heo[1], M. Acharya[1], C. Kim[1], J. Jo[1], A. Maharjan[1], S. Yang[1], R. Gautam[1], Y. Han[1], Y. Song[1], G. Kim[1], Y. Lee[1], J. Lee[2], G. Lee[2], M. Kim[2], and H. Son[2]. *[1]Daegu Catholic University, Gyeongsan, Korea, Republic of; and [2]Daegu Catholic University GLP Center, Gyeongsan, Korea, Republic of.*

Microplastics could be exposed through inhalation, oral intake, or skin absorption, which could lead to various health implications related with inflammation, genotoxicity, and oxidative stress. No systemic investigation has been conducted to evaluate immune toxicities involved with microplastics exposure, and furthermore, generation immune toxicity has not been reported yet. Immune modulation in neonatal day 8 ICR mice, which mice were born from dams intratracheally exposed to microplastics (polyethylene microspheres with 10~45 μm diameter) for 12 days from pregnant day 9 to neonatal day 7. Intratracheal instillation of the microplastics suspended in 3rd distilled water has been performed to three pregnant dams per group (60 or 6 μg/50 μl/instillation for high or low dose group, respectively), and control group was instilled with 3rd distilled water. Five neonatal mice per group were used for the evaluation. No significant difference in proportion of thymic $CD4^+CD8^+$, $CD4^+$, and $CD8^+$ T lymphocyte. Proportion of splenic helper T lymphocyte was lower in the low (27.6±3.0%) and high (32.3±4.1%) dose group than the control (35.6±4.1%), and cytotoxic T lymphocyte was also lowered in the low (14.5±1.7%) and high (13.9±1.8%) dose group than the control (15.9±1.5%), but B lymphocyte population was higher in the low (25.3±3.6%) and high (24.1±4.0%) dose group than the control (20.8±4.2%) without statistical significances. Considering the skewedness of helper T cell immune reactivity, splenocytes were stimulated with anti-CD3 mAb for 48 hours, and interferon-γ:IL-4 ratio in the culture supernatants was dose-dependently higher in the low (14.2±3.0) and high (16.9±4.6) dose group than the control (8.8±2.5). The level of TNF-α was also higher in the both low and high dose group than the control without statistical significance. The level of serum IgG1 was dose-dependently lowered in the low (0.38±0.02 mg/ml) and high (0.32±0.04 mg/ml) dose group than the control (0.47±0.08 mg/ml), which tendency was also observed with serum IgG2a level. The present study demonstrated the certain magnitude of immune alterations, especially inflammatory response in neonatal mice born from dams exposed to microplastics. *Supported by Ministry of Environment, the education program for the management of information on the hazard and risk of chemical substances.*

PS 1211 Glucocorticoids Rescue TGF-β1-Mediated β2-Adrenergic Receptor Dysfunction by Attenuating Gene Expression

E. Chung[1], C. A. Ojiaku[2], G. Cao[2], B. Deeney[2], V. Parikh[2], R. A. Panettieri Jr.[2], and C. Koziol-White[2]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; and [2]Rutgers Institute for Translational Medicine and Science, New Brunswick, NJ.*

Glucocorticoids (GCs) and β-adrenergic receptor (β2AR) agonists decrease asthma symptoms in most patients. GC treatment results in gene expression changes in human airway smooth muscle (HASM), thereby modulating the inflammation and airway reactivity that are hallmarks of asthma. Our previous studies showed that the pro-fibrotic cytokine, transforming growth factor β-1 (TGF-β1), may be blunting the effects of intracellular cAMP to induce airway relaxation by increasing its breakdown through upregulation of enzymes called phosphodiesterases (PDEs). We hypothesize that dexamethasone (DEX), a GC, rescues TGF-β1-induced β2-agonist hyporesponsiveness by attenuating PDE4D gene expression in HASM cells. HASM cells were stimulated in serum-free F12 media with dexamethasone (DEX, 1000 nM; 30 min) prior to TGF-β1 (10 ng/mL; 18 hr). Subsequently, HASM cells were treated with β_2-agonist, isoproterenol (ISO, 1 μM; 5 min) or G_s activator, cholera toxin (CTX, 0.25 μg/mL). HASM cells were lysed and intracellular cAMP levels were determined by chemiluminescent immunoassay. RNA was isolated and purified from HASM cells using the RNeasy Mini Kit. cDNA was generated using SuperScript IV First-Strand Synthesis System. Relative cDNA quantification was performed using qRT-PCR. Overnight TGF-β1 treatment significantly decreased ISO-induced cAMP levels by 44.82% ± 8.56 (P=0.0064) and DEX rescued the reduction in cAMP levels induced by TGF-β1 treatment (25.83% ± 12.66; P=0.057 compared to TGF-β1 treatment). Additionally, TGF-β1 significantly attenuated CTX-induced cAMP levels (59.97% ± 10.01; P=0.004), which was then reversed by DEX pretreatment (71.47% ± 7.11; P=0.0017 compared to TGFβ1 treatment). Our RNAseq data shows little difference between *pde4d* expression in the presence or absence of DEX alone. We found that DEX (100 nM pretreatment) significantly decreases TGF-β1-induced *pde4d* expression (77.09% ± 8.17; P=0.0002). Our data show that TGF-β1 induces β2AR hyporesponsiveness through attenuation of β_2AR agonist- and G_s-induced cAMP production via *pde4d* upregulation in HASM. Reversal of the effects of TGF-β1 by DEX suggests a novel mechanism underlying GC-dependent effects on β2AR hyporesponsiveness in asthma.

PS 1212 Chronic Dermal Exposure to Soil Contaminated with Spent Engine Oil Induced Haematobiochemical and Spermatogenic Alterations in Wistar Rats

A. O. Adeyi, O. M. Fadoju, and G. Obiyo. *University of Ibadan, Ibadan, Nigeria.*

Indiscriminate disposal of spent engine oil (SEO), a major source of environmental pollution in Nigeria poses physiological risk to humans and aquatic organisms. This study was aimed at investigating the effects of chronic exposure to SEO contaminated soil as beddings on the physiology of male Wistar rats. Animals were dermally exposed to soil contaminated with SEO (200, 300 and 400 mL) for 120 consecutive days and compared with uncontaminated soil (negative control). Heavy metal (Pb, Ni, Zn and Cd) accumulations, haematology, biochemical (AST, ALT, ALP, BUN and CREA) parameters, sperm morphology and histopathology (liver, kidney, lungs, brain, skin and testis) were evaluated. Results revealed that the heavy metals in SEO contaminated soil were far above the WHO permissible limits, with significant ($p < 0.05$) increases of Pb and Ni present in the brain, and Pb and Cd in the serum compared with the control. Significant ($p < 0.05$) increases in haematological (lym-

phocytes and neutrophils only) and biochemical (AST and ALP) parameters, and sperm abnormalities were observed in the SEO-contaminated soil compared with control. Histopathological changes were not evident in the brain but significant lesions were observed in the liver, kidney, skin and testis of exposed rats. Results herein suggest that the constituents of SEO contaminated soil could elicit harmful physiological effects to humans who are intentionally or mistakenly exposed to spent engine oil.

1213 Potentiation of Dioxin-Induced Edema by LPS in Larval Zebrafish

H. Adachi, K. Tanaka, H. Kitamura, T. Kitazawa, and H. Teraoka. *Rakuno Gakuen University, Ebetsu, Japan.*

It is not well understood that inflammatory responses triggered by Toll like receptor (TLR) agonists in eleutheroembryos of teleost including zebrafish that lack adaptive immune system. Otherwise, involvement of aryl hydrocarbon receptor (AhR) has been reported in inflammatory responses by TLR agonists in mammalian system. In this study, the effects of lipopolysaccharide (LPS), one of representative TLR agonists on early edema caused by TCDD in larval zebrafish were investigated. Water-borne exposed LPS did not affect edema by itself but augmented edema caused by lower concentration of TCDD in a concentration-dependent manner. LPS even caused edema in the presence of very low concentration of TCDD that never induced edema. Edema caused by LPS plus very low concentration of TCDD (LPS+low TCDD) were abolished by cyclooxygenase 2 (COX2) inhibitor, a thromboxane receptor (TP) antagonist and prostacyclin receptor agonist, all of which inhibited high concentration of TCDD-induced edema. Edema caused by LPS+low TCDD were abolished by an antioxidant and activator of Nrf2, a master regulator of anti-oxidative responses. LPS also enhanced edema caused by TP agonist in antioxidant- and Nrf2 inducer-sensitive manner. LPS did not affect expression of type 2 AhR, CYP1A, markers for neutrophils and macrophages, and interleukin-6 and TNFα irrespective of co-treatment of TCDD. Reduction of neutrophils and macrophages by morpholino antisense oligos to G-CSF receptor and PU.1/Spi1 did not affect edema caused by LPS+TCDD. These results suggest that LPS augments TP receptor signaling through oxidative stress resulting in potentiation of edema by TCDD in developing zebrafish.

1214 Non-Monotonic Metabolic Dysregulation by Chronic Exposure of Low-Level Organochlorine Pesticides Mixture

H. Lee, S. Jeong, E. Min, H. Cha, K. Kim, and S. Yoon. *Seoul National University of Science and Technology, Seoul, Korea, Republic of.*

Exposure of organochlorine pesticides (OCPs), a class of persistent organic pollutants, has shown strong relationship with metabolic syndrome such as type 2 diabetes and obesity in epidemiological studies. To demonstrate metabolic adverse effects of OCPs mixture, 12 months-old female and male zebrafish adults were exposed to 0, 0.05, 0.25, 2.5, and 25 μg/L of five predominant organochlorine (i.e., p,p'-DDT, chlordane, heptachlor, beta-HCH (beta-hexachlorocyclohexane), and hexachlorobenzene (HCB)), for three months using an automatic flow-through exposure system. We measured typical blood index for metabolic effects (i.e., glucose, insulin, triglyceride, and free fatty acid level), and analyzed the alteration of gene expression through RNA-sequencing. The significant change of blood sugar regulation (i.e., high glucose and low insulin level) was observed non-monotonically at lower concentration of 0.05 μg/L than 0.5 and 25 μg/L, in only female zebrafish. These phenotypic changes were closely consistent with the transcripts differentially expressed by exposure of OCPs mixture. The metabolic pathways on PPAR-signaling, mitophagy, insulin signaling, lipid metabolism, glycolysis and carbohydrate metabolic process (i.e., citrate cycle, pyruvate metabolism) were found to be significantly affected in the transcription level. Therefore, our results suggest that chronic exposure of low-level OCPs leads to metabolic dysregulation, especially diabetic effects, in a non-monotonic manner in female zebrafish.

1215 Early-Life PBDE Exposure in Mice Persistently Dysregulates Intermediary Metabolites and Expression of Xenobiotic Biotransformation and Epigenetic Genes in Adult Liver

D. K. Scoville[1], J. L. Dempsey[1], D. Wang[2], D. Raftery[1], H. Gu[3], and J. Y. Cui[1]. *[1]University of Washington, Seattle, WA; [2]Peking University, Beijing, China; and [3]University of Arizona, Phoenix, AZ.*

Exposures to environmental toxicants during development can alter adult disease risks. The former flame retardants polybrominated diphenyl ethers (PBDEs) are bio-accumulative and readily detectable in humans. We have previously shown that acute exposure to PBDEs in adult mice alters abundances of hepatic intermediary metabolites and expression of xenobiotic biotransformation genes. Here, we tested our hypothesis that short-term exposures to PBDEs in neonatal mice persistently dysregulates hepatic intermediary metabolism and expression of xenobiotic biotransformation genes into adulthood. During postnatal days (PND) 2-3, male and female C57BL/6J mice were exposed to PBDE congeners BDE-47 (5, 50, 150 μmol/kg), BDE-99 (1, 5, 50 μmol/kg), or corn oil (vehicle, 10 ul/g) once per day via intraperitoneal injection. Tissues were collected at PND5, PND15 and 30 (adolescent ages), and PND60 (adulthood). Liver gene expression was quantified with RNA-Seq. Reads were aligned to mm10 using HISAT2. Genes were counted using featureCounts. DESEQ2 was used for differential expression analysis. LC-MS was used to measure hepatic aqueous metabolites. We found that early-life exposure to BDE-47 and -99 increased the abundances of amino acid, nucleotide, and carbohydrate metabolites in the livers of adult male and female mice at PND60. Expression of xenobiotic biotransformation genes including Cyp2, Cyp4, Gst, and Ugt isoforms and intermediary metabolism genes including Hk2 was down-regulated. Overall, BDE-99 altered the abundances of more hepatic metabolites and transcripts than BDE-47. However, the magnitude and direction varied by dose and sex. Notably, low-dose BDE-99 males exhibited the largest number of dysregulated metabolites and genes. In contrast both congeners at all doses down-regulated genes in females at PND60. Genes that epigenetically regulate transcription, including histone lysine demethylases (Kdm) and Pdp1 which coordinates certain methyltransferases, were also dysregulated through Day60. Significant correlations were observed between epigenetic genes Kdm5d and Pdp1 and P450 isoforms (Cyp2a and Cyp4a) and Hk2 both at PND60. In summary, early-life PBDE exposure persistently altered adult mouse intermediary metabolism and xenobiotic gene expression in a congener-, sex-, dose-dependent manner. Correlations between PBDE-regulated epigenetic genes and xenobiotic biotransformation and intermediary metabolism genes suggest that epigenetic modifications likely contribute to the sustained nature of observed PBDE effects on metabolite abundances and gene expression.

1216 Effect of Polychlorinated Biphenyl (PCB) Exposure on Mitochondrial DNA (mtDNA) Copy Number

S. VanEtten[1], M. Bonner[1], X. Ren[1], L. Birnbaum[2], P. Kostyniak[1], and J. Olson[1]. *[1]University at Buffalo, Buffalo, NY; and [2]National Cancer Institute, Research Triangle Park, NC.*

Mitochondria are intracellular organelles that contain their own genome and are responsible for biological oxidation and energy production. Mitochondrial DNA (mtDNA) is highly susceptible to damage from oxidative stress and exposure to polychlorinated biphenyls (PCBs) has been shown to significantly increase oxidative stress. The copy number of mtDNA varies depending on cell type and can be modulated by changes in physiological conditions or mitochondrial damage. The National Toxicology Program (NTP) conducted two year studies exposing female Sprague Dawley rats to various doses of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), the dioxin-like compounds (DLC) PCB 126 and PCB 118, the non-DLC PCB 153, and a mixture of PCB 126 and PCB 153. mtDNA copy number was assessed by quantitative PCR utilizing DNA that was isolated from banked liver and lung tissue obtained from the NTP studies. Relative to time-matched vehicle controls, the changes in mtDNA copy number observed varied depending on the exposure compound, exposure length, dose, and tissue type. Following 13 weeks of TCDD exposure there were significant increases in mtDNA copy number in the liver of animals exposed at the two highest doses. Similarly, 30 weeks of TCDD exposure at the two highest doses resulted in significant increases in mtDNA copy number in lung tissue. This significant increase was also seen in the lung tissues of animals exposed to the highest dose of TCDD for 52 weeks. Similarly, exposure to PCB 118 caused significant increases in mtDNA copy number in liver and lung tissues of animals exposed at the two highest doses for 13 weeks. Exposure to PCB 126 at the lowest dose tested showed significant decreases in mtDNA copy number in lung tissues of animals exposed for 13 and 52 weeks. Following an exposure to PCB 153 there was a trend toward decreases in mtDNA copy number. 52 weeks of exposure to the mixture of PCB 126 and

PCB 153 showed a significant increase in mtDNA copy number in liver of animals exposed to a mid-level dose, while the highest dose caused a significant decrease in mtDNA copy number. Changes in mtDNA copy number can serve as a biomarker that may be associated with neoplastic and/or non-neoplastic responses observed with subchronic and chronic exposures to TCDD and PCBs. *Supported in part by the intramural research program of NCI/NIH.*

1217 Keyword Analysis Tool: A Case Study Analysis of Congener-Specific Half-Lives for Polychlorinated Biphenyls (PCBs)

K. A. Shipkowski[1], J. Trgovcich[1], N. Vetter[1], B. L. Ingle[1], R. Silva[1], L. M. Carlson[2], D. F. Kapraun[2], P. M. Schlosser[2], and G. M. Lehmann[2]. *[1]ICF International Inc., Durham, NC; and [2]US EPA/ORD, Research Triangle Park, NC.*

Toxicity resulting from human exposure to PCBs is highly dependent on the absorption, distribution, metabolism, and excretion (ADME) properties of the individual PCB congeners. A database of half-life of elimination values for individual PCB congeners was assembled to advance the development of a comprehensive kinetic model for PCB mixtures relevant to human exposures. A novel strategy was employed to identify relevant literature. First, a literature search of the PubMed, Web of Science, and ToxLine databases was conducted using keywords related to PCBs; this generated a database of 58,051 studies. Next, the Keyword Analysis Tool (KAT) was applied to select studies related to PCB half-life and elimination. KAT is a software tool designed to increase efficiency in literature screening; it allows users to calculate metrics on the utility of each keyword. By applying keywords related to half-life, elimination, and clearance, KAT identified 5,956 potentially relevant studies from the PCB literature database. A text analytics approach was implemented to further select for studies considered relevant for data extraction based on an evaluation of PCB half-life or elimination rates in humans or other mammals. Specifically, sentences from the full text of each study that harbored a keyword were reviewed in conjunction with titles and abstracts to ascertain study relevance. This effort identified 312 potentially relevant studies, 98 of which contained half-life values for 95 PCB congeners across all species, lifestages, biological matrices, and exposure routes. A retrospective analysis of the KAT search results was undertaken to measure the utility of each keyword alone and in combinations in retrieving relevant studies. Of the 64 keywords used, only 28 were associated with studies considered relevant, and the top 10 keywords identified almost 80% of studies with half-life or elimination data. Additionally, by including keywords relevant to ecological studies, KAT successfully identified studies of PCB elimination in non-biological matrices such as air, water, and soil, which helped prioritize other studies more likely to be relevant to PCB elimination in mammalian species. Thus, KAT identified a highly effective keyword set that could be applied to increase efficiency of future literature searches for chemical half-lives of elimination in humans and other mammals.

1218 A Broadly Applicable Method for Identification and Analysis of Polychlorinated Biphenyl Sulfates in Human Serum

D. Zhang, M. W. Duffel, P. Saktrakulkla, K. C. Hornbuckle, H. Lehmler, R. F. Marek, and K. Tuttle. *University of Iowa, Iowa City, IA.*

Polychlorinated biphenyls (PCBs) are a class of toxic persistent chemicals with both legacy sources (e.g., Aroclors) and new current sources (e.g., unintentionally produced contaminants in some pigments and varnishes). PCB sulfates are derived from further metabolism of hydroxylated PCBs (OH-PCBs), which are oxidative metabolites of PCBs. Both OH-PCBs and PCB sulfates exert multiple toxicological effects on human health such as disrupting thyroid hormone transport and inhibiting steroid sulfotransferases (SULT1E1 and SULT2A1). Although PCB 11 sulfate has been previously detected in human serum samples by LC-MS, this is not a generally applicable method for a broad range of PCB sulfates in human serum (e.g, the theoretical number of mono-hydroxylated PCBs from which these PCB sulfates might arise is 837 congeners). This has limited our understanding of their prevalence and importance. We propose a method that employs acetonitrile extraction of the PCB sulfates from serum followed by differential analysis with, and without, hydrolysis to OH-PCBs catalyzed by a purified sulfatase from *Helix pomatia*. After purification of the sulfatase by affinity chromatography, its broad specificity for PCB sulfates indicated the feasibility of its use for their quantitative hydrolysis to OH-PCBs. These OH-PCBs were quantitated by GC/MS/MS after derivatization to their corresponding methoxy PCBs. Using 13C-OH-PCB 29 as surrogate standard, we were able to recover 64 ± 4 % of 10 ng of 4-PCB 11 sulfate added to 2 g of pooled human serum. An initial evaluation of this method led to the observation of several PCB sulfates, including 4′-PCB 26 sulfate, 3-PCB 54 sulfate, 4′-PCB 25 sulfate, and 4-PCB 52 sulfate, in a pooled human serum sample. Further analyses of serum samples for PCB sulfates are in progress. *Supported by NIH: P42 ES013661.*

1219 Analyzing the Effect of Pooled Samples on Interpreting the NHANES Dioxin Serum Data

A. Killius, and B. L. Finley. *Cardno ChemRisk, Brooklyn, NY.*

From 1999–2004, blood samples from individuals in the National Health and Nutrition Examination Survey (NHANES) were collected and analyzed as individual measurements. Beginning in the 2005-2006 cycle, blood samples from eight individuals were pooled into a single sample based on demographic characteristics and analyzed as a whole. This resulted in a significant reduction in limits of detection (LODs), which could make it difficult to compare the NHANES congener and toxic equivalency (TEQ) data from individual (1999–2004) to pooled (2005–6) biennials. Specifically, it has been suggested that there may be artificial decreases in mean congener and/or TEQ concentrations in the pooled data due to the lower LODs; this concern would be particularly applicable to congeners with a low detection frequency (DF) in the individual biennials but a high DF in the pooled biennials (non-detect values are approximated by substituting the LOD/square root of 2). The purpose of this analysis was to assess the influence that sample pooling may have had on NHANES data interpretation. It was found that the LODs of all congeners decreased substantially (up to 154-fold) as a result of the transition from individual to pooled samples (2003/4 vs 2005/6). However, it was also found that in white 60+ males, there was no difference in the congener fingerprint (% contribution to total mass) of the individual vs. pooled data. Specifically, the congeners OCDD, 123678HxCDD, and 1234678HpCDD comprised approximately 71%, 9% and 9% of the total congener mass (respectively) in both biennials. Time trend analyses also show that the blood levels of the congeners that comprise the majority of the TEQ in any given biennial (12378PeCDD, 123678HxCDD, 23478PeCDF, and 2378TCDD) did not exhibit an implausible decrease in the transition from individual to pooled data; indeed it would appear that blood concentrations of 12378PeCDD, 23478PeCDF, and 2378TCDD have remained stable in white 60+ males since the 2003/4 individual biennial. These congeners have relatively high DF in both the individual and pooled data, and as a result the transition to significantly lower LODs had little impact on the blood TEQ. The congeners associated with the largest decreases in mean values do not contribute substantially to the TEQ. These findings suggest that it may be appropriate to include all NHANES sampling cycles (individual and pooled) when investigating time trends of blood TEQ or the individual congeners that comprise the majority of TEQ.

1220 Evaluating the Effects of the Persistent Organic Pollutant Aroclor 1260 on Gut Microbiome in CAR and PXR Knockout Mice

N. C. Alexander II, B. Wahlang, X. Li, T. C. Gripshover, and M. C. Cave. *University of Louisville, Louisville, KY.*

Polychlorinated biphenyls (PCBs) are persistent organic pollutants associated with multiple health problems in exposed population, including nonalcoholic fatty liver disease (NAFLD). Previously, our group demonstrated that exposure to the PCB mixture, Aroclor 1260 (Ar), exacerbated NAFLD in diet-induced obese mice and activated the pregnane-xenobiotic receptor (PXR) and constitutive androstane receptor (CAR). Recent studies have also reported that PCBs can induce changes in gut microbiome, thereby promoting liver toxicity and worsening NAFLD. The objective of this study is to examine PCB effects on the gut-liver axis and characterize the role of CAR and PXR in PCB-induced alterations on microbiome and intestinal function. Methods: C57Bl/6 (wild-type, WT), $PXR^{-/-}$ and $CAR^{-/-}$ mice were fed a high fat diet (HFD) for 12 weeks and exposed to corn oil or Ar (20 mg/kg) *via* oral gavage. Cecal and ileal samples were collected for 16S rDNA sequencing and RT-PCR analysis. Results**:** Metagenomics analysis revealed that the bacterial species (alpha diversity) in WT mice were significantly different from both $PXR^{-/-}$ and $CAR^{-/-}$ mice; implicating involvement of these receptors in bacterial homeostasis. $PXR^{-/-}$ and $CAR^{-/-}$ mice also exhibited higher beta diversity than WT mice, irrespective of Ar exposure. Additionally, Ar induced changes in bacterial richness and diversity between groups in WT, $PXR^{-/-}$ and $CAR^{-/-}$ mice. In terms of bacterial composition, both knockout groups displayed decreased firmicutes/bacteroidetes ratio, accompanied by increased relative abundance for bacteroidetes, verrucomicrobia and TM7, and short chain fatty acid producers including bifidobacterium and lacto*Bacillus*. Further analysis of ileal gene expression showed that Ar decreased tight junction protein (*Tjp1*) mRNA levels in the knockout *vs.* WT groups. Moreover, $CAR^{-/-}$ mice exposed to Ar had decreased mRNA levels for genes encoding intestinal permeability and function markers including occludin, claudin3 and mucin2. Conclusion: Taken together, the results suggested that CAR and PXR ablation as well as Ar exposure modified

gut bacterial diversity; Ar also appeared to compromise intestinal integrity/function with CAR ablation. Future studies include further analysis of bacterial composition related to inflammation, lipid and bile acid metabolism to gain more insight into the observed gut dysbiosis.

PS 1221 The Ionic Liquid M8OI (C8[mim]) Inhibits Complex I of the Mitochondrial Electron Transport Chain

A. C. Leitch, T. Abdelghany, S. Miwa, and M. C. Wright. *Newcastle University, Newcastle upon Tyne, United Kingdom.*

Ionic liquids are organic salts that have been proposed as a "green" alternative for currently used solvents due to their low volatility and other desirable physicochemical properties. However, they may persist in the environment due to their water solubility and low biodegradability. Recent environmental sampling around a landfill site in the north east of England discovered high levels of the ionic liquid 1-octyl-3-methylimidazolium (M8OI, C8[mim]) based on its inhibition of oxygen consumption and toxicity to a liver progenitor cell. It was proposed that this chemical could adversely affect the liver and trigger cholestatic-related disease such as primary biliary cholangitis (PBC). It was therefore hypothesised that M8OI interacted with a component of the mitochondrial electron transport chain, inhibiting oxidative phosphorylation, increasing ROS production to induce apoptosis. To test this hypothesis, the rat hepatic progenitor B-13 cell line was exposed to M8OI. Exposure after 24 hours reduced cell viability (EC50 = 10μM) and induced apoptosis (≥100μM). Complex specific activity was measured in permeabilised cells using extracellular flux analysis. M8OI inhibited oxygen consumption in the presence of a complex I-linked substrate. Oxygen consumption in the presence of the complex-II linked substrate, succinate, was not inhibited by M8OI, suggesting complexes II, III and IV are not involved in the mechanism of inhibiting oxidative phosphorylation. Measurement of oxygen consumption through complex III (using duroquinol as an electron donor) and complex IV (using tetramethyl-*p*-phenylene diamine as an electron donor to cytochrome c) confirmed M8OI did not interact with either of these complexes. To confirm the inhibition of complex I by M8OI, hydrogen peroxide release from isolated mitochondria was measured using the fluorescent probe amplex red. In the presence of complex I substrate, M8OI increased H_2O_2 release, and in the presence complex II-linked substrate, M8OI decreased H_2O_2 release (through the inhibition of reverse electron flow). These data are indicative of a complex I inhibitor. M8OI has been identified in the environment and data suggests that it is acutely toxic, likely through the inhibition of oxidative phosphorylation. Therefore M8OI (and potentially other structurally related ionic solvents) may be toxic via an interaction with complex I in the mitochondria of sensitive cells.

PS 1222 Physiologic and Metabolic Impact of Persistent Organic Pollutants on Gut Microbiota

Y. Tian, W. Gui, B. Rimal, I. Koo, P. B. Smith, R. G. Nichols, J. Cai, and A. D. Patterson. *Pennsylvania State University, State College, PA.*

Emerging evidence supports that exposure to persistent organic pollutants (POPs) can impact gut microbiota-host metabolic homeostasis. Here, we examined the direct effects of POPs including 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), 2,3,7,8-tetrachlorodibenzofuran (TCDF), and polychlorinated biphenyls (PCB-126 and PCB-153) on the microbiota using *in vitro* models. Mouse cecal microbiota and seven individual bacteria species were incubated with two doses of TCDD (high: 1 μM and low: 0.1 μM), TCDF (high: 10 μM and low: 1 μM), and PCBs (high: 10 μM and low: 1 μM) in an anaerobic chamber. NMR- and mass spectrometry-based metabolomics combined with flow cytometry and growth rate measurements (OD_{600}) were used to systematically profile the direct impact of TCDD, TCDF, and PCBs on the microbiome. This study demonstrated that (1) 4 h incubation of TCDD, TCDF, and PCBs resulted in significant decreases in cecal microbial metabolic activity in a dose-dependent manner (carboxyfluorescein diacetate stained bacteria decreased from 65.9 ± 5.2% [vehicle] to 37.5 ± 5.4% [TCDD H], 38.8 ± 4.5% [TCDF H], 29.5 ± 5.6% [PCB-126 H], and 42.7 ± 3.7% [PCB-153 H]); (2) 4h exposure of TCDD, TCDF, or PCB directly and rapidly affect cecal bacterial global metabolism including disrupted amino acid, nucleotide, lipids, and carbohydrate metabolism (e.g., branched-chain amino acids decreased to 0.91-fold [TCDD H], 0.97-fold [TCDF H], 0.96-fold [PCB-126 H], and 0.90-fold [PCB-153 H]; xanthine decreased to 0.65-fold [TCDD H], 0.77-fold [TCDF H], 0.76-fold [PCB-126 H], and 0.64-fold [PCB-153 H]; lipid increased 1.10-fold [TCDD H], 1.16-fold [TCDF H], 1.17-fold [PCB-126 H], and 1.18-fold [PCB-153 H]); (3) individual bacteria species showed extreme variation in response to TCDD, TCDF, or PCB exposure; (4) the membrane destructive effect of (non-coplanar) PCB-153 is more dramatic than (coplanar) PCB-126 on microbiota. These data provide new insights into the direct role of POPs on the gut microbiota and begin to establish possible microbial toxicity endpoints which may help to better inform risk assessment.

PS 1223 Multigenerational Impacts of Dietary Exposure to the Flame Retardant BDE-99 in the Atlantic Killifish (*Fundulus heteroclitus*)

N. McNabb[1], B. Clark[2], M. Francoeur[2], H. Schrader[2], D. Champlin[2], S. Jayaraman[2], L. Mills[2], D. Nacci[2], and A. Whitehead[1]. *[1]University of California Davis, Davis, CA; and [2]US EPA, Narragansett, RI.*

Polybrominated diphenyl ethers (PBDEs) are a class of flame retardants that are persistent, bioaccumulative, and ubiquitous environmental pollutants linked to a variety of adverse health effects, including endocrine disruption and developmental neurotoxicity. Although maternal transfer of PBDEs has been documented, relatively few studies have investigated effects propagated across generations. To first characterize physiological and molecular outcomes in the exposed generation, we assessed the effects of dietary exposure to a predominant PBDE congener, BDE-99, in the Atlantic killifish (*Fundulus heteroclitus*). Adult wild-caught killifish were fed diets amended with a range of concentrations of BDE-99 for 38 days. Bioaccumulation was assessed, and measured internal dose ranged from 2.4 to 35.9 μg/g fish dw by termination of the exposure. Fish length, weight, and fecundity were measured at three time points throughout the exposure period. On days 10 and 39, subsets of fish were sampled, and tissues (gonads, liver, abdominal fat, and brains) were weighed and archived for molecular analyses. Energetic reserves (fat and liver mass) were affected and reproduction significantly impaired by all concentrations of BDE-99 compared to control. Next, to evaluate multigenerational impacts, adults were again exposed through diet to BDE-99 for 64 days. Target BDE-99 concentrations were 1 and 4 μg/g fish dw to achieve doses similar to and lower than the prior exposure. Fish were manually strip spawned at five time points and eggs fertilized to produce the F1 generation. At termination of the dietary exposure, the F0 adults were sampled, terminal measurements taken, and tissues archived for molecular analyses. No significant differences in growth, tissue indices, reproduction, or fertilization rate were observed between treatments. Chemical analyses are ongoing to quantify body burden and maternal transfer, but preliminary results suggest that a similar bioaccumulation rate was achieved with both exposures. F1 larval behavior was assessed at 3 and 14 days post-hatch by analysis of activity during alternating light/dark conditions. Ongoing experiments are testing for both short-term and persistent behavioral alterations in the F1 generation, as well as impacts propagated across generations from these parental exposures.

PS 1224 Developmental Exposure to Polychlorinated Biphenyls (PCBs) Causes Voiding Dysfunction in Young Adult Mice

K. P. Keil[1,2], C. Cardenas[2], H. Wildermuth[2], R. Manuel[2], Z. Wang[2], D. E. Bjorling[2], and P. J. Lein[1]. *[1]University of California Davis, Davis, CA; and [2]University of Wisconsin–Madison, Madison, WI.*

Lower urinary tract symptoms (LUTS), which can affect individuals of all ages, severely reduce quality of life. Despite their prevalence, risk factors and mechanisms responsible for LUTS onset and progression are poorly defined. PCBs remain a current and significant environmental risk to human health, yet whether PCBs impact the developing bladder and contribute to LUTS risk is unknown. We tested the hypothesis that developmental exposure to PCBs alters voiding function in young adult male and female mice. Wild type mice were exposed throughout gestation and lactation to 0, 0.1, 1 or 6 mg/kg/d PCB mix via the maternal diet. The PCB mix proportionally mimics the 12 most abundant PCB congeners in serum of women at increased risk of having a child with a neurodevelopmental disorder. Voiding function was tested in male and female offspring at ~6 weeks of age using three different methods; the spontaneous void spot assay, uroflowmetry, and anesthetized cystometry. These methods allow for quantification of voiding function in awake freely moving mice and anesthetized mice. Effects of PCBs on voiding function were sex- and dose-dependent. Preliminary results of the void spot assay revealed a significant increase in the number of small urine spots (0-0.1cm) produced by male mice in the 0.1 and 1 mg/kg/d PCB group vs. vehicle control, while this increase was only seen in female mice in the 6mg/kg/d PCB group. Uroflowmetry identified a significant decrease in strength of urine stream in male mice in the 0.1 mg/kg/d PCB group vs. vehicle control. Anesthetized cystometry revealed a significant decrease in time between voids, regardless of sex, in the 0.1 and 6 mg/kg/d PCB group vs. vehicle control. Together, these results indicate that males are more sensitive than females to developmental PCB effects on voiding; PCB exposure produces more frequent voids of small volume; effects of PCBs on voiding are not completely behavioral since anesthetized animals display voiding dysfunction. Overall, these results indicate

that developmental PCB exposure affects voiding function and further support the hypothesis that urinary function is influenced by early-life exposure to environmental pollutants. *Supported by (K99 ES029537 KPK; U54 DK104310 DEB; R01 ES014901, P01 ES011269 PJL).*

1225 Dioxin and Furan Congener Contributions to Blood TEQ in the Current NHANES Database

A. Killius, and B. L. Finley. *Cardno ChemRisk, New York, NY.*

Dioxins and furans are primarily produced as industrial byproducts, while PCBs are typically associated with historical use of Aroclors. Certain PCB congeners are assumed to possess "dioxin-like" potencies, and these congeners and the dioxin/furans comprise the blood total toxic equivalency (TEQ) for any given individual. The purpose of this analysis was to use the National Health and Nutrition Examination Study (NHANES) data to assess the most current (2005-2010) congener-specific percent contribution to blood TEQ in the general US population and in various demographic groups. In the general population, the primary contributors to blood TEQ were 12378PeCDD (32%), 123678HxCDD (16%), PCB-126 (13%), 23478PeCDF (11%), and 2378TCDD (9%). The remaining TEQ was made up of 13 dioxin/furan and 10 PCB congeners, contributing 0-3% each. In general, very similar patterns were observed in all demographic groups, and the congener-specific percent contribution to TEQ appears to be relatively stable throughout the 2005-2010 sampling period. However, there were some exceptions, for example the percent contribution of PCB-126 in black males and females 40-59 years old increased from 2005-2006 to 2009-2010, and TCDD in white males 12-19 and 20-39 years old appears to be increasing over that time period as well. It is worth noting that the blood TEQ patterns observed in NHANES are generally consistent with those reported in various beef and pork products consumed in the US The point sources for the primary contributors 12378PeCDD and 123678HxCDD are not well understood, but the half-lives of these congeners are estimated to be 11.2 and 13.1 years, respectively (vs 7.2 years for 2378-TCDD), which likely explains their relatively high body burdens in humans and livestock. Interestingly, similar blood TEQ patterns to those reported here have also been reported in the literature in individuals purportedly exposed to elevated levels of TCDD in contaminated environmental sources.

1226 Strategizing Read-Across in Toxicological Risk Assessments of Medical Devices Using Potency and Severity Indices from Data-Rich Toxicological Substances

S. K. Mishra, P. S. Alwin, S. M. Street, B. Prabhakar, K. Ohneswere, C. D. Christensen, J. N. Eucher, F. Wang, M. Cabonce, and S. P. Parker. *WuXi AppTec, Saint Paul, MN.*

Recent changes in ISO 10993-1:2018 and the 2016 FDA Guidance regarding ISO 10993-1 have made chemical characterization necessary for most medical devices. Extractions of medical devices in the recommended solvents and use of advanced analytical instrumentation have resulted in identification of numerous chemicals lacking sufficient toxicological data for risk assessment. Read-across is a commonly used technique that predicts hazard in the absence of empirical data. However, it is an evolving approach with several open issues, including a lack of consensus regarding the extent and type of evidence necessary to support its use. This study established a standardized workflow of using a read-across tool along with the potency and severity of harm indices in a large data set of commonly extracted chemicals from medical devices. To determine the feasibility of effective grouping of medical device chemicals for use of read-across, a publicly available software tool, ChemACE (Chemical Assessment Clustering Engine), was applied across a large chemical inventory from the ECHA database to cluster chemicals based on structural features. Points of departure (POD) values were identified from multiple endpoint toxicity studies of high reliability score (Klimisch score of 1 or 2) for these chemicals. Per ISO/TC 194/WG 11, potency and severity of harm categories were determined for these chemicals, and trends were examined. Although the PODs of chemicals within clustered groups exhibited a considerably wide range, similar potency and severity categories were observed within the clusters. Overall, results show that when chemical clustering predictions were analyzed along with the experimental data from well-conducted toxicological studies, read-across may be a viable option for filling in data gaps for data poor chemicals. However, consideration of strategies such as use of uncertainty factors may be justified when extrapolating toxicological data from data rich group members to other group members lacking toxicological data.

1227 Risk Assessment of Extractables from Warmed and Room Temperature Dental Composite Restoratives

B. D. Bagley[1], D. Dreher[1], T. Dunbar[2], J. Fitch[2], and K. Olson[2]. *[1]3M Corporate Toxicology and Environmental Science, Saint Paul, MN; and [2]3M Oral Care Solutions Division, Saint Paul, MN.*

Dental composite restoratives are critical to the oral health of patients worldwide. In the past decade, dental composite warmers that can heat composites up to 70°C have been suggested to improve product flowability and adaption with minimal heat transfer to the pulp. The purpose of this study was to investigate the effects of composite warming on product extractables and biocompatibility. Triplicate samples of two dental composites, 3M ESPE Filtek Universal Restorative (FUR) and 3M ESPE Filtek Supreme Ultra Flowable Restorative (FSUF), were subjected to a warming procedure consisting of either a single 1-hour heating event (70°C) for single-use capsule packaging (FUR) or 20 repeated 1-hour cycles of heating to 70°C and cooling to room temperature for reusable syringe packaging (FSUF). The three warmed samples of each product and three room temperature samples (RT) of each product were cured according to manufacturer's instructions and extracted according to ISO 10993-12 at 37°C for up to 35 days (exhaustion) in methanol, heptane, and 5% ethanol. In each case, 1) no new extractables were identified in the warmed samples relative to the RT samples, 2) most extractables were released from the warmed samples at similar or decreased concentrations relative to the RT samples, and 3) extractables with increased concentrations from the warmed samples relative to the RT samples were released at amounts that compared favorably to toxicological thresholds (e.g., ICH M7). These results indicated that the warmed and RT samples of each product were toxicologically equivalent according to ISO 10993-18: 2005. Based on a detailed risk assessment of the extractables, FUR in capsules and FSUF in syringes are safe for their intended use when warmed to 70°C for up to 1 hour prior to application. This risk assessment approach may be applicable to the biocompatibility evaluation of other dental composite restoratives prepared under warmed conditions.

1228 Establishing a Tolerable Intake for Dimethyl 4-Toluidine through Use of Benchmark Dose Modeling

M. Boylan, B. Wang, and M. H. Whittaker. *ToxServices LLC, Washington, DC.*

As specified in ISO 10993-17:2002, "The determination of the suitability of a medical device for a particular use involves balancing any identified risks with the clinical benefit to the patient associated with its use. Among the risks to be considered are those arising from exposure to leachable substances arising from medical devices." Dimethyl 4-toluidine is used to make acrylic resins and is used in the cement in most hip and bone replacements. After dimethyl 4-toluidine was detected during extraction testing of a medical device, a risk assessment was performed to calculate a tolerable intake (TI). A TI is defined as the estimate of the average daily intake of a substance over a specified time period that is considered to be without appreciable harm to health. Dimethyl 4-toluidine is a potential human carcinogen based on chronic oral studies in rodents conducted by the National Toxicology Program. Increased tumor incidences were reported at multiple sites, including liver, nose, thyroid, and/or lung in rats and mice. We selected hepatocellular carcinomas in male mice to derive a cancer slope factor (CSF) for dimethyl 4-toluidine as this tumor type had the highest incidence and was detected across both species and sexes. The resulting CSF should be protective of other tumor types. Duration-adjusted doses and liver tumor incidences were fit to the multistage cancer model using US EPA Benchmark Dose Software (BMDS) with a 10% increase in tumor incidence as the benchmark response. Relevant fit parameters and a visual curve inspection indicated that the model fit adequately. The resulting animal CSF of 0.0257 $(mg/kg/day)^{-1}$ was scaled to a human-equivalent CSF by multiplying by the $(human\ body\ weight/animal\ body\ weight)^{1/4}$ ratio; this yielded a human CSF of 0.1579 $(mg/kg/day)^{-1}$. The TI is derived by dividing an acceptable cancer risk level by the human CSF, which can be adjusted by less-than-lifetime exposure for medical devices with shorter patient contact. While ISO 10993-17:2002 specifies an acceptable cancer risk level of 10^{-4}, ICH M7 Guidance and US FDA use an acceptable risk level of 1 in 10^{-5}, which represents the potential for 1 in 100,000 people to develop cancer following a lifetime of daily exposure. Using a cancer risk value of 10^{-5} and 0.1579 $(mg/kg/day)^{-1}$ CSF results in a 0.0633 µg/kg/day TI for dimethyl 4-toluidine extracting from permanent contact devices. This TI can be compared to expected exposure levels to dimethyl 4-toluidine resulting from use of a specific medical device.

1229 Toxicological Risk Assessment of Simulated Isopropyl Alcohol (IPA) Exposure Dose Estimates in Neonates

H. Shin, B. Oktem, and A. Hood. *US FDA, Silver Spring, MD.*

IPA-filled caps are single-use devices attached to luer access values to prevent central line-associated blood stream infections. Sauron et al. (2015) simulated clinical use of IPA caps in neonatal intensive care units (NICUs) neonates and reported altered appearance of luer valves, as well as excess IPA quantity in simulant, and posited IPA caps should not be used for neonates without additional research. Analytical chemistry and toxicological risk assessment methods used by Sauron et al. were not reported in sufficient detail to assess data reliability and confidence in the findings. We conducted an independent study of the impact of IPA caps on luer valves by performing worst-case *ex vivo* simulations of IPA cap use in neonates. Results from a survey of NICUs were used to plan our simulation to identify the worst-case scenario. To simulate clinical use, a circuit was created consisting of a SmartSite luer valve, SwabCap, Y-connector with crimp, and a glass collection vial with a septum cap. Worst-case clinical conditions included (a) incubating luer valves with IPA caps at 37ºC, (b) simulating 20 drug infusions that occur at four periods over a day, (c) swiping proximal end of the luer value with an IPA pad, and (d) simulating drug administration using water (simulant) that included a prewash (0.5 mL), drug infusion (0.3 mL), and post-wash (0.5mL). We also used the standard patient care of swiping valves with IPA pads after removal, and before subsequent attachment, of IPA-filled caps. The quantity of IPA in infusates was then determined by gas chromatography with flame ionization detector. Simulating worst-case number of drug infusions in a single day resulted in IPA concentrations of 32.33 mg/dL IPA (with IPA cap) and 2.37 mg/dL (swiping only). The *ex vivo* worst-case use of IPA impregnated caps in neonates resulted in IPA quantities that exceeded the blood toxicity threshold for children (25 mg/dL); whereas, swiping luer access with an alcohol pad alone did not. In conclusion, the result of our *ex vivo* simulation studies provide additional evidence that an excess amount of IPA could be unintentionally administered into the bloodstream of neonates hospitalized in NICUS. Furthering our understanding of how an excessive amount of IPA could be administered to neonates is needed.

1230 A New Approach to Assessing Toxicity of Detergent Residuals for Reusable Device Cleaning Validations

D. S. Olsen, C. Summers, and A. Patel. *Nelson Laboratories LLC, Salt Lake City, UT.*

The accurate validation of cleaning procedures for reusable medical devices is a critical step in protecting patient safety. As part of the validation process, many residual endpoints are often addressed, as recommended in AAMI TIR30. Among these endpoints is detergent residual testing to verify that detergents used in the cleaning process do not remain on the medical device in cytotoxic concentrations after the cleaning procedure is complete. AAMI TIR30 suggests that the toxicity of detergent residuals may be addressed using the cytotoxicity testing methods outlined in ISO 10993-5. However, because ISO 10993-5 is designed to address the cytotoxicity of the medical device materials and manufacturing processes, this suggestion often leads to the inclusion of an exaggerated extraction procedure in serum supplemented cell culture media which is intended to extract all potentially cytotoxic chemicals from the device materials. This can result in an overly stringent test method for assessing the effect of residual detergent. Although extractions in cell culture media are frequently performed for biocompatibility assessments, ISO 10993-5 allows for other extraction conditions which simulate the extraction that occurs during clinical use if they provide an adequate measure of the hazard potential. Herein, we present an alternative approach to assessing the toxicity of detergent residuals for use in validating cleaning procedures of reusable medical devices. This approach utilizes water based extractions commonly used for other cleaning validation residual marker tests (total organic carbon, hemoglobin, protein, etc.) to assess detergent residuals in a more clinically relevant manner. Using quantitative cytotoxicity testing - which measures the metabolic activity of cells exposed to the detergent solution to calculate a percent viability value - we are able to construct dose response curves for commonly used detergents. This allows us to determine the concentration of residual detergent on a device following a cleaning procedure and provides detailed data that can be used to efficiently assess the associated toxicological risk.

1231 A Flow Cytometry Method for Characterizing Platelet Activation

B. R. Alzua, M. Smith, and Y. Chen. *American Preclinical Services LLC, Minneapolis, MN.*

Hemocompatibility testing is critical for assessing the safety of blood-contacting medical devices. Comprehensive hemocompatibility testing requires examining a wide range of possible adverse effects cause by direct or indirect blood contact, such as hemolysis, complement activation, and thrombus formation. Moreover, these domains each encompass complex intercellular processes with many potential targets for analysis. For example, the current testing paradigm of platelet function may involve exposing the device to human whole blood and performing simple blood counts and/or macroscopic evaluation to determine the extent of platelet activation and clot formation as described in ASTM F2888-19. However, this approach does not capture any observations for device-mediated initiation of any steps in the platelet activation sequence prior to aggregation. We have validated a method to evaluate platelet activation by quantifying surface p-selectin expression after exposure to various materials. This method will provide an additional level of detail about potential platelet activating properties of a medical device. Flow cytometry has been used previously to measure platelet activation for clinical and research purposes. We sought to adapt this method to test for platelet activation induced by exposure of blood to medical devices or materials. We determined that processing fresh whole blood to platelet-rich plasma (PRP) by gentle centrifugation enhanced the signal compared to fresh blood itself. In each experiment, devices were exposed to PRP according to an extraction ratio of 6 cm^2/mL for 1 hour. A blank control consisting of untreated PRP, and a positive control consisting of ADP, a potent agonist, were also used. After the exposure, excess plasma was removed from the articles and combined with anti-CD61 (to stain for platelets) and anti-CD62P (to stain for activated platelets) antibodies. Flow cytometry was then performed to quantify the percentage of CD62P+ over the total CD61+ cells to measure the percentage of activated platelets. In order to optimize the method, we investigated the effect of several experimental factors, including anticoagulant usage, donor variability, and selection of reference materials to serve as controls. Our results indicate that the flow cytometry-based method is consistent and reproducible, easy to perform with short time to results, and well-correlated with results from the standard platelet and leukocyte count assay. The flow cytometry-based platelet activation method is a powerful supplement to the standard medical device hemocompatibility testing.

1232 Quantification of Aluminum Release in a Smiths Medical Intravenous Fluid Administration Set via ICP-MS

A. Nelson[1], L. Borton[2], D. Jensen[1], Y. Chen[1], and M. Smith[1]. *[1]American Preclinical Services LLC, Minneapolis, MN; and [2]Smiths Medical, Minneapolis, MN.*

Recent attention has been drawn to the tendency of aluminum-plate intravenous fluid warming devices to release concentrations of aluminum into the administered fluid. The risk of aluminum leaching into warmed fluids delivered via Massive Transfusion Protocols in emergency care during trauma, organ transplantation, vascular emergencies and postpartum hemorrhage was explored in a complex simulated-use study outside of traditional ISO 10933 conditions to better elucidate aluminum exposure levels consistent with clinical use. We designed a study to quantify aluminum release from the Level 1® Normothermic I.V. Fluid Administration Set with an uncoated aluminum-plate warming system in three clinically simulative solutions: 0.9% sodium chloride, Lactated Ringer's Solution, and bovine whole blood. The disposable-hardware system was evaluated during one hour of use at 42°C and a clinically relevant flow rate of 30 mL/min. Samples from the effluent were obtained at regular intervals and were analyzed via ICP-MS, revealing different aluminum release profiles depending on the solution. Exposed to 0.9% sodium chloride, the concentration of aluminum in solution gradually increased from undetectable to 6.90 ng/mL. When Lactated Ringer's Solution was used, a consistently increasing aluminum release was measured over time starting at 74.6 ng/mL at 10 minutes and ending the one hour period at 277 ng/mL. An erratic profile of release into bovine whole blood was detected, varying from 434 ng/mL to 75.0 ng/mL, with the rate of aluminum leaching generally decreasing over time. Samples of cumulative aluminum leaching revealed negligible overall release into 0.9% normal saline and bovine whole blood over the entire course of the assessment (one hour), with a release of 98.1 ng/mL into Lactated Ringer's Solution. Our findings indicate that the evaluation of devices under simulated use utilizing clinically-relevant fluids and conditions can enhance the evaluation of device safety by providing a realistic exposure assessment.

1233 Chemical Analysis of Medical Device Materials to Support Equivalency Determination

B. Oktem, K. Nahan, E. M. Sussman, and S. Wickramasekara. *US FDA, Silver Spring, MD.*

Biological evaluation of medical devices often includes chemical characterization (as described in ISO 10993-18). Device materials are subject to extraction where by materials, processing additives, residues, as well as material breakdown products may be released. These extractables have potential consequence on the biological response to the device during its use. Chemical characterization studies are followed up by toxicological risk assessments which evaluates potential harm from exposure to the extractables. In some cases, evaluation of material equivalence of similar device materials is required. Following extraction, chemical analysis is performed by various methods, such as GC/FID/MS, FTIR, and LC/UV/MS. Current technology in high resolution mass spectrometry may improve these analyses. This presentation discusses development of improved data analysis methods to probe chemical analysis data from two materials' equivalency. A panel of medical device materials all composed of polypropylene were analyzed. Multiple rounds of extractions (24 hour at 50°C 200 rpm) were used to obtain non-volatile residue. (NVR) Test extracts were introduced to different instruments: a GC/FID/MS (7890B/5977B Agilent) equipped with an internal splitter enabled FID and MS signal to be acquired simultaneously. An UHPLC-QTOF-MS system (6540 UHD- Agilent). Amounts of extractables were estimated semi quantitatively by comparing to a set of internal standards. FTIR data is also obtained for NVRs. Standards of various polymer additives were prepared and analyzed by LC-UV-MS system where the UV absorbance and MS data were acquired together. Processed and raw polypropylene materials were extracted by isopropanol and hexane. GC/FID/MS analysis are acquired for every sample to add additional dimension of data. The GC/MS data were also processed for identification of analytes using the 2017 NIST Mass Spectral Library. Preliminary results showed more than 20 compounds tentatively identified. Ongoing work includes the use of Q-TOF MS with greater resolution (~40,000) for unknown identification using a commercial E&L Database as well as open access databases. A scoring scheme for binary comparison of the data was utilized using Principal Component Analysis.

1234 Using Physics-Based Models to Provide Conservative, Clinically-Relevant Estimates of Patient Exposure to Extractables from Medical Device Polymers

P. Turner[1], K. Nahan[1], S. Shah[2], A. Talley[1], V. Chandrasekar[1], S. Wickramasekara[1], B. Oktem[1], T. Duncan[2], and D. Saylor[1]. *[1]US FDA/CDRH, Silver Spring, MD; and [2]US FDA/CDRH, College Park, MD.*

Biocompatibility assessment of new medical devices remains a challenging and resource-intensive burden to all types of FDA submissions. Extraction testing, outlined in ISO-10993, prescribes conditions for identifying and quantifying compounds that may be released from medical devices. Our objective is to harness data from common extraction techniques in a diffusion-limited transport model to forecast a worst-case, clinically relevant exposure. For devices of a given geometry with stable physicochemical properties *in vivo* and homogenous and dilute additive content, exposure may be estimated based on total additive mass and a diffusion coefficient (D_p) for the additive within the matrix material. The latter may be conservatively provided by an upper bound based on literature data for relevant polymer matrices and the additive molecular weight. Samples were produced via twin-screw extrusion and injection-molding from materials including high-density polyethylene (HDPE) containing 1 wt% additive chosen from common antioxidants including β-hydroxy toluene (BHT; Mw 220 Da), Irganox 1076 (Mw 531 Da) and 1010 (Mw 1178 Da). Extraction testing was performed in accordance with ISO10993-12 under exaggerated conditions, using polar (H2O), mid-polar (IPA), and non-polar (hexane) solvents at 50°C. Samples were analyzed via liquid chromatography mass spectrometry (LC-MS) for the target additive masses to determine release rates, which were used to calculate diffusion (D_e) and partition (K) coefficients for each additive-solvent combination. D and K values were used to assess the suitability of common extraction conditions to recover total additive mass needed for the exposure model. Extraction results from HDPE samples consistently indicated greater diffusion rates (D_e) relative to model predictions (D_p) - $4.7x10^{-8}$ vs $1.2x10^{-9}$ cm^2/s for BHT; $1.5x10^{-8}$ vs $5.8x10^{-11}$ for 1076; $1.8x10^{-9}$ vs $2.2x10^{-12}$ for 1010. Consequently, extraction studies implied greater exposure rates than predicted by the model - 235 vs 65 µg/day for BHT; 216 vs 14.6 µg/day for 1076; 131 vs 2.9 µg/day for 1010. Samples swelled significantly (~1 vol% in IPA, ~15 vol% in Hexane), contributing to their increased diffusion and release relative to model predictions. Results suggest physics-based models may provide an improved approach to assessing worst-case, clinically relevant exposure within a toxicological risk assessment framework.

1235 A Critical Evaluation of the NAVI Model for Thrombogenicity Evaluation of Cardiovascular Medical Devices: Correlation between *In Vitro* Hemocompatibility Test Results and *In Vivo* Thrombus Scores

F. K. Hsia[1], S. P. Parker[2], S. L. Huebert[1], and C. D. Christensen[2]. *[1]Boston Scientific Corporation, Maple Grove, MN; and [2]WuXi AppTec, Saint Paul, MN.*

According to ISO 10993-4: 2017, direct blood-contacting medical devices should be evaluated for thrombogenic potential, and the *in vivo* 4hr non-anticoagulated venous implant (NAVI) model is a standard test procedure used to assess acute thrombogenicity. However, limitations in test methodology such as inherent differences in individual animal thrombogenic reactivity, lack of statistical power, placement in venous anatomy, incubation period, and lack of anticoagulants may limit the NAVI model's predictiveness of the thrombogenic potential of a medical device under clinical-use conditions. ISO 10993-4:2017 also indicates that the manufacturer may decide if *in vitro* tests are an appropriate alternative to *in vivo* testing. Common *in vitro* tests are used to assess coagulation [partial thromboplastin time (PTT)], platelet counts (% loss), and complement (SC5b-9) activation. To determine if there is a correlation between *in vitro* test results and elevated *in vivo* thrombus scores, the results of *in vivo* thrombogenicity studies were compared to corresponding *in vitro* data (PTT, platelet counts and SC5b-9 complement activation) in the same devices. Results from 15 NAVI studies showed thrombus scores were variable among individual animals (i.e. scores differed by 2 among three animals in half of the dataset). In this analysis, studies were divided into two groups: thrombogenic group with scores of ≥3 in at least 2 animals; less thrombogenic group with scores of ≤ 2 in at least 2 animals. Although no association between platelet counts and elevated thrombus scores was observed, PTT results (clotting time normalized to plasma) were on average 20% lower, and SC5b-9 levels were statistically significantly higher in the thrombogenic group. These results suggest reduced PTT and increased SC5b-9 may be associated with *in vivo* thrombogenicity in the NAVI model. Historically, platelet counts have been assessed using sodium citrate anticoagulation. Platelet counts utilizing heparinized human blood per ASTM F2888:2019 may improve the correlation. In conclusion, *in vitro* hemocompatibility tests, possibly combined with data from a dynamic *in vitro* flow loop may provide a feasible and appropriate alternative to *in vivo* thrombogenicity testing.

1236 Cytotoxicity and Mutagenicity Assessment of Lithium Phenyl(2,4,6-trimethylbenzoyl) phosphinate (LAP) Photoinitiator with Exposure to 405 nm Light

A. K. Nguyen[1,2], P. L. Goering[2], R. K. Elespuru[2], and R. J. Narayan[1]. *[1]North Carolina State University, Raleigh, NC; and [2]US FDA, Silver Spring, MD.*

The use of photosensitive resins in biomedical applications exposes embedded cells and/or surrounding tissue to stressors such as chemicals, light, and heat, which might lead to cell injury. Photosensitive resins are made reactive to light by addition of a photoinitiator; concurrent exposure of the photoinitiator to a compatible light wavelength initiates a polymerization reaction that exposes cells to free radicals, which can be cytotoxic, genotoxic, and mutagenic. LAP is a photoinitiator popular in bioprinting due to its water solubility and compatibility with visible (405 nm) light but is a lithium salt that can accumulate in renal collecting duct cells causing loss of urine concentrating ability or cell injury. This project investigates the effect of LAP exposure on cytotoxicity in M-1 murine collecting duct cells and concurrent exposure of LAP and 405 nm light on mutagenicity in TA98 and TA 100 *S. typhimurium*. Confluent M-1 monolayers with observed "domes" indicative of active water transport were exposed to LAP concentrations ranging from 1 to 20 mg/mL or the corresponding equimolar concentration of lithium chloride for 24 hr; cadmium chloride (1 mM) was used as the positive control. No significant decrease in viability was observed after exposure to 5 mg/mL LAP using the Neutral Red or Alamar Blue assays; viability decreased to 49% and 70% with exposure to 7.5 mg/mL. Exposure to 10 mg/mL or above resulted in low viability indistinguishable from the positive cytotoxicity control. For the bacterial mutagenicity assay, no increase in revertant colonies above the background was observed in TA100 exposed to LAP concentrations up to 10 mg/mL with 15 minutes of 3 mW/cm2 405 nm light from an LED source, an exposure previously determined to exaggerate conditions during bioprinting. Exaggerated exposure of 15 mg/mL LAP with 1 or 5 min of 224 mW/cm2

light exposure to TA100, TA98, or WP2uvrA also showed no mutagenic effect; however, a cytotoxic response was observed with 5 min light exposure. UV-C light, 4-Nitroquinoline-1-oxide for TA100 and TA98, and 2-nitrofluorene for WP2uvrA were used as positive mutagenicity controls. Typical LAP concentrations used in bioprinting (<5 mg/mL) were not cytotoxic to confluent M-1 cell layers and exposures, even under exaggerated conditions, using the Ames assay to LAP and 405 nm light showed no evidence of mutagenicity.

1237 The *In Vitro* Toxicity of a Dental Resin Monomer Varies among Different Cell Culture Models

J. Samuelsen, S. Uvsløkk, and E. Morisbak. *NIOM, Oslo, Norway.*

In vitro cytotoxicity tests are routinely carried out during biocompatibility evaluation of medical devices. By using immortalized cell lines, such tests become relatively simple and fast to perform. However, a wide range of cell lines is available and various protocols describe the use of specific cell types without a thorough justification. Cell lines that are commonly used for toxicity studies differ both in source (species and organ) and how they have become immortalized (e.g. cancer cells and virus transfected cells). Based on this, it can be assumed that they differ in many properties, including their capacity to handle different exposure scenarios. Hence, we hypothesize that results obtained by *in vitro* cytotoxicity tests depend strongly on the chosen cell line. In this study, we have compared how four commonly used cell lines respond to 2-hydroxyethylmethacrylate (HEMA) exposure. 1) A549 cells (human, alveolar carcinoma), 2) BEAS-2B cells (human normal bronchial epithelium, SV40 transformed), 3) RAW 264.7 cells (murine, macrophage-like, Abelson leukemia virus transformed) and 4) L929 cells (murine, fibro-sarcoma). All cell lines were exposed to 1-8 mM HEMA (a methacrylate monomer that both dental personnel and dental patients are exposed to during treatment). The endpoints used to measure cellular responses to HEMA were 1) viability (MTT assay), 2) cell death analyses (fluorescence microscopy of Hoechst/propidium iodide stained cells) and 3) cell growth pattern (flow cytometry of DAPI-stained cells). The relative viability (% viable cells compared to unexposed cell culture) after 24 h HEMA exposure (8 mM) varied from 86 % (L929 cells) to 32 % (RAW 264.7 cells). Similarly, the portion of dead cells varied from 4% (L929 cells) to 72 % (RAW 264.7 cells). HEMA also caused altered cell growth pattern in some of the cell lines. In A549 cells, an increased portion of cells in S-phase was measured, while a decreased portion of cells in S-phase was observed in RAW264.7 cells. No significant difference was measured in exposed BEAS-2B and L929 cells. In summary, our results show that the outcome of an *in vitro* cytotoxicity test may depend on the cell line used.

1238 Thrombogenicity Testing Results for Legally Marketed Comparator Devices (LMCD): Comparison between the Traditional NAVI Assay and an *In Vitro* Ovine Blood Loop

Y. Chen, and M. E. Smith. *American Preclinical Services LLC, Minneapolis, MN.*

ISO 10993-4 thrombogenicity testing is widely used for meeting regulatory requirements for approval of blood-contacting medical devices. We are continuing to develop an *in vitro* thrombogenicity assay using minimally heparinized ovine blood that has been successfully used in lieu of the non-anticoagulated venous implant (NAVI) assay in recent submissions with the US FDA. Our blood loop assay is primarily used for testing thrombogenicity of test articles (catheter-shaped devices typically less than 18 Fr) and comparing them to similar predicate devices. We also frequently perform the traditional NAVI model in canines. The NAVI test requires 2-3 naïve animals, typically large dogs, and also compares the performance of a test article (a new product or new manufacturing procedures/materials in development) to a predicate. In both the blood loop and the NAVI assays, predicate devices are typically legally marketed comparator devices (LCMD). One observation that is rarely discussed are the high thrombogenicity scores of LCMD's in the NAVI assays. Ideally it is expected that the test article will have an equal or lower relative thrombus score than the LCMD. Using the ISO 10993-4, Table C.2 scoring scheme, a score of 2 or lower (<50% of surface covered with thrombus) is associated with minimal to no risk for thrombogenicity in clinical use. If the LCMD scores a 3 or higher (>50% of surface covered with thrombus), the interpretation of the test becomes problematic even if the test article is equivalent to the LCMD. In this retrospective analysis, we have compiled thrombogenicity scores of control/predicate devices (limited to assays which used LMCD's), both the discrete score from the classification standard scoring scheme and the continuous values obtained from the percent surface area associated with thrombus. We have compared results from >75 NAVI studies and >50 *in vitro* blood loop studies. These compiled results show ~25% of LMCDs score >3 (>50% of the surface covered in thrombus) in the NAVI model while <5% of LMCDs score >3 (>50% thrombus) in the Blood-Loop assay. In addition, the median score and mean % thrombus for LMCD in the blood loop assay is substantially lower that the median and mean scores for LMCD in the NAVI assay. This retrospective assessment highlights a high proportion of false positive scores for LMCD in a large number of NAVI assays. This is an alarming observation; that a standardized assay so frequently yields scores for LMCD's in a range that would predict a risk for clinical use (>50% of material surface covered with thrombus). Overall, these results are strong supportive evidence for the superiority of the Blood Loop assay over the *in vivo* alternative NAVI.

1239 Dose- and Time-Dependent Formation of γ-H2AX, a Biomarker for Early Detection of Bladder Carcinogens, and Its Potential Role in Tumorigenesis in the Rat Urinary Bladder

T. Yamada[1,2], T. Toyoda[1], K. Matsushita[1], T. Morikawa[1], and K. Ogawa[1]. *[1]National Institute of Health Sciences, Kawasaki, Japan; and [2]Tokyo University of Agriculture and Technology, Tokyo, Japan.*

We previously reported that immunostaining for γ-H2AX, a biomarker of DNA damage, in the rat urinary bladder is useful for early detection of bladder carcinogens in 28-day toxicity studies. Here, we examined the dose and time dependency of γ-H2AX formation and its role in tumorigenesis in the rat urinary bladder. In experiment 1, 6-week-old male F344 rats were orally administered *N*-butyl-*N*-(4-hydroxybutyl)nitrosamine (BBN; 0%, 0.0001%, 0.001%, 0.01%, 0.02%, or 0.05% in drinking water), a genotoxic bladder carcinogen, and melamine (0%, 0.3%, 1.0%, or 3.0% in the diet), a nongenotoxic bladder carcinogen, for 2 days or 4 weeks. Immunohistochemical analysis demonstrated that γ-H2AX-positive epithelial cells in the bladder mucosa were significantly increased in a dose-dependent manner in the BBN and melamine groups. The ratios of γ-H2AX-positive cells at week 4 in the BBN and melamine groups were higher than those on day 2, demonstrating a time-dependent increase in γ-H2AX formation. Immunofluorescence staining showed that although γ-H2AX formation and Ki67 expression were colocalized in bladder epithelial cells of rats in the melamine groups, many γ-H2AX single-positive cells without Ki67 expression were detected in the BBN groups, suggesting that the associations of genotoxic mechanisms induced by chemicals could be determined by analyzing the colocalization of γ-H2AX and Ki67. In experiment 2, 6-week-old male F344 rats were administered 500 ppm BBN for 4 weeks and necropsied at 0, 2, 4, 8, 16, or 32 weeks. Although diffuse simple hyperplasia found at week 0 was recovered to the normal-like urothelium until week 4, newly developed focal proliferative lesions, such as focal simple and papillary/nodular hyperplasia, were increased after week 4 and progressed to papilloma and carcinoma in a time-dependent manner. γ-H2AX-positive cells persisted at significant high levels not only in focal proliferative lesions but also in the normal-like urothelium, even after withdrawal of BBN. These results suggested that γ-H2AX formation was increased in a clear dose- and time-dependent manner. In addition, γ-H2AX could be a useful biomarker associated with the development of bladder tumors rather than a temporal response to chemicals.

1240 Characterization of Casting-Induced Muscle Injury and Inflammation in a Mouse Model

D. M. Hamlin, A. E. Schultze, R. L. Johnson, and D. G. Hall. *Eli Lilly and Company, Indianapolis, IN.*

The mouse casted limb (immobilization) model induces skeletal muscle atrophy and may be used to study drug efficacy for recovery from atrophic conditions. In this model, one hind limb is casted to induce atrophy and the contralateral uncasted limb is typically used as an unaffected comparator. Uncasted mice (shams) are often included for reference. Two studies conducted in female C57BL/6J mice employed 2 weeks of casting followed by 1 week of uncasted recovery, with cohorts necropsied at interim time points during the casting and recovery phases. In study 1, skeletal muscle degeneration biomarkers [skeletal troponin I (sTnI) and myosin light chain (Myl3)] and inflammation biomarkers [neutrophil gelatinase-associated lipocalin (NGAL) and tissue inhibitor of metalloproteinase (TIMP1)] were measured in serum and in tissue lysates (from casted and contralateral limbs separately). Increased serum concentrations of sTnI and Myl3 24 and 48 hours after casting with a correlative decrease of these markers in tissue lysates were indicative of muscle degeneration and release of sarcomeric proteins. Although there were small increases in NGAL and TIMP1 during 2 weeks of casting, these inflammation biomarkers in serum and tissue lysates increased markedly and were concurrent with minimal changes in the muscle-related degeneration biomarkers after cast removal, which allowed re-loading of both the casted atrophied limb and the contralateral leg. In study 2, to correlate histologic changes with the serum biomarkers, skeletal muscles (gastrocnemius, quadri-

ceps, biceps femoris) and skin from casted and contralateral limbs were examined microscopically at similar time points explored in study 1. The histologic examination confirmed muscle degeneration and associated inflammation in both the casted and contralateral limbs, but also revealed inflammation related to skin ulceration over the casted leg. The potential impact of muscle degeneration in the non-immobilized limb and cast-related cutaneous ulceration should be considered in the design and interpretation of studies using the casted mouse model.

1241 Elucidating the Gut Microbiome-Metabolome Correlation in Wistar Rats

A. Murali[1], H. Cameron[2], V. Giri[1], C. Behr[1], S. Sperber[1], N. Habermehl[1], T. Walk[3], and B. van Ravenzwaay[1]. *[1]BASF SE, Ludwigshafen am Rhein, Germany; [2]BASF Plant Science LP, Research Triangle Park, NC; and [3]BASF Metabolome Solutions GmbH, Berlin, Germany.*

The gut microbiome is known to play a huge role in the health and development of the host organism. 'Omics technologies' can provide better understanding of gut microbial functionality. We investigated the correlation between gut microbial communities with changes in the metabolome of plasma, feces and caecum matrices following a 28-day oral treatment with 6 antibiotic (streptomycin, vancomycin, roxithromycin, sparfloxacin, lincomycin and clindamycin) in rats. A predictive functional profiling was developed to predict the metagenomic composition and to associate it with the metabolome profiles. Antibiotics were observed to specifically alter the levels of lipids and fatty acid, bile acid and amino acid metabolism. In particular hippuric acid and indole-3-acetic acid were strongly downregulated. Tested antibiotics had specific influences on the gut flora composition and the two lincosamides show very similar effects, confirming a class-dependent effect. Relative abundances of family-level taxonomy of different treatments were derived. Streptomycin treatment showed similar bacterial abundance as the controls, with Bacteroidetes and Firmicutes as the dominant families. Vancomycin and Sparfloxacin showed reduced Bacteroidetes and Proteobacteria families while the two lincosamides showed increased Firmicutes and Proteobacteria levels. Dose-dependent alterations in Actinobacteria levels was observed in lincomycin treatment. PCoAs of microbiome data showed clustering similar to the PCA of the metabolome data, indicating dependence of various metabolite levels on the gut community. Strong correlations between the gut flora composition (fecal microbiome) with the caecum and feces metabolome profiles of the antibiotic treated rats have been observed. Whereas the correlation with plasma metabolic profiles have been observed to be weaker in comparison. Differential gene regulation with respect to antibiotic treatments was observed and could be associated with the metabolite profiles. Hence, the gut microbial composition but also gene regulation profile could be correlated with the metabolome data.

1242 Mechanistic Modeling Aids in the Interpretation of Alanine Aminotransferase Elevations Associated with Clinical Idiosyncratic Drug-Induced Liver Injury

R. J. Church[1,2], G. Taneja[3], and P. B. Watkins[1,2]. *[1]University of North Carolina Institute for Drug Safety Sciences, Research Triangle Park, NC; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [3]DILIsym Services Inc., Research Triangle Park, NC.*

The DILIsim Initiative, a public-private partnership, has been developing mechanistic modeling software, DILIsym®, that can use serial assessments of serum alanine aminotransferase (ALT) to estimate % hepatocyte loss and corresponding elevations in serum total bilirubin (TBIL) due to the resulting impaired liver function. The model parameters were optimized to data from acetaminophen overdose patients where observed peak TBIL values were correlated with % hepatocyte loss assessed by liver biopsy (PMID 1214189). Although the modeling has been used in regulatory communications to refine interpretation of Hy's Law cases [i.e. patients experiencing elevations in ALT > 3 X upper limit of normal (ULN) and TBIL> 2 X ULN], the ability of DILIsym to predict peak TBIL values in patients with idiosyncratic drug-induced liver injury (IDILI) has not be tested. An equation P_{ALT}, has recently been proposed to estimate the hepatocyte loss predicted by DILIsym (PMID 30303523). Serial serum ALT values were curve fit (DILIsym v8A) from lab data obtained in clinical drug trials from 39 IDILI patients (n=28 due to anti-tuberculosis treatments and n=11 due to other drugs). P_{ALT} was calculated as: P_{ALT}= ALT_AUC*Peak $ALT^{0.18}/10^5$ $((U/L)^2*h$. The peak TBIL values predicted by DILIsym were significantly correlated with the observed peak TBIL values (r=0.3595; $p<0.05$) and this correlation improved (r=0.7715; $p<0.0001$) as expected with the removal of cholestatic/mixed IDILI cases (R<5, n =3) and cases in which gaps in blood sampling times likely precluded measurement of the true ALT peak (n=5). We next examined the accuracy of the model in predicting Hy's Law cases. TBIL 2 X ULN over or under predictions only occurred in n=3 patients (<10%). Hepatocyte loss predicted by P_{ALT} strongly correlated with the level of hepatocyte loss predicted by DILIsym (r=0.9411; $p<0.0001$). In this study, DILIsym accurately estimated changes in TBIL due to reduction in global liver function in patients experiencing IDILI. Because P_{ALT} also predicts maximum hepatocyte loss, it should be possible to use this open-source tool to predict peak TBIL levels. Because most drugs causing IDILI have characteristic ALT kinetic patterns, P_{ALT} may be useful in clinical trials to predict the peak ALT level that will be observed before functional impairment occurs.

1243 Discovery of Biomarkers to Differentiate Liver Injury and Benign ALT Elevations

J. H. Vazquez[1], M. M. Clemens[1], F. D. Allard[1], E. U. Yee[1], H. Jaeschke[2], M. D. Hambuchen[3], and M. R. McGill[1]. *[1]University of Arkansas for Medical Sciences, Little Rock, AR; [2]University of Kansas Medical Center, Kansas City, KS; and [3]Marshall University, Huntington, WV.*

Alanine aminotransferase (ALT) is the standard serum biomarker of liver injury, but ALT elevations can occur without tissue damage. Several drugs and diseases are thought to be associated with increased circulating ALT without cell death. Our goal was to identify biomarkers that can differentiate between true liver injury and benign ALT elevations using both animal models and patients. Methods: In an initial experiment, mice were treated with 100 mg/kg dexamethasone (Dex) to induce benign ALT elevations, 300 mg/kg acetaminophen (APAP) to cause true liver injury, or vehicle. Serum was collected for untargeted proteomics. In a second experiment, mice were treated with the same doses of Dex and vehicle, but a lower dose of APAP (175 mg/kg) to achieve milder ALT elevations similar to the Dex model. Serum was collected to confirm results from the first experiment by immunoblotting. In a third experiment, the biomarkers were measured in plasma and serum from APAP overdose patients without liver injury (peak ALT<100U/L; n=5), overdose patients with mild liver injury (peak ALT 100-1,000 U/L; n=10), and clinical trial subjects with mild ALT elevations thought to be benign based on transience and absence of liver dysfunction (n=3). Finally, rats were subjected to bile-duct ligation (BDL) as a model of cholestasis. Serum ALT was significantly increased in APAP (2,368±223 U/L) and Dex (113±18 U/L) treated mice compared to vehicle groups. Results from qPCR, immunoblotting, and enzyme kinetics confirmed that the ALT elevations in the Dex group were due to increased expression in the liver and muscle, and absence of necrosis in livers from those mice was independently confirmed by two blinded pathologists. Proteomics studies identified 165 proteins detectable mainly in serum from the APAP group, including Aldehyde dehydrogenase 1A1 (ALDH1A1), Alcohol dehydrogenase 1 (ADH1), and Argininosuccinate synthetase 1 (ASS1). Similar results were obtained for all three proteins by immunoblotting when the experiment was repeated with the lower dose of APAP to achieve milder ALT elevations (401±127 U/L), and when comparisons between groups were limited to mice with similar ALT values. The results were further confirmed in the patient samples. Interestingly, none of the proteins were elevated in the rat BDL model of cholestasis. Our data indicate that several novel biomarkers may differentiate between hazardous and benign elevations in circulating ALT and may be specific for hepatocellular injury. *Funded in part by the AASLD Foundation and NIH T32 Grant GM106999.*

1244 Novel Proteomic Biomarkers for the Prediction of Renal Recovery from Dialysis-Dependent AKI Patients

L. Yu[1], J. R. Daniels[1], Z. Cao[1], J. Sun[1], R. D. Beger[1], D. Choudhury[2,3], P. M. Palevsky[4], J. Z. Ma[2], and D. Portilla[2,3]. *[1]US FDA/NCTR, Jefferson, AR; [2]University of Virginia, Charlottesville, VA; [3]Salem VA Medical Center, Salem, VA; and [4]University of Pittsburgh, Pittsburgh, PA.*

Acute kidney injury requiring dialysis (AKI-D) is associated with prolonged length of stay, mortality, and progressive chronic kidney disease (CKD) among survivors. Functional renal recovery leading to discontinuation of dialysis is an important clinical outcome. Previous studies have examined few urine or serum biomarkers to predict renal recovery from AKI, however, the performance of biomarkers of renal recovery has not been established. To identify new serum biomarkers that predict renal recovery from AKI-D, study day 8 samples from 76 patients enrolled in the Veteran's Affairs/National Institutes of Health Acute Renal Failure Trial Network study were analyzed by the slow off-rate modified aptamers scan (SOMAscan) proteomic platform to profile 1305 proteins in each sample. Of these patients, 38 recovered kidney function and dialysis was discontinued, while another 38 patients remained on dialysis by day 28. Changes in the serum levels of 81 proteins, 45 of which increased and 36 of which decreased, were detected when comparing samples of patients who were taken off dialysis versus patients who remained on dialysis

by day 28. Serum levels of mortality-associated proteins such as FGF23 and IL-6 were reduced in those that recovered, which was corroborated by Olink analysis. Several kinases related to growth and survival increased in recovered patients, such as tyrosine-protein kinase Fyn, protein Wnt-7a, and Myc proto-oncogene protein, which either regulate glomerular integrity through the Wnt/beta-catenin signaling pathway or regulate angiogenesis, illustrating potential mechanisms of kidney recovery. Receiver operating characteristic (ROC) analysis resulted in AUC of 0.64-0.75 for these kinases and inflammation biomarkers. Thus, this study identifies potential novel predictive biomarkers of renal recovery from AKI-D patients.

1245 Decreased Trf1-Trf2 Negatively Regulates Telomere Length and DNA Damage Foci in Rat Liver Tissue after a High-Fat Diet and Welding Fume Exposure

M. Shoeb. *NIOSH, Morgantown, WV.*

Telomeric DNA and shelterin proteins prevent loss of essential genetic information during cell division. Telomere attrition resulting in DNA damage contributes to liver pathology. The telomeric repeat-binding factor 1 (Trf1) and 2 (Trf2), and the protection of telomere 1 (Pot1) are involved in telomere maintenance by preventing telomere end-to-end fusion through proper folding of the telomere. The goal of this study was to describe the regulation of expression of these genes and proteins along with their relationship to telomere length in an animal model comparing different diets and a simulated occupational exposure. Male Sprague-Dawley rats were maintained on a regular (REG) or high fat (HF) diet for 24 wk. At wk 7 during diet maintenance, groups of rats from each strain were exposed by inhalation of stainless-steel welding fume (WF; 20 mg/m^3 x 3 hr/d x 4 d/wk x 5 wk) or filtered air until wk12, at which time some animals were euthanized. A separate set of rats were allowed to recover from WF exposure until the end of the 24 wk period. At 12 and 24 wk, the effect on shelterin proteins and telomere length was examined in peripheral blood mononuclear cells (PBMCs) and homogenized liver tissue. Double- and single-stranded telomere DNA-binding proteins Trf1/Trf2 and Pot1, as well as telomeric DNA damage foci λH2AX and 53BP1, were influenced at 12 wk and 24 wk by both diet and exposure. A significant reduction in telomere length in PBMCs was observed in the WF+REG and Air+HF groups, which was further shortened in WF+HF group. However, an opposite telomere length trend was observed in livers obtained from the same groups at both 12 and 24 wk. ATM kinase phosphorylation and DNA damage activation was observed in the liver at 12 wk of WF exposure. Single-stranded binding protein Pot1, initially up-regulated at 12 wk in the WF+REG group, was later down-regulated in liver tissue at 24 wk along with the WF+HF group. In conclusion, our data suggest that disruption/down-regulation of single-stranded Pot1 and double-stranded Trf1/Trf2 expression in liver might act as an anti-apoptotic mechanism in the DNA-damage response leading to multistep liver injury by involvement in the telomere response to diet changes and WF exposure.

1246 A Comparative Analysis of KIM-1 as a Kidney Injury Biomarker in Rat: Plasma and Urine Protein Levels and Kidney Gene Expression

K. Vlasakova. *Merck & Co. Inc., West Point, PA.*

Kidney injury molecule-1 (Kim-1), also known as T-cell immunoglobulin mucin-1 (TIM-1) and hepatitis A virus cellular receptor 1 (havrc1) is now a well-established urinary biomarker for detection of kidney proximal tubule injury in rat and human. It has been shown that urinary Kim-1 outperforms traditional serum biomarkers blood urea nitrogen (BUN) and serum creatinine (SCr). However, unlike blood, urine is often not collected in animal studies conducted early in drug development and therefore a sensitive blood-based biomarker of kidney injury would be beneficial. We have evaluated Kim-1 as a potential blood-based (plasma) kidney toxicity biomarker and compared its performance to that in kidney tissue and urine, and also to the performance of BUN, SCr and histopathology outcomes in 10 rat *in vivo* studies with known kidney toxicants. To confirm specificity, Kim-1 was also measured in plasma of 11 rat studies with target organ toxicities other than kidney. The most sensitive Kim-1 endpoint (highest fold change observed) was gene expression in kidney. RNA increases were occasionally detected prior to the onset of injury as defined by histopathological changes as shown by ROC exclusion and inclusion models (AUC exclusion = 0.99, AUC inclusion = 0.81). While urinary Kim-1 generally matched kidney RNA expression, smaller fold changes observed with RNA were often not observed when urinary Kim-1 was evaluated. Plasma Kim-1 was the least sensitive method of kidney injury detection, increasing only when higher grade kidney injury was observed, and its performance was comparable to that of the BUN and SCr biomarkers (AUC BUN 0.84, KIM-1 0.85, SCr 0.78 in exclusion model). Plasma Kim-1 is mostly unchanged in non-kidney injury studies; however, in cases where T-cell numbers are decreased (cyclophosphamide) or increased (concanavalin A), plasma Kim-1 reflects those changes, indicating that the source of plasma Kim-1 could be both immune cells and kidney. In conclusion, even though plasma Kim-1 increases with kidney injury, it did not outperform traditional serum biomarkers BUN and SCr. Kim-1 gene expression analysis followed closely by urinary Kim-1 protein measurement are the most sensitive Kim-1-based endpoints to detect kidney injury.

1247 Detection of Anti-Polyethylene Glycol IgM Antibodies in Healthy Individuals

J. Fang[1], Y. Tang[1], S. R. Roffler[2], and F. A. Beland[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]Institute of Biomedical Sciences, Academia Sinica, Taipei, China.*

Polyethylene glycol (PEG) is a biocompatible polymer that is widely used in biopharmaceuticals to increase bioavailability, reduce frequency of administration, and optimize pharmacokinetics. Anti-PEG antibodies have been detected in healthy individuals and may result in decreased efficacy and alter pharmacokinetics of pegylated biopharmaceuticals; however, the prevalence of anti-PEG antibodies is unclear. We have developed a flow cytometry assay to detect anti-PEG IgM antibodies and have assessed their presence in the plasma of 300 heathy individuals. Anti-PEG IgM antibodies were observed in 45% of the individuals, with values ranging from 15 ng/ml to 12 µg/ml. Their presence was confirmed by Western blotting assay. The prevalence of positive samples was 60% in individuals 15-24 years old, 43% in individuals 25-64 years old, and 20% in individuals ≥ 65 years old. The prevalence of anti-PEG IgM antibodies did not differ between sexes or among races (Black, Caucasian, or Hispanic). Our study indicates that the flow cytometry can be used to measure the presence of anti-PEG IgM antibodies in healthy individuals.

1248 Can Ethyl Glucuronide in Hair Be Associated with Alcohol Use in Heavy Drinkers?

S. Ghosh, R. Jain, R. Rao, S. Jhanjee, and A. K. Mishra. *AIIMS, New Delhi, India.*

Ethyl Glucuronide (EtG) in hair is proposed as a biomarker for assessment of long-term alcohol consumption. The present study evaluated the association between EtG in hair with alcohol use. Using cross-sectional study design, ninety-one alcohol dependent patients (diagnosed as per International Classification of Diseases, Version-10) with last alcohol consumption within 24 hours were recruited after their consent. The subjective information included: socio-demographic details, alcohol use details and alcohol amount consumed in past three months (by beverage-specific quantity-frequency method). Three centimetre of hair from the posterior vertex region of the head was collected and analysed using gas chromatography-mass spectrometry. The obtained EtG values were compared and correlated with the amount of alcohol consumed. The mean age of the participants was 37.7 (SD: 7.7) years. All participants used alcohol daily, locally brewed liquor being the preferred beverage (51.6%). The mean age of onset of daily alcohol consumption was 27.7 (SD:6.3) years and the mean age of onset of early morning drinking was 32.8 (SD:7.3) years. Mean quantity of alcohol consumed in past three months was 261.7 grams per person per day. All hair samples showed EtG value higher than the cut-off (i.e. 30pg/mg). EtG values expressed a positive correlation ($r = 0.508$, $p = 0.01$) with quantity of alcohol consumed. A simple linear regression was calculated to predict EtG values based on amount of alcohol consumed in last three months, $b= 0.608$, $f (89) =4.213$, $p<0.001$. A significant regression equation was found; $F (1,89) = 52.084$ $p<0.001$, with an R^2 of 0.369. Wilcoxon signed rank test showed statistically significant differences between the hair EtG and quantity of alcohol consumed ($Z= -8.28$, $p<0.001$). The study showed that EtG hair can also be objectively used to assess the quantity of alcohol consumed.

1249 Comparison of Routine Clinical Pathology Parameters of Sprague Dawley Rats by Different Blood Collection Sites

H. Pei, and M. Chen. *WuXi AppTec, Suzhou, China.*

The Sprague Dawley rat (*Rattus norvegicus*) is commonly used in preclinical toxicity studies. Blood collection sites from either abdominal aorta or vena cave at termination are routinely used for a preclinical study. However, it is certainly necessary to evaluate the drug potential toxicity at interim period of a given study by collecting blood from the jugular vein for clinical pathology evaluations for some sub-chronic and/or long-term toxicology studies.

Therefore, it is important to evaluate the variation of clinical pathology data by the different sites. A comparison of common hematology and clinical pathology data from different blood collection sites, i.e., at the abdominal aorta and the jugular vein, was made. Approximately 30 animals' data for each sex was collected. Data of control animals from completed toxicology studies were used to see if there were any difference for clinical pathology data at different blood collection sites. Analysis of the clinical chemistry data showed that significantly reduced glucose (GLU) (98% for male and 76% for female) was noted for the blood samples from jugular vein when compared with the samples from abdominal aorta. Slightly increase in total protein (TP), albumin (ALB), alkaline phosphatase (ALP) were observed for the samples from jugular vein compared with the samples from abdominal aorta. Difference in clinical hematology parameters included increases in leukocyte (WBC), erythrocyte (RBC), and hemoglobin (HGB) the samples from jugular vein relative to the samples from abdominal aorta. Analysis of clinical chemistry showed that a moderate difference was noted at glucose due to blood collection site difference. Whilst the data showed no significant difference in rest parameters of clinical pathology between the two sites. It is strongly recommend that the separate data sets are maintained for the interpretation of clinical pathology data.

PS 1250 A 12-Month Randomized Controlled Trial Evaluating the Effects of Switching from Smoking to Using a Tobacco Heating Product on Health Effect Indicators: Preliminary Findings

N. Gale, M. McEwan, F. Lowe, G. Hardie, J. K. Ebajemito, O. M. Camacho, and C. J. Proctor. *British American Tobacco (Investments) Ltd, Southampton, United Kingdom.* Sponsor: M. Gaca

Tobacco harm reduction; replacing smoking with potentially reduced-risk nicotine products, could offer substantial health benefits to those who will otherwise continue to smoke. Confined 5-day clinical studies have shown that toxicant exposure reduces when using the glo tobacco heating product compared to smoking cigarettes. While the short-term confinement data are encouraging, longer term data is needed to determine if toxicant reductions are sustained and if those reductions translate into an improvement in a variety of health effect indicators. This was investigated in the current study. Regular smokers were randomized to either continue smoking (CTS; N=79) or glo use (N=197) for one year. Arms of never-smokers (N=40) and of regular smokers intending to quit (N=190) who were provided with assistance to do so were also enrolled. Biomarkers of exposure (BoE) to a suite of cigarette smoke toxicants were measured at baseline and throughout the study. Given the potential for product use compliance issues in the study cohorts, the acrylonitrile haemoglobin adduct; *N*-(2-cyanoethyl)valine (CEVal) was also measured to provide longer-term information on non-compliant combustible product use. A planned interim analysis was performed on a subset of subjects (CTS (N=33), glo (N=76), cessation (N=133) and never-smoker (N=37)). Rapid and sustained decreases from baseline for BoE endpoints in the glo arm were observed, including markers for NNK (110 ng/24h; 60%), benzene (3.55 µg/24h; 89%), acrylonitrile (151 µg/24h; 91%), crotonaldehyde (313 µg/24h; 74%) and 1,3-butadiene (2.92 µg/24h; 86%), approaching or reaching similar levels to the smoking cessation and/or never-smoker arms. Furthermore, preliminary data for biomarkers of potential harm (BoPH) show improvement in the areas of oxidative stress, inflammation and platelet activation. Pre-specified thresholds for CEVal indicate a high level (80%+) of compliance in this interim analysis. The findings demonstrate that when smokers switched from smoking combustible cigarettes to using glo, reductions in their exposure to smoke toxicants were sustained for the 90-day period, and favourable changes were also observed in BoPH. This shows that glo is a potentially reduced exposure tobacco product.

PS 1251 Gulf War Illness as a Potential Autoimmune Disease: Neurodegeneration-Induced Autoantibodies against Neural Proteins

M. B. Abou-Donia[1], M. V. Brahmajothi[1], E. S. Lapadula[1], L. A. Conboy[2], E. Kokkotou[3], E. Jacobson[4], N. Klimas[4], and K. Sullivan[5]. *[1]Duke University Medical Center, Durham, NC; [2]New England School of Acupuncture, Massachusetts College of Pharmacy and Health Sciences, Boston, MA; [3]Beth Israel Deaconess Medical Center, Boston, MA; [4]Nova Southeastern University, Fort Lauderdale, FL; and [5]Boston University, Boston, MA.*

Previously, we used our autoantibodies against neural proteins to develop diagnostic markers in veterans of the 1991 Gulf War (GW). Approximately one third of the American military personnel who served in the GW experienced chronic symptoms of Gulf War Illness (GWI), including: fatigue, headaches, memory and concentration problems, joint pain and gastrointestinal distress. In the present study, we used western blot assay to screen plasma for the presence of autoantibodies (AA) against the following neural proteins: neurofilament triplet proteins (NFP), tubulin, microtubule associated tau proteins (tau), microtubule associated protein-2 (MAP-2), myelin basic protein (MBP), myelin associated glycoprotein (MAG), calcium-calmodulin kinase II (CaM-KII) and glial S100B protein. Plasma reactivity was measured as arbitrary chemiluminescence units. The study included 180 veterans with GWI and 52 non-veteran asymptomatic controls. None of the participants showed any significant change in the level of AA against S100B. Veterans with GWI showed increased AA when compared with controls in descending order: MAP-2 > MBP > NFP > Tubulin > Tau > MAG > SNCL > GFAP > CaMKII. We have demonstrated that veterans with GWI had consistent patterns of increased autoantibodies against neural proteins. These autoantibodies may also be markers of disease and may contribute to the pathogenesis of GWI (i.e, they may be the cause for the symptoms). Such autoantibodies can cross the damaged BBB into the brain resulting in brain alterations characteristic of GWI. Our conclusion is consistent with results other recent studies. We hypothesize that neurodegeneration, resulting from combined chemical exposures in GW veterans, is the cause of GWI. Following brain injury neural proteins cross the breached BBB into circulation, triggering the formation of IgG autoantibodies. We propose that these circulating autoantibodies may serve as biomarkers for screening, diagnosis and treatment of GWI. *Supported in part by DOD Contract No. W81XWH-15-1-0641, W81XWH-15-1-0640, and W81XWH-18012.*

PS 1252 Impaired Toll-Like Receptor 3 (TLR-3) and Retinoic Acid Receptor Beta (RARβ) Expression in Poly I:C Activated Prostate Stem Cells Malignantly Transformed with Sodium Arsenite

I. Alvarado-Morales[1], E. Tokar[2], V. Olivares-Illana[1], E. Layseca-Espinosa[1], and C. Escudero-Lourdes[1]. *[1]Universidad Autónoma de San Luis Potosí, San Luis Potosí, Mexico; and [2]NIEHS/NTP, Research Triangle Park, NC.*

Cancer stem cells (CSCs) are associated with the initiation, progression and recurrence of cancer. The non-tumorigenic prostate epithelial cell line, RWPE-1, chronically exposed to iAs develops into an aggressive cancer cell line (CAsE-PE) and shows increased expression of CSC markers SOX2, Notch-1, CD44 and CD133, as well as multidrug resistance proteins. A therapeutic strategy in prostate cancer is the administration of agents that promote the differentiation of CSCs, such as retinoic acid (RA), which interacts with its specific receptor (RARβ) to induce the expression of genes associated with differentiation and decrease CSC markers. The co-administration of RA with the synthetic ligand of TLR3, polyinosinic:policitidylic acid (PIC), induces both inflammatory and pro-apoptotic responses, as well as the differentiation of CSCs by increasing the expression of RARβ. Synergy between RA and PIC has proven to be effective in prostate cancer *in vitro* models, sensitizing CSCs to conventional chemotherapies and inducing apoptosis. However, our group demonstrated that the iAs malignantly-transformed cell lines CAsE-PE and As-CSCs, show a significant decrease in TLR3 expression, suggesting that the combination of RA+PIC may be ineffective in inducing cell death in these cells. The aim of this study was to determine whether the administration of PIC+RA can induce apoptosis and cell differentiation in these iAs-transformed cell lines. As-CSCs and CAsE-PE, and their respective normal counterparts, WPE-stem and RWPE-1, were exposed to PIC, AR or the combination. Results showed that in As-CSC and CAsE-PE cells, the combination of RA+PIC did not modify the expression of SC markers CD44, CD133 and SOX2, nor induce significant apoptosis, compared to non-transformed parental cells, RWPE-1 and WPE-stem. These results suggest that iAs induces a decrease in TLR3 expression making these cells non-responsive to the treatment with PIC+RA.

PS 1253 Identification of Mechanistic microRNA Biomarkers for Ketoconazole-Induced Liver Injury

D. Li, B. Gong, Z. Liu, B. Knox, W. Zhuang, W. Tong, and B. Ning. *US FDA/NCTR, Jefferson, AR.*

Drug induced liver injury is a major reason for drug withdrawal from the market and termination of clinical trials during drug development. Increasing studies have indicated that microRNAs (miRNAs) are critical modules in hepatotoxicity. However, the potential of using miRNAs as robust and reliable biomarkers for hepatotoxicity remains to be further elucidated, especially via uncovering the underlying mechanisms. In this study, we employed a systematic approach to identify mechanistically-meaningful miRNAs associated with hepatotoxicity induced by ketoconazole. We performed miRNA-sequencing with liver tissues from Sprague-Dawley rats treated with ketoconazole at three doses (10, 30 and 100 mg/kg) and four time points (3, 7, 14 and 28 days).

We profiled miRNA expression using the miRDeep2 software and identified differentially expressed miRNAs (DEMs) at different treatment conditions using DESeq2, an R/Bioconductor package. The time- and dose-dependence of miRNA differential expression were then examined to explore miRNAs with early and sensitive response to ketoconazole treatment. To understand the mechanism underlying the association of the DEMs with ketoconazole-induced hepatotoxicity, we identified protein coding genes targeted by these DEMs via computation prediction. Using ArrayTrack and Ingenuity Pathway Analysis tools, we conducted pathway analysis to identify biological pathways that DEMs and their target genes were enriched in. Finally, candidate miRNAs responsible to ketoconazole-induced hepatotoxicity were proposed.

1254 Circulating miRNA Signatures Associated with NAFLD in Obese Adolescents

H. Lin[1,2], E. Tas[1,2,3], E. Børsheim[1,2,3,4], B. Spray[4], and K. E. Mercer[1,2,3]. *[1]Arkansas Children's Nutrition Center, Little Rock, AR; [2]University of Arkansas of Medical Sciences, Little Rock, AR; [3]Center for Childhood Obesity Prevention, Little Rock, AR; and [4]Arkansas Children's Research Institute, Little Rock, AR.*

Accumulating evidence indicates circulating microRNAs (miRNAs) potentially play important roles in metabolic organ crosstalk, thereby acting as non-invasive biomarkers or indicators for diagnosis and progression of metabolic disorders. In this study, we aimed to investigate serum miRNA signatures of obesity-associated non-alcoholic fatty liver disease (NAFLD) in adolescents and identify circulating miRNA markers to improve the risk prediction of NAFLD in obese children. Thirty-five, obese (BMI≥ 95th percentile), adolescents (aged 10-17 years) were recruited from a weight management clinic. Fasting blood sampling and liver MRI for hepatic fat quantification were performed at the initial visit and a 6-month follow up visit. Serum miRNA signatures were determined by quantitative RT-PCR-based miRNA array (180 miRNAs) and their associations with clinical indices, i.e. ALT, HOMA-IR, were analyzed using Pearson's correlation analysis. Profiled miRNAs were assessed using ROC curve analysis to discriminate NAFLD (hepatic fat ≥ 5%) versus non-NAFLD (hepatic fat < 5%). Seven miRNA expressions, miR-150, -221, -155, -122, -24a, -21, and -34a were significantly increased in the NAFLD group compared to the non-NAFLD group ($p < 0.05$). Of them, miR-34a and miR-122 were positively correlated with ALT levels ($p < 0.05$) and were potential discriminators between NAFLD and non-NAFLD (AUROC = 0.782, $p = 0.005$ for miR-34a; AUROC = 0.741, $p = 0.016$ for miR-122). Moreover, mir-21, which is associated with steatohepatitis, was highly expressed (5.6-fold) in the NAFLD group at the 6-month follow up compared to the initial visit ($p < 0.05$). These findings support the use of miRNAs as biomarkers for NAFLD-diagnosis and progression in adolescents.

1255 Optimization of Tissue and RNA Preparation to Facilitate RNA-Seq Analysis of Metabolic Syndrome Biomarkers in a Diversity Outbred Mouse Population

N. Bell[1], D. You[2], M. Huang[2], B. Elgart[2], N. Clausen[2], M. Weick[2], N. Reeves[2], J. Foley[2], G. Solomon[2], M. DeVito[2], and A. H. Harrill[2]. *[1]East Carolina University, Greenville, NC; and [2]NIEHS, Research Triangle Park, NC.*

With obesity steadily rising in the US, development of assay systems that enable identification of adverse chemical effects on a backdrop of genetic variability and metabolic disease becomes increasingly important toward protection of public health. The NTP is investigating use of the Diversity Outbred (DO) mouse population as a surrogate for human diversity and has performed a 13-week high fat diet study to investigate transcriptional biomarkers that inform development of metabolic disease in susceptible individuals. As part of a summer undergraduate internship at NIEHS, RNA isolation conditions were optimized from three tissues relevant to metabolic syndrome - skeletal muscle, liver, and white adipose. To optimize the experimental workflow, a pilot study was performed to optimize variables that affect RNA yield and integrity. Test variables included the tissue disruption tube type and the effect of freezing post-homogenate tissue samples. Tissues were homogenized in either Lysing Matrix A or Lysing Matrix D tubes (MP Biomedical). The D tube proved to be the most favorable choice for complete tissue disruption. Following tissue homogenization, RNA was extracted, and the yield and integrity assessed. RNA concentrations from 10 mg liver (68.5 ng/µL to 259 ng/µL) and 10 mg muscle (3.5 ng/µL to 57.1 ng/µL) were acceptable for RNA-seq analysis. Increasing tissue sample input from 10 mg to 60 mg yielded satisfactory concentrations for adipose (11 ng/µL to 69 ng/µL). There was no significant difference in RNA quantity or quality between fresh and frozen post-homogenized samples (RNA Integrity Number greater than 8). However, for efficient workflow optimization, freezing the homogenates increased sample throughput. In summary, there was no significant difference in RNA yield or quality when freezing the tissue homogenate, therefore frozen homogenate was used to optimize the workflow. Lysing matrix tube D was preferable to use because there was less foaming, complete tissue disruption, and a clear homogenate. 10 mg of liver tissue, 20 mg of muscle tissue, and 60 mg of adipose tissue was used for RNA extraction. Optimized assay conditions identified here were carried forward to the DO transcriptomic study.

1256 Exploration of Small RNA Biomarkers in Serum Exosomes for Testicular Injury in Rats

R. Kawata[1,2], T. Kagawa[1], S. Oda[1], and T. Yokoi[1]. *[1]Nagoya University Graduate School of Medicine, Nagoya, Japan; and [2]Otsuka Pharmaceutical Co. Ltd., Tokushima, Japan.*

Testicular injury is often observed in a drug development. Serum hormones are usually used as non-invasive biomarkers for testicular injury. However, sensitivities of the markers are low. Therefore, it is difficult to monitor testicular injury in pre-clinical and clinical drug developments. In recent years, molecules in body fluid exosomes attract attention as disease biomarkers such as cancer. In this study, small RNAs in serum exosomes were analyzed for identifying non-invasive biomarkers of testicular injury in rats, which are mainly used in a pre-clinical drug development. Testicular injury models in rats were prepared by a single oral administration of 2000 mg/kg ethylene glycol monomethyl ether (EGME) or 400 mg/kg carbendazim (CBZ). Spermatocytes degeneration and sertoli cells vacuolation were observed in the testes in EGME-administered rats. Spermatocytes degeneration and dilation of seminiferous tubules with shedding of seminiferous epithelial cells were observed in CBZ-administered rats. Exosomes were isolated from serum of these models by an ultracentrifugation method, and exosomal small RNA-seq analysis was performed. The analysis identified some small RNAs that fluctuated in common between the two models, and selected miR-423-5p and miR-128-3p as candidate markers. For qPCR validation of the candidate markers, testicular injury models were further prepared by a single oral administration of 60 mg/kg 1,3-dinitrobenzene (1,3-DNB) or 500 mg/kg nitrofurazone (NF) in which spermatocytes degeneration and sertoli cells vacuolation were observed. In qPCR analysis, both exosomal miR-423-5p and miR-128-3p levels were upregulated in EGME, CBZ and NF models, but not 1,3-DNB model in which severe hemolysis was observed. On the other hand, the miRNA levels in serum samples did not change significantly in these models. In conclusion, we identified miR-423-5p and miR-128-3p in serum exosome as biomarkers for testicular injury in rats.

1257 Role of Iron Status in Manganese Toxicokinetics in Humans

Y. Lin, M. Wright, P. Schlosser, A. Kadry, S. Vulimiri, and S. Ramasamy. *US EPA, Washington, DC.*

Manganese (Mn) is both an essential trace element and a toxic metal that shares similar properties with iron (Fe). Animal studies have shown that Mn is mainly excreted into feces and urine, and that increased absorption and retention of Mn could occur as result of iron-deficiency (ID). However, human evidence on Mn toxicokinetics is limited. This study is to examine the hypothesis that ID will promote the body retention of Mn due to decreased elimination in humans. The elimination of Mn was assessed by creatinine-adjusted urine Mn levels in the absence of fecal data. The analysis was restricted to 580 non-pregnant females aged 16-49 years who had valid urinary and blood Mn and Fe measurements as part of the 2015-2016 National Health and Nutrition Examination Survey. Iron status was assessed by total body iron (TBI) scores that was calculated from measured serum ferritin and transferrin receptor. Iron deficiency was defined as TBI score <0. Demographic factors including age, race, body mass index (BMI), smoking, socioeconomic status, and glomerular filtration rate were examined in the multiple linear regression analysis. Logarithmic transformations were applied when necessary. In this current analysis, an estimated 8.5% (age-standardized) of the study population has ID. Whereas there is a positive correlation between blood and urine Mn levels (Spearman correlation= 0.08, p =0.09), the unadjusted analysis showed that the ratio of urine-to-blood Mn was significantly lower in subjects with ID than their counterparts (0.15 vs. 0.19 dL/g creatinine). Similar findings were observed that the ratio of interest was approximately 30% lower in individuals with ID compared to those without ID in the multivariate analysis (p =0.02). Of the covariates examined, race and BMI were the predominant determinants that the urine-to-blood Mn ratio tended to be lower in African Americans and those with higher BMI. In summary, this analysis suggested that iron status may play a role in Mn toxicokinetics. Further studies in humans that include urinary and fecal measurements are warranted to confirm the current findings. A better understanding of the key determinants in the body burden of Mn, one could further advance Mn exposure assessment.

1258 Circulating Cell-Free DNA Concentrations in CD-1 Mice following a Combination Exposure of the Antiretroviral Drugs Emtricitabine, Tenofovir, and Efavirenz

J. F. Foley[1], M. Weick[1], B. Elgart[1], N. Clausen[1], B. Merrick[1], A. Dzierlenga[1], H. Cunny[1], K. Ryan[1], J. Furr[2], C. Hébert[2], and K. Gerrish[1]. *[1]NIEHS, Research Triangle Park, NC; and [2]Southern Research, Birmingham, AL.*

There is keen interest in the clinical and toxicology disciplines to explore circulating cell-free DNA (ccfDNA) as a blood-based biomarker of diagnostic and predictive value. Current blood-based applications for ccfDNA in the clinical realm include oncology, fetal diagnostics, organ transplantation, and autoimmune disorders. The aim of this study was to evaluate changes in levels of ccfDNA as a toxicological indicator in a rodent model following *in utero* exposure to a standard combination antiretroviral therapy (ART). Plasma ccfDNA was quantified in time-mated CD-1 mice administered vehicle control (0.5% methylcellulose in water) or a drug cocktail [Emtricitabine (50 mg/kg), Tenofovir (75 mg/kg), and Efavirenz (150 mg/kg)], non-treated pregnant, and non-pregnant vehicle controls. Pregnant dams (F0) were dosed by oral gavage starting on GD 5 (gestational day 5) through PND 20 (postnatal day 20). First generation (F1) male and female pups were continuously dosed from PND 13 until the day prior to euthanasia (PND 35). Whole blood was collected on GD 15 (F0), PND 21 (F0), and PND 35 (F1). ccfDNA was extracted from plasma, quantified, and sample integrity determined by DNA fragment analysis. In GD 15 dams, ccfDNA concentrations of the pregnant vehicle control, treated and non-treated dams were significantly elevated (27% increase) compared to the non-pregnant vehicle control mice, indicating pregnancy itself accounted for increased ccfDNA. This result agreed with human ccfDNA findings in pregnant women. By PND 21, ccfDNA levels in non-treated dams returned to normal, baseline non-pregnant control values. Even though increased levels were observed at PND 21 in vehicle control and treated dams, the difference was not statistically significant. ART exposure in pregnant and lactating mice, and their offspring (PND 13 through 35) did not affect ccfDNA concentrations. The ccfDNA data correlated with an absence of a body weight, food consumption, or clinical observation study phenotype. Despite the lack of chemical-mediated effects on ccfDNA levels, this study demonstrated that liquid biopsy by ccfDNA measurement may be a viable tool to screen responses to xenobiotic agents in rodent toxicology studies.

1259 Upregulation of Metastasis-Associated Lung Adenocarcinoma Transcript 1 and Growth Arrest Specific 5 Genes in Prostate Cancer Subjects in Southern Nigeria: A Risk for Genome Protection

F. A. Idomeh[1], H. B. Osadolor[1], J. E. Idomeh[2], O. G. Igharo[1], and E. L. Igharo[1]. *[1]University of Benin, Benin City, Nigeria; and [2]Nigeria Maritime University, Warri, Nigeria.*

Prostate cancer is the most diagnosed solid tumour and second leading cause of cancer related deaths worldwide. A number of toxic metals have been reported to have direct genotoxic effect and disruption of gene repair mechanisms in prostate carcinogenesis. There is currently a dearth of information in the status of genotoxicity biomarkers and the use of prostate specific genes in the diagnosis of prostate cancer in Nigeria. This study is aimed to evaluate the expression of some prostate specific genes [Metastasis-associated Lung Adenocarcinoma Transcript 1 (MALAT-1) and Growth Arrest Specific 5 (GAS 5)], antioxidant enzymes: superoxide dismutase (SOD), glutathione reductase (GR), glutathione peroxidase (GRx), catalase (CAT) and the status of genotoxicity biomarkers: wild type tumour suppressor protein 53 (p53), DNA repair protein: 8-oxoguanine DNA glycosylase (OGG_1) and oxidative DNA damage biomarker: 8-hydroxydeoxyguanosine (8-OHdG) and correlate with toxic and essential metals in 150 prostate cancer subjects, 100 benign prostatic hyperplasia subjects and 100 age-matched control subjects in Southern Nigeria. From the blood samples collected, Reverse transcriptase polymerase chain reaction (RT-PCR) method was used to determine expression of prostate specific genes, Spectrophotometric methods to determine antioxidant enzymes in serum, Enzyme linked immunosorbent Assay was used to determine the genotoxicity biomarkers in serum while Inductively Coupled Plasma Mass Spectrophotometer (ICPMS) was used to determine toxic and essential metals levels in whole blood. From the results, we observed upregulation of MALAT-1, GAS 5 genes, significantly higher levels of toxic metals and 8-OHdG, significantly lower levels of essential metals and antioxidant enzymes in prostate cancer subjects. Additionally, there was down regulation of p53 and OGG_1 in prostate cancer subjects compared to benign prostatic hyperplasia and control subjects. There data provides evidence of upregulation of prostate specific genes, oxidative stress and DNA damage as reflected in heavy toxic metal burden, lowered antioxidants defense system, down-regulation of p53 and OGG_1 which is a key. These finds are suggestive of possible disruption of the genome protection mechanism, a key mechanism in the development and progression of prostate cancer.

1260 Chronic Electronic Cigarette Use Elicits Changes in Biomarkers Related to Pulmonary Pathogenesis

K. L. Marshall[1,2], Z. Liu[1], M. Olfert[2,3], and W. Gao[1]. *[1]West Virginia University School of Public Health, Morgantown, WV; [2]West Virginia University School of Medicine, Morgantown, WV; and [3]West Virginia University, Morgantown, WV.*

Electronic cigarettes (e-cigs) primarily originated as smoking cessation devices aimed at modifying the risk of developing pulmonary diseases associated with combustible tobacco use. However, more frequently never-smokers are adopting e-cig use *de novo*, and the relative safety of chronic exposure to e-cig vapor remains unclear in terms of lung pathogenesis. Thus, this study aims to evaluate gene/protein biomarkers, which are associated with cigarette-induced chronic obstructive pulmonary disease (COPD) and/or idiopathic pulmonary fibrosis (IPF), in animals chronically exposed to nicotine containing e-cig vapor. C57BL/6J mice (n=15/group) were randomly assigned to one of three 8-month exposure groups: e-cig vapor (commercially available, 18 mg/mL nicotine), UK 3R4F reference cigarette smoke, or filtered air as a control. Lung tissues and paraffin embedded slides were used to evaluate gene and/or protein expressions of COPD and IPF biomarkers from the CYP450 metabolism (CYP2A5, CYP3A11), oxidative stress (superoxide dismutase 1 (SOD1)), epithelial–mesenchymal transition (E-cadherin, vimentin), and survival/apoptotic pathways (p-AKT, B-cell lymphoma extra-large (BCL-XL), p53, p21, and chromosome region maintenance 1 (CRM1)). Results from the cigarette group were consistent with previously published studies. Expressions of E-cadherin and CRM1 were significantly decreased in the e-cig group as compared to the control group (E-Cadherin: <75.3%, CRM1: <74.5% of control; $p<0.05$). Expressions of SOD1 and BCL-XL were significantly upregulated in the e-cig group as compared to the control group (SOD1: 135%, BCL-XL: >151% of control; $p<0.05$). Nuclear sub-cellular localization of p53, evaluated by immunohistochemistry staining, in bronchiolar tissues was higher in the e-cig group (25.3±0.9%) as compared to controls (12.1±0.6 %) ($p<0.01$). Moreover, there were few significant differences observed between the e-cig and cigarette groups. As these related molecular changes are involved in the pathogenesis of cigarette-induced COPD and IPF, the possibility exists that e-cigs can produce a similar outcome, although further investigation is warranted.

1261 Cell-Free Circulating microRNAs Associated with Arsenic Exposure through Drinking Water Reflect Environmental Health Risks

J. Krauskopf[1], M. Y. Rehman[2], D. Hauser[1], M. van Herwijnen[1], A. Farooqi[2], R. Malik[2], J. J. Briede[1], and J. Kleinjans[1]. *[1]Maastricht University, Maastricht, Netherlands; and [2]Quaid-i-Azam University, Islamabad, Pakistan.* Sponsor: J. Aubrecht

Arsenic (As) is a toxic metalloid which is naturally present in the environment throughout the air, water and land. The greatest public health threat of As arises from high levels in the groundwater which result in contamination of drinking water, food and crops. The WHO estimated that worldwide more than 200 million people are chronically exposed to As levels that are higher than the prescribed limits. Epidemiological studies have shown that long-term exposure to As increases the risk of developing cancer as well as cardiovascular, metabolic, and more recently also multiple liver diseases. Recently, cell free, circulating microRNAs (cimiRNAs) have shown a promise as biomarkers of environmental exposure and health effects. In this study we explored the potential of cimiRNA signatures for biomarker based risk-assessment of chronic As exposure. Here, we present a global analysis of cell-free, cimiRNAs in a human population (n = 24) upon As exposure through drinking water in a rural setting of Punjab in southeast Pakistan. We determined urinary As levels using atomic absorption spectrophotometer coupled with hydride generation as a proxy for the internal As exposure and analyzed global plasma cimiRNAs using next-generation sequencing technology across all subjects. Lastly, we applied linear mixed effect models to identify associations between internal As levels and cimiRNA levels, thereby adjusting for batch effects, sex, age, BMI as well as genotype (False discovery rate < 0.2). The data revealed a signature comprising of 14 cimiRNAs to be significantly associated with internal As levels. Interestingly, the cimiRNA signature featured multiple emerging biomarkers for various types of liver injury (miR-122-5p and miR-192-5p), type 2 diabetes mellitus (miR-375-5p and miR-181b) and colorectal cancer (miR-17-3p), as well as the anti-inflammatory miR-146a-5p. Despite the limited

sample size, the present study provides molecular insights into the health effects of chronic As exposure. Although more confirmatory studies are needed, this study indicates that the cimiRNA signature approach has great potential to improve biomarker based environmental health-risk assessment.

1262 Urinary microRNA Profiles in Rat Models of Chronic Kidney Injury: Is there a Benefit of Exosome Enrichment?

B. J. Petzuch, and H. C. Ellinger-Ziegelbauer. *Bayer AG, Wuppertal, Germany*.

Exosomes are extracellular vesicles (EVs) secreted into various biofluids including urine. They enclose micro-RNAs (miRNAs), which are involved in the posttranscriptional regulation of gene expression. In the context of chronic kidney injury (CKI) like diabetic nephropathy (DN), altered exosomal composition and urinary miRNA profiles were reported previously. As exosomes are remarkably stable, they are considered as a promising source for miRNA investigations. We compared miRNA profiles of whole urine and urinary exosomes in two rat models of genetically and toxin-induced CKI: (1) Obese ZSF1 rats (14 to 26 weeks of age) and (2) Wistar rats with nephrotoxic serum-induced glomerulonephritis (GN). Animals were compared to respective controls. Kidney injury was confirmed in both models by histopathology and by quantification of the urinary proteins KIM1, OPN, CLU and CysC. EVs including exosomes were enriched using the miRCURY exosome precipitation kit (Qiagen). miRNAs from EVs and total urine were isolated by the miRNeasy kit (Qiagen) and quantified by miRCURY LNA qRT-PCR (Qiagen). Disease association and potential target genes were determined with Ingenuity pathway analysis (IPA) Qiagen). Exosomal association was assessed by qEV size exclusion chromatography (SEC) columns (Izon). Results were analyzed using the modified dCt method (Pavkovic et al 2014). Compared to ZSF lean rats, 67 EV-associated miRNAs and 52 miRNAs in total urine were significantly altered in ZSF1 obese rats from 14 to 26 weeks of age, with 8 miRNAs in common. IPA-derived annotation showed strong association with renal inflammation and glomerular injury, which is more prominent after EV-enrichment. In addition, many miRNAs have been described in the context of human DN, like members of the let-7 family, which we detected mainly in whole urine of obese ZSF1 rats. EV-enrichment added further miRNAs with implications in human CKI, some being described in the context of podocyte function. The exosomal association and significantly increased levels in urine of obese compared to lean rats were confirmed for selected miRNAs including miR-10a-5p by SEC. Increased levels of selected miRNAs were also found in urine of GN rats, supporting a role of miRNA in both subacute and CKI models. In summary these results show the added value of EV enrichment on miRNA detection, support a translational value of the ZSF1 animal model and contribute to further characterization of miRNAs in CKI.

1263 Potentially Translatable Biomarkers for Monitoring Progressive Colorectal Cancer

Y. Chen, M. Sysko, J. Kanerva, W. Chen, and J. E. McDuffie. *Janssen Research & Development, San Diego, CA.*

Colorectal cancer (CRC) is the third most common cancer among men and the second most common cancer among women worldwide. In Vietnam, CRC is the fifth most common cause of cancer-related incidence, with most patients being diagnosed at stage II. Several factors impact CRC treatment, including but not limited to tumor size, location, stage, phenotype (benign or malignant), local and/or metastatic recurrence, wellness of the patient, and modulation of signaling pathways [e.g. IGFBP7 (insulin-like growth factor binding protein 7)]. IGFBP7 is normally expressed in colonic mucosa and inactivated by DNA methylation in human CRC. Metabolomic studies revealed methylation of the tumor suppressor gene adenomatous polyposis coli (APC) and IGFBP7 gene promoter region in cancerous tissue. In combination with the predominance of methylation in normal tissue, this may serve as a prognostic indicator in CRC patients. Interestingly, Vietnamese CRC patients exhibit higher IGFBP7 gene methylation in colorectal adenoma versus matched normal tissue. Therefore, investigating molecular response profiles downstream IGFBP7 methylation could reveal novel biomarkers in CRC which is poorly predicted based on a single gene/protein. We explored the feasibility and potential usefulness of cytokine/chemokine profiling of tumors and adjacent normal tissues (as self-controls) in a cohort of 13 Vietnamese patients diagnosed with adenocarcinoma at different stages. Colorectal tissue levels of 41 different inflammatory mediators were measured using the MILLIPLEX MAP Human Cytokine/Chemokine Magnetic Bead Panel and Luminex MAGPIX platform. There were 22 out of 41 measurable cytokines/chemokines in normal and tumor tissues. Statistically significant increases in EGF ($p<0.0001$), TGF-α ($p<0.0001$), G-CSF ($p=0.0003$), Fractalkine ($p=0.0001$), INF-α2 ($p<0.0001$), GRO ($p=0.0178$), PDGFAB/BB ($p=0.0027$), IL-10 ($p=0.0069$), IL-12 ($p=0.001$), IL-12β ($p=0.0024$), IL-13 ($p=0.006$), IL-15 ($p=0.0163$) and MCP-1 ($p=0.0375$) were associated with increased severity of CRC. The tumor tissue-based changes in inflammatory mediators clustered with stage II adenocarcinoma at different severity grades, suggesting potentially translatable biomarker profiles may be monitored in tissue and/or liquid biopsy format(s) from animal models for CRC that exhibit normal or aberrant IGFBP7 methylation phenotypes during target validation and derisking studies as well as human clinical trials.

1264 Cancer Driver Mutations as Quantitative Biomarkers of Cancer Risk: Interspecies Analyses Using CarcSeq

K. Harris, K. McKim, B. Gong, M. Myers, J. Xu, and B. Parsons. *US FDA/NCTR, Jefferson, AR.*

Unmet needs in cancer risk assessment include the ability to predict rodent life-time tumor responses from short-term exposures and a scientific basis for rodent to human extrapolation. As an approach to address these needs, the use of hotspot cancer driver mutations (CDMs) as biomarkers of cancer risk was integrated with an error-corrected, next generation sequencing (NGS) approach. We developed a high-throughput NGS method called CarcSeq. The method involves performing multiple, high-fidelity PCR reactions to amplify the most prevalent mutations reported to occur in human tumors, tagging the amplicons with 9 bp unique identifier sequences at each end, constructing libraries using Illumina ChIP Seq kits, sequencing the libraries on an Illumina NextSeq500 platform and generating single-strand consensus sequences (SSCS), bioinformatically, as a means of error-correction. We validated CarcSeq mutant fraction measurements through observations related to known cancer driver tissue-specificities and mutation spectra for normal human breast and lung, ductal carcinoma, and lung adenocarcinoma samples. A reconstruction experiment established CarcSeq has a sensitivity of 10^4. We adapted this approach to analyze analogous conserved codons in rat and mouse. For each of the three species, the developed panel includes 13-15 amplicons encompassing known cancer driver genes (e.g., *KRAS*, *PIK3CA*, and *TP53*) encompasses the equivalent of 30 known human hotspot codons and has a combined target sequence length of ~1 kb. Amplicons were generated from DNA isolated from 16-week-old, untreated rodent tissue samples with known differences in spontaneous tumor incidence: female Wistar, Sprague Dawley, and F344 rat mammary samples and male and female $B6C3F_1$ and CD-1 mouse lung samples. The rat panel was optimized to generate ~100,000 SSCS/amplicon. CDMs were observed at conserved codons in young, untreated rats, and preliminary results are consistent with what was expected based on strain differences in spontaneous tumorigenesis.

1265 Evaluation of Extracellular Vesicles (EVs) as Toxic Biomarkers in Mouse

R. Ono[1], Y. Yoshioka[2], Y. Furukawa[1], T. Ochiya[2], S. Kitajima[1], and Y. Hirabayashi[1]. *[1]National Institute of Health Sciences, Kawasaki, Japan; and [2]Tokyo Medical University, Tokyo, Japan.*

Recent findings reveal that extracellular vesicles (EVs), secreted from cells, are circulating in the blood. EVs are classified into exosomes (40-120 nm), microvesicles (50-1,000 nm) and apoptotic bodies (500-2,000 nm). EVs contain mRNAs, microRNAs, and DNAs and have the ability to transfer them from cell to cell. Recently, especially in humans, the diagnostic accuracy of tumor cell type-specific EVs as biomarkers is more than 90%. In addition, microRNAs contained in the EVs are being identified as specific biomarkers in blood for chemical-induced inflammation and organ damage. Therefore, microRNAs contained in the EVs released into the blood from tissues and organs in response to adverse events such as chemical substances are expected to be useful as novel biomarkers for toxicity assessment. In this study, we aimed to identify target organs by comprehensive analysis of EV RNAs in the blood of mice after chemical exposure, and establish a highly sensitive "Next Generation type" toxicity test. At first, we compared the protocols for the isolation of EV RNA from mouse blood, including blood collection methods, serum isolation methods, and exosome purification methods, to standardize the isolation of EV RNA from mouse blood. Quantity of exosomes were determined by Nanosight, a special optical microscopy adapted to quantify small particles, and western blot using anti-CD9 antibody. EV RNAs were further evaluated by deep sequencing. By using our optimized protocol, we succeeded in isolating more than 50 novel small RNAs, which could be used as novel highly sensitive biomarkers for hepatotoxicity due to carbon tetrachloride (CCl4). These results will accelerate a rapid evaluation of chemical substances and medicine in Nonclinical Safety Evaluation.

1266 Understanding the Context of Tobacco Smoke Exposure in a Cohort of Canadian Infants Using Biomarkers, Questionnaires, and Machine Learning

J. Parks[1], K. McLean[2], L. McCandless[1], J. R. Brook[3], S. E. Turvey[4], P. J. Mandhane[5], A. B. Becker[6], P. Subbarao[7], M. Azad[6], T. J. Moraes[7], D. Lefebvre[8], M. R. Sears[8], and T. K. Takaro[1]. *[1]Simon Fraser University, Burnaby, BC, Canada; [2]BC Centre for Disease Control, Vancouver, BC, Canada; [3]University of Toronto, Toronto, ON, Canada; [4]University of British Columbia, Vancouver, BC, Canada; [5]University of Alberta, Edmonton, AB, Canada; [6]University of Manitoba, Winnipeg, MB, Canada; [7]University of Toronto, and The Hospital for Sick Children, Toronto, ON, Canada; and [8]McMaster University, Hamilton, ON, Canada.* Sponsor: T. Takaro, American Association for the Advancement of Science

Accurately assessing tobacco smoke exposure in early life is important to understanding and preventing childhood asthma. This study of the CHILD cohort study examined urinary concentrations of common nicotine biomarkers (cotinine and trans-3′-hydroxycotinine (3HC)) and evaluated their ability to be validated by questionnaire responses related to smoking. The low level of detection (0.03ng/mL), young study population, and low prevalence of reported smoking in this cohort add valuable knowledge to this area of exposure assessment. Urine was collected at 3-4 months of age during home visits. The concentrations were log-transformed and corrected for specific gravity. Multivariable linear regression (MLR) and random forest (RF) methods were used to assess the ability and relative importance of questionnaire responses to predict urinary cotinine concentrations. While just 12% of our sample (n=2509) reported recent tobacco smoke exposure to their child, 76% and 89% of the infants had detectable cotinine and 3HC levels. Questionnaire-based models incompletely predicted urinary concentrations, explaining only 32% and 41.0% of the variance in cotinine, and 3HC levels, respectively. Models may not adequately explain this variation because the half-life of cotinine leads to more variability for those with low or inconsistent exposure, questionnaires cannot adequately detect thirdhand smoke exposure, and/or detectable levels may in-part result from dietary nicotine sources. Breastfeeding, housing, and third-hand smoke exposures such as carpeting, appear to be important in explaining cotinine and 3HC concentrations, identifying priority areas for targeted disease prevention. Researchers must use context-specific exposure assessment measures, and the ability of machine learning to support purposeful analysis should be explored further.

1267 Identification of Metabolic Changes That Indicate Gentamicin-Induced Kidney Damage in the Laboratory Rat

V. R. Pannala[1,2], K. C. Vinnakota[1,2], S. K. Estes[3], I. Trenary[4], T. P. O'Brien[3], R. L. Printz[3], J. A. Papin[5], J. Reifman[1], T. Oyama[1,2], M. Shiota[3], J. D. Young[3,4], and A. Wallqvist[1]. *[1]US Army Medical Research and Development Command, Fort Detrick, MD; [2]Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD; [3]Vanderbilt University School of Medicine, Nashville, TN; [4]Vanderbilt University School of Engineering, Nashville, TN; and [5]University of Virginia, Charlottesville, VA.*

Identifying early indicators of toxicant-induced organ damage is critical to provide effective treatment. To discover such indicators and the underlying mechanisms of toxicity, we used gentamicin as an exemplar kidney toxicant and performed systematic high-throughput perturbation studies in Sprague Dawley rats and identified global changes in genes in the liver and kidneys, metabolites in the plasma and urine, and absolute fluxes in central carbon metabolism. We then used the measured changes in genes in the liver and kidney as constraints to a rat multi-tissue genome-scale metabolic network model to investigate the mechanism of gentamicin-induced kidney toxicity and identify metabolites associated with changes in tissue gene expression. Our analyses revealed that, compared to blood metabolites, urine metabolites have greater potential to serve as kidney-injury indicators, as several metabolites in the amino acid-, carbohydrate-, and lipid-metabolism pathways increased significantly as early as 7 h after gentamicin exposure. Thus, our analyses identified 1) several significantly enriched injury-specific pathways in the kidney underlying gentamicin-induced toxicity and 2) metabolites in these pathways to further target and clinically assess for their ability to serve as early markers of kidney damage. Together with our recent work on acetaminophen-induced liver toxicity, these results demonstrate how our platform can be broadly applied to analyze and mechanistically interpret large-scale high-throughput data to identify early indicators of organ injuries.

1268 Characterization of Linear and Non-Linear Associations between Physiological Indicators and All-Cause Mortality

V. K. Nguyen[1], J. Colacino[1], J. Chung[2], A. Le Goallec[2], N. Pho[2], O. Jolliet[1], and C. Patel[2]. *[1]University of Michigan, Ann Arbor, MI; and [2]Harvard University, Boston, MA.*

Numerous epidemiological and *in vivo* studies have documented associations between toxicant exposure and altered physiological indicators, but it is unclear how such chemical-mediated effects increase the risk of death. Characterization of the type of association (e.g., linear dose-response or non-linear) between physiological indicators and mortality will provide the foundation to understand how chemical exposures result in physiologic dysfunction associated with increased risk for death. In this study, we applied a machine learning approach to characterize the linear and non-linear associations between physiological indicators and mortality to identify populations who are at risk to physiologic dysfunction. We studied 27 biomarkers and physiological measurements in 47,025 participants of the US CDC National Health and Nutrition Examination Survey (NHANES) sampled from the US population from 1999-2014. We selected these particular indicators as they characterize physiological strain from a wide range of regulatory systems, have high sample size (>10,000 participants), and high overlap with the mortality data (>12 years). We used linked National Death Index to ascertain mortality status and time to death. We assessed linear associations with death and non-linear associations by discretizing each indicator into 9 quantiles. We conducted 10-fold cross validation (while adjusting for age, sex, and race/ethnicity) to compare the predictive capability of the linear versus non-linear models. Linearity was the worst at describing the associations between mortality and biomarkers of inflammation such as C-reactive proteins, white blood cell counts, and alkaline phosphatase with R2's of 0.06, 0.04, and 0.001, respectively and non-linearity improved the fit of the model by 3, 5, and 150 folds, respectively. For HDL, LDL, and a biomarker of renal function Glomerular Filtration Rate, we found that higher risk of death is associated with being in either extremes of the distributions instead of being in just one extreme. We present a framework to systematically characterize the type of association that best explains the relationship between a given physiological indicator and mortality. To better characterize toxicity associated with chemical exposures, understanding the associations between physiological indicators and mortality is salient to evaluate how toxicant exposure disrupts physiologic function that leads to higher risk of death.

1269 Demonstrability of an Enzyme-Linked Immunosorbent Assay to Simultaneously Quantify Histamine in Multiple Nonclinical Species and Matrices in a Single Analytical Run

A. Morris, J. England, N. Makori, and V. Peachee. *Charles River, Ashland, OH.*

In investigational new drug enabling studies two species (rodents and large animals) are commonly tested. However, in most instances separate sample analytical procedures (AP) are developed for each species and matrix. The objective of this study was to validate an enzyme-linked immunosorbent assay (ELISA) to measure histamine from different matrices and species simultaneously in a single analytical run. Large quantities of histamine are released during an allergic reaction, but the timing of histamine release is critical, and hence multiple sampling is needed. Developing blood matrix-based assays where multiple sampling can be limited due to constraints in sample volume may be inadequate. Hence, it is more practical to develop an AP that can also measure histamine levels from urine where daily sampling is achievable. A commercially available histamine ELISA kit that cross reacts with NHP, canine, and rat histamine was used. A standard curve consisting of eight non-zero standards and quality control samples was established in assay buffer. Parameters such as blank checking to estimate the endogenous histamine concentrations, the determination of the optimal dilutions for study samples, and the evaluation of the expected histamine recovery in each matrix were conducted. Recovery was calculated by spiking with a known amount of histamine at three different concentrations into individual lots of matrices. Lastly, inter- and intra-assay precision, linearity, and endogenous quality control ranges were evaluated. A standard curve capable of determining histamine concentration from 0.098 to 25 ng/mL with acceptable accuracy and precision of 20% to 25% was established. The optimal dilution for sample analysis of NHP and canine plasma and serum was 1:10 and for urine it was 1:5. For rat plasma and serum, the dilution was 1:40 and for urine it was 1:20. The recovery (close to 100%) was established when samples were spiked with histamine at 0.188 ng/mL in all three species, except in canine serum, where it was 1 ng/mL. Inter- and intra-assay precision analyses in serum, plasma, and urine were established. In conclusion, we demonstrated the use of an AP in a

single run to simultaneously quantify histamine in multiple species and matrices. This experimental approach improves efficiencies and gives the possibility for repeated histamine sample analysis using urine samples.

1270 Altered SIRT1 Activity and Plasma Cortisol as Biomarkers of Circadian Disruption in Night Shift Workers

M. Fang, K. Black, Z. Yang, B. Estrella, P. A. Ohman-Strickland, J. M. Graber, H. Kipen, and H. Zarbl. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Disruption of circadian rhythm by persistent night-shift showed to increase the risk of breast cancer. Identification and validation of biomarkers is essential to the development of preventive strategies for individuals, especially nurses, at elevated risk of breast cancer due to shift work. Our animal studies indicate that NAD^+/NADH and SIRT1 are key regulators of circadian gene expression, which play important roles in mammary carcinogenesis associated with disruption of circadian rhythm. We used a two-phase approach to assess NAD^+/NADH and SIRT1 activity in peripheral blood mononuclear cells (PBMC) as biomarkers for circadian disruption in night-shift workers. In Phase I, we analyzed circadian rhythm of NAD^+/NADH and SIRT1 activity in day- vs night-shift workers over 24 hr; in Phase II, we assessed the same markers in another group of day- vs night-shift workers at two selected time points. In the both phases, peripheral blood was collected and PBMC were isolated from plasma. NAD^+/NADH and SIRT1 activity were analyzed in PBMC, and melatonin and cortisol were analyzed in plasma. In Phase I (n=22), SIRT1 activity differed significantly over time points across a day with an increase from early to late night in day-shift workers, while the levels were largely unchanged over time in night-shift workers. These resulted in the largest difference in SIRT1 activity at late night (midnight) between day- and night-shift workers, although no statistical significance observed. NAD^+/NADH did not have any significant differences between day- and night-shift workers, and between early and late night. In Phase II (n=39), a similar pattern was observed with a late night increase in SIRT1 activity in the day-shift but not in the night-shift workers, showing a low to moderate reliability. In addition, while the plasma melatonin did not show difference over 24 hr in day- vs night-shift workers with a peak at 4 am, night-shift dampened rhythmic secretion of cortisol over a day, resulting in significant reduction of cortisol level at morning and further misalignment of cortisol to melatonin. These preliminary results suggest that suppression of the SIRT1 activity increase at late vs early night, and suppression of early morning plasma cortisol warrant further investigation as biomarkers of circadian disruption in night-shift workers. *Supported by 1 NIH/NIEHSR21 and 1 NIH/NIEHS ES005022-27.*

1271 Proposed Biomarkers from Lipidomics Analysis for Ethionamide-Induced Hepatic Steatosis in Rats

K. Muta[1], K. Saito[2], K. Goda[1], A. Kobayashi[1], Y. Saito[2], and S. Sugai[1]. *[1]Japan Tobacco Inc., Yokohama, Japan; and [2]National Institute of Health Sciences, Kawasaki, Japan.* Sponsor: E. Spicer

Drug-induced hepatic steatosis is one of the adverse liver events often encountered in clinical trials or non-clinical toxicity studies and is recognized to be, in some cases, a serious concern in the development of new drugs. Therefore, a biomarker for drug-induced hepatic steatosis could be an important tool for managing the risk for new drug development. Ethionamide (ETH), a second-line drug for multi-drug resistant tuberculosis, is known to cause hepatic steatosis followed by hepatic injury in rats and humans. To find a suitable biomarker for ETH-induced steatosis, we performed lipidomics analysis using plasma and liver samples from steatosis model rats treated orally with ETH at 30 and 100 mg/kg for 7 and 14 days. The ETH-treated rats showed increased hepatic content and decreased plasma levels for triglycerides and total cholesterol on day 14 with 100 mg/kg, and they developed hepatic steatosis, shown by Oil Red O staining-positive vacuolation in the centrilobular hepatocytes on day 14 with 30 mg/kg and on days 7 and 14 with 100 mg/kg. A multivariate analysis for lipid profiles in the liver and plasma obtained on day 14 revealed that there were differences in the 35 lipid species in the plasma and 35 lipid species in the liver between the control and the ETH-treated rats at 100 mg/kg. Of those lipids, phosphatidylcholine (PC[18:0/20:4]) and lysophosphatidylcholine (LPC[18:0]) decreased dosedependently in both plasma and liver after administration of ETH. Since arachidonic acid (20:4) containing PC is known to be related to the secretion of very low-density lipoproteins from the liver, the decrease in PC[18:0/20:4] is considered to be involved in ETH-induced hepatic steatosis. In conclusion, plasma PC[18:0/20:4] and LPC[18:0] were considered to be appropriate biomarkers for ETH-induced hepatic steatosis.

1272 Next-Generation DILI Biomarkers: Prioritization for Qualification and Best Practices for Biospecimens

S. Roth[1], D. Bourdet[2], D. Brott[3], R. Church[4], A. Dash[5], D. Keller[6], S. Lentini[7], M. Merz[8], L. Ramaiah[9], S. Ramaiah[9], P. Sherratt[10], A. Stanley[11], P. Watkins[4], L. Westcott-Baker[1], and J. Marcinak[12]. *[1]Otsuka America Pharmaceutical Inc., Rockville, MD; [2]Theravance Biopharma, South San Francisco, CA; [3]Takeda Pharmaceutical Company Limited, Cambridge, MA; [4]University of North Carolina at Chapel Hill, Chapel Hill, NC; [5]Genentech Inc., South San Francisco, CA; [6]Sanofi, Bridgewater, NJ; [7]Bayer AG, Wuppertal, Germany; [8]AstraZeneca, Gaithersburg, MD; [9]Pfizer Inc., Cambridge, MA; [10]Celgene Corporation, Summit, NJ; [11]IQ-DILI, Washington DC, DC; and [12]AbbVie Inc., North Chicago, IL.*

Drug-induced liver injury (DILI) remains a diagnostic and clinical challenge in drug development. The qualification of emerging biomarkers capable of predicting DILI soon after the start of treatment, differentiating DILI from underlying disease, identifying the causal entity, and assigning appropriate treatment options after DILI is diagnosed are needed. Qualification efforts have been hindered by lack of properly stored and consented biospecimens that are linked to clinical data relevant to a specific context of use. Recommendations are highlighted for biospecimen collection procedures and qualification efforts should be focused by using a few specific emerging biomarkers, such as GLDH, HMGB1, K18, MCSFR1, OPN, and bile acids. These are based on extensive literature review and consensus achieved between the International Consortium for Innovation & Quality (IQ) DILI members and academic and regulatory experts. Member companies (11) of IQ DILI responded to a survey to provide insight into how samples are collected and stored, and on the availability of samples and data that can be used for qualification. Key takeaways include (i) Collect, with broad and ethical consent, and properly store biospecimens in clinical trials following procedures that allow for qualification of biomarkers. (ii) Collect clinical data concurrent with biospecimen and store data in a manner that is easily linked to the biospecimen, using graphical tools if possible. (iii) If DILI risk is predicted, collect data on emerging biomarkers, either during clinical trial development or a *post hoc* study setting, to advance biomarker qualification efforts. Additional clinical research is needed to develop DILI biomarkers. There are a few that are currently considered to be exploratory by the Food and Drug Administration and the European Medicines Agency. With the unmet need, there is opportunity to collaborate and advance the understanding of the diagnosis, management, and prevention of DILI by driving forward the qualification of biomarkers. *Acknowledgements: Mark I. Avigan, MD CM, US FDA.*

1273 Stratum Corneum Biomarkers of Skin Barrier and Immune Response in Patch Test Reactions to Common Contact Allergens and Irritants

S. Kezic[1], I. Jakasa[2], and R. Brans[3]. *[1]Amsterdam UMC, Amsterdam, Netherlands; [2]University of Zagreb, Zagreb, Croatia; and [3]Universität Osnabrück, Osnabrück, Germany.* Sponsor: H. Maibach

Patch testing is a commonly used diagnostic tool for contact sensitization (CS), however it is associated with false-positive and false-negative outcomes. The patch test baseline series contains several hapten mixes in one patch test preparation. In case of a positive reaction to a mix, patch testing of the individual haptens is performed to identify the causative hapten(s). However, some subjects show a negative reaction in subsequent testing which might indicate a previous false-positive, possibly irritant reaction. As irritant and allergic reaction have different pathophysiology (CS is a type IV hypersensitivity reaction involving T-cells while activated innate immunity and skin barrier damage underlie skin irritation), we investigated whether suitable biomarkers might assist in discrimination between irritant and allergic reaction. In the present study, we determined various biomarkers of skin barrier and immune response in patch test to fragrances. We included 23 persons with previously positive patch test to at least one compound from the baseline fragrance mix I and II. These subjects underwent subsequent patch testing with the single fragrances. All allergens were applied in petrolatum that was also used as a control test site. 72 hrs after patch testing, samples of the stratum corneum (SC), the uppermost epidermal layer, were collected from the test sites by using adhesive tapes. In the SC tapes, 15 cytokines of different signature (Th1, Th-2 and innate markers) were determined by a multiplex immunoassay. Next, filaggrin degradation products (NMF) as an indicator of skin barrier damage were measured. From 23 tested subjects, seven had negative reaction after patch testing to a single fragrance. Of 15 detected cytokines, seven cytokines showed significant difference between a hapten and petrolatum (CCL17, CXCL10, CCL22, CXCL8, CCL2 and IL-22). We compared the sub-group of subjects who did not have a positive reaction to a single fragrance with the

group who did show a positive reaction to both, mix and a single fragrance. A significant difference between these sub-groups was found for IL-16 and CXCL10. IL-16 has previously been shown as a biomarker to distinguish irritant from allergic reaction. In addition, a sub-group with negative patch test to a single fragrance showed decrease in NMF further supporting the hypothesis that the positive reaction to the mix was caused by an irritant reaction. This study confirms previous findings that IL-16 might be a suitable biomarker to distinguish irritant from allergic reaction. This might be of relevance in diagnostics of contact dermatitis and interpretation of allergen patch testing.

PS 1274 Assessment of Aflatoxin and Ochratoxin Exposure among Mothers and Children in Nepal

J. Wang[1], K. S. Xue[1], L. Tang[1], M. Limoran[1], N. Dietz[1], J. Alcala[1], R. Wang[1], J. Andrews-Trevino[2], K. Baral[3], S. Ghosh[2], and P. Webb[2]. *[1]University of Georgia, Athens, GA; [2]Tufts University, Boston, MA; and [3]Patan Academy of Health Sciences, Lalitpur, Nepal.*

Contamination of mycotoxins in human diets are unavoidable, especially in the developing world. Aflatoxin B_1 (AFB_1), the most potent mycotoxin, is classified by IARC as a Group 1 human carcinogen. Recent evidences have shown that exposure to AFB_1 links to adverse maternal and children's health effects in various low- and middle-income nations. Additionally, AFB_1 was found to be capable of crossing blood-placental barrier and can result in adverse developmental outcomes, including low-birth weight. Ochratoxin A (OTA) is a toxicologically significant mycotoxin and has been frequently found to contaminate many food items. In this study assessment of these two mycotoxins was conducted using biomarker approaches in serum samples collected from the AflaCohort Birth Cohort Study (2015-2019) in Banke, Nepal, where healthy pregnant women were enrolled, and the mother-child pairs were followed-up to examine the potential adverse effects of mycotoxins exposure to the mother and children. The results presented here consist of blinded analyses which utilizes the latest batch of serum samples collected from this study, which consisted of a total of 699 serum samples divided into two batches (n1=486, n2=213). In addition to measurement of serum AFB_1-lysine adduct to quantify AFB_1 exposure, the levels of serum OTA were analyzed to assess exposure to OTA. Overall, AFB_1-Lysine was detectable in 81.48% of samples from first batch and 93.43% of samples from second batch, whereas OTA was detectable in all serum samples in both batches. For the first batch, the mean, median, and geometric mean for serum AFB_1-lysine were 2.13 (SD: 7.20), 1.01 (q1: 0.58, q3: 1.81), and 1.15 (95% CI: 0.93, 1.38) pg/mg albumin, respectively, while those for serum OTA were 0.47 (SD: 2.15), 0.26 (q1: 0.17, q3: 0.38), and 0.27 (95% CI: 0.09, 0.45) ng/mL serum, respectively. For the second batch, the mean, median, and geometric mean for serum AFB_1-lysine were 2.98 (SD: 9.06), 1.30 (q1: 0.84, q3: 4.80), and 1.52 (95% CI: 1.19, 1.86) pg/mg albumin, respectively, while those for serum OTA were 0.51 (SD: 0.61), 0.38 (q1: 0.28, q3: 4.84), and 0.41 (95% CI: 0.17, 0.64), respectively. The samples from the second batch showed higher overall exposure levels for both AFB_1 and OTA compared to those from the first batch, which may reflect seasonal variations of dietary exposure. Further analyses will be conducted to evaluate the association between levels of mycotoxin exposure and children's health outcomes.

PS 1275 Identification of Predictive Biomarkers Associated with Antibiotic-Associated Nephrotoxicity in Cystic Fibrosis Patients Using a Kidney Microphysiological Device

K. P. Van Ness, E. J. Kelly, and P. Bhatraju. *University of Washington, Seattle, WA.*

The longevity of individuals living with cystic fibrosis (CF) through successful treatments and lung transplantation has brought with it unforeseen problems and complications: one being the emergence of acute kidney injury from antibiotic treatment stemming from colonized pulmonary microbes in these patients. We have employed a kidney microphysiological device system (MPS)with cultured human proximal tubule epithelial cells (PTECs) to identify potential sensitive renal biomarkers arising from exposure to aminoglycosides and polymyxins commonly used to treat CF patients. Specifically, we exposed PTECs to various concentrations of Polymyxin B (PMB), Polymyxin E (colistin) and tobramycin for 72 hours and collected daily effluents as a source for nephrotoxicity biomarker discovery. Biomarkers associated with epithelial cell injury KIM-1 (Kidney Injury Molecule 1) and NGAL (Neutrophil Gelatinase-Associated Lipocalin), inflammation (soluble Fas Receptor, Fas Ligand and TNF RI) and apoptosis (caspase-cleaved cytokeratin 18 and intact cytokeratin 18) were chosen to evaluate kidney chip effluents by ELISA. We observed an antibiotic-specific biomarker response with elevations of KIM-1 in the effluents at 24 hours with PMB, increased NGAL and FAS concentrations at 24 hours with colistin exposure and increased NGAL concentrations with tobramycin. These data suggest that the mechanisms of PTEC nephrotoxicity associated with antibiotic exposure can produce antibiotic-dependent biomarker response patterns that reflect underlying cellular injury. Follow up analyses with PTEC RNA transcript (RNAseq) evaluations from these studies along with microRNA analyses of the effluents will provide additional information for the selection of biomarker candidates.

PS 1276 Next-Generation Sequencing Pipeline for Genome-Scale Analysis of Circulating microRNAs as Discovery Approach for Safety Biomarkers

K. Khamina[1], C. Fournier Aquino[2], A. T. Smith[3], W. E. Glaab[4], H. Rehrauer[2], and M. Hackl[1]. *[1]TAmiRNA GmbH, Vienna, Austria; [2]Functional Genomics Center Zurich, Zurich, Switzerland; [3]Eli Lilly and Company, Indianapolis, IN; and [4]Merck & Co. Inc., West Point, PA.*

MicroRNAs are small non-coding RNAs that regulate gene expression in virtually all humans cells. Changes in tissue-specific microRNA expression patterns have been associated with a variety of human diseases. These changes reflect re-modelling of the biological pathways during disease onset and progression that make microRNAs attractive potential drug targets as well as sensitive and specific biomarkers. Tissue-specific microRNAs have been identified in various cell-free biofluids including plasma, serum, CSF and urine. The levels of tissue-specific microRNAs in liquid biopsies can be used for early detection of drug-induced organ injuries, such as miR-122 for liver[1], and offer a novel class of safety and toxicity biomarkers[2]. The Translational Safety Biomarker Pipeline (TransBioLine) IMI2 consortium aims to discover and qualify novel microRNA safety biomarkers for five organ systems (kidney, liver, pancreas, vascular and central nervous systems) by 2024. Furthermore, TransBioLine aims to characterize inter- and intra-individual variability of circulating microRNAs through investigation of several healthy volunteer populations. Next-Generation Sequencing (NGS) technology enables to analyze circulating microRNAs expression patterns in the biofluids and/or tissues of diseased and healthy individuals on a genome-scale level. However, small RNA sequencing suffers from potential biases (e.g. adapter ligation bias) and often lacks absolute transcript quantification. In order to establish a reliable biomarker discovery and quantification pipeline for circulating microRNAs, a systematic comparison of four commercially available small RNA library preparation protocols for NGS has been completed: QIAseq (Qiagen), CleanTag (TriLink Biotechnologies), RealSeq-Biofluid (Somagenics) and NEXTFLEX v3 (BIOO Scientific). The performance of the selected kits in terms of sensitivity, repeatability, ligation bias, usability and cost has been evaluated using RNA isolated from human plasma and liver tissue as well as miRXplore Universal Reference (Miltenyi Biotec). The total number of unique microRNAs identified in human plasma samples varied between the selected NGS protocols: 357 for QIAseq, 360 for CleanTag, 393 for RealSeq-Biofluid and 359 for NEXTFLEX v3. A proprietary panel of exogenous small RNA spike-in controls[3] has been developed for monitoring ligation bias and to enable absolute quantification of microRNAs levels and hence comparability of data across independent datasets. This work will allow establishment of a best-in-class NGS pipeline for microRNA biomarker discovery and quantification in liquid biopsies. *References 1. Howell, L. S., Ireland, L., Park, B. PS 1277 Identification of Biomarker Genes in LUHMES Neurons to Screen for Neurodegenerative Toxicants

Z. Tong, J. Braisted, P. Chu, H. Kim, and D. L. Gerhold. *NIH/NCATS, Rockville, MD.*

Neurodegenerative diseases result from environmental and genetic factors, yet the environmental causes for Parkinson's disease, Alzheimer's disease, Amyotrophic Lateral Sclerosis, *etc*. have not been identified. In order to screen chemical libraries for candidate neurodegenerative toxicants we identified and validated biomarker genes that respond to a variety of toxicants in LUHMES neurons. Initially, LUHMES conditionally immortalized human dopaminergic neurons were treated with seven neurotoxicants and subjected to RNA sequencing. Twenty-four genes responded to multiple toxicants, including three metallothionein genes that were dynamically increased by all seven toxicants. Testing of additional toxicants in additional cell types established that *MT1-G* responded to diverse toxicants in LUHMES cells, in SH-SY5Y cells, and in non-neural cell lines such as HepG2 and HUVEC. Finally, we investigated the mechanisms of regulation that have been described for metallo-

thionein using LUHMES neurons. Inhibitor drugs for the Metal-Responsive Transcription Factor 1 (MTF1, inhibited by APTO253) and the oxidative stress responsive/NRF2 pathway (NRF2, inhibited by ML385) decreased transcriptional induction of *MT1-G* in LUHMES neurons in response to some toxicants such as $CuCl_2$. Other toxicants such as Ziram induced *MT1-G* in LUHMES neurons but were unaffected by these two inhibitors, suggesting a third pathway can regulate this gene. These studies indicate that the *MT1-G* gene is a sensitive detector of diverse cell stresses in the LUHMES neuron model and may be useful for primary screens of environmental toxicant libraries to identify the neurodegenerative toxicants.

PS 1278 Characterization of an Aryl Hydrocarbon Receptor Response in Whole Blood at the Single-Cell Level

J. Yee, K. Malecki, J. Fechner, J. Mezrich, R. Wilson, N. Goetz, R. Swearingen, A. Shen, E. Glover, S. Moran, and C. Bradfield. *University of Wisconsin–Madison, Madison, WI.*

The aryl hydrocarbon receptor (AhR) is a ligand activated transcription factor that binds many different chemicals, including toxic compounds such as polycyclic aromatic hydrocarbons and halogenated dibenzo-p-dioxins. Activation of the AhR leads to upregulation of genes driven by specific sequences in their promoters called aryl hydrocarbon response elements (AHRE). Here we examine upregulation of classic AhR responsive genes in the whole blood of the laboratory mouse for their potential as biomarkers of exposure to AhR ligands. Using the prototype AhR ligand beta-napthoflavone (BNF), a non-toxic AhR agonist, and the C57BL/6J mouse, we observed the marked upregulation of AhR responsive genes aryl hydrocarbon receptor repressor (Ahrr) and Cytochrome P450 1a1 (Cyp1a1) over time, with maximal expression between 4 and 5 hours and almost complete reduction by 10 hours. We determined that the expression of the Ahrr was the more sensitive upregulated gene when using Next Generation RNA sequencing protocols. To improve the sensitivity of the approach, we hypothesized that certain cell blood types were more sensitive than others and tested that idea by multiple methods. Flow cytometry, magnetic bead separations, and single cell sequencing suggests that AhR target genes were differentially inducible in different blood cell types. We observed Ahrr being the most highly induced in CD4+ cells while Cyp1a1 was most inducible in Cd11+ cells. We also examined the pharmacokinetics via mass spec of the BNF disposition in the blood of the mice and demonstrate that levels of this ligands precede the induced mRNA expression and are reduced in keeping with the RNA expression data. In summary, these data support the use of RNA targets of the AhR as proxies of exposure to AhR ligands, but also demonstrates considerable caution should be employed as the time course is more adept at identifying short-term (recent) exposures.

PS 1278a The Function of lncRNA RPL34-AS1 in Esophageal Cancer Cells

H. Zhang, Y. Zhang, C. Zhao, Q. Lu, J. Zhou, Y. Pu, and L. Yin. *Southeast University, Nanjing, China.* Sponsor: L. Yin, Environmental Mutagenesis and Genomics Society

Studies have shown that the abnormal expression of lncRNAs contributes to specific changes in tumor, and lncRNAs have been known as key biomarkers for cancer diagnosis, cure and prognosis. This study is to explore the function and potential mechanism of lncRNA RPL34-AS1 in esophageal cancer cells. Based on screening esophageal cancer cohorts from TCGA database, we identified RPL34-AS1 as a functional lncRNA in esophageal cancer. We evaluated the expression of RPL34-AS1 by qRT-PCR in EC109 and EC9706 human esophageal cancer cell lines, and Het-1A human esophageal immortalized epithelial cell line, respectively. Gain- and loss-of-functional of RPL34-AS1in EC109 cells were achieved by knock-in (plasmid transfection) and knock-down (RNAi) techniques. The transfection efficiency of RPL34-AS1 was analyzed by qRT-PCR. To evaluate the effects of RPL34-AS1 on the biology behaviors of esophageal cancer cells, cell proliferation, apoptosis, cycle, migration and invasion were examined by CCK-8, Edu staining, flow cytometry and Transwell assay. The results showed that RPL34-AS1 was down-regulated in esophageal cancer cells. Compared with Het-1A, the expression level of RPL34-AS1 in EC109 cells was decreased significantly($P<0.05$). After transfection by RNAi and plasmid techniques, the relative expression level of RPL34-AS1 decreased to 0.21 and increased by 7855 folds ($P<0.05$), respectively. Gain- and loss-of-functional assays revealed that RPL34-AS1 inhibited EC109 cells proliferation, cycle progression, invasion, and migration and promoted apoptosis. In conclusion, our finding suggests that lncRNA RPL34-AS1 is a tumor suppressor and a potential therapeutic choice for esophageal cancer. *(This study is supported by National Nature Science Foudation of China 81573191, 81872588).*

PS 1279 Examining the Transgenerational Effects of Environmental Cues in *C. elegans*

L. Truong, J. Camacho, D. Vo, C. E. Moore, and P. Allard. *University of California Los Angeles, Los Angeles, CA.*

In sexually reproducing organisms, germ cell development is vital for the faithful transmission of the genome and epigenome across generations. Recent studies have shown that germ cell development is affected by different environmental toxicants, resulting in a decrease in germ cell health and number. Here, we examine and compare the transgenerational impact and mechanisms of two prevalent toxicants, the plastic chemical Bisphenol A and ethanol. Both have well-described impacts on the developing fetus; however, their effects on developing germ cells and subsequent generations are less explored. We analyze the transgenerational effects of both compounds in *Caenorhabditis elegans*. We hypothesize that exposure disrupts the epigenetic machinery in germ cells, causing changes in histone modifications, fertility defects, and germline dysfunction in a transgenerational manner. First, we show that BPA exposure causes a transgenerational two-fold increase in germline chromatin desilencing with $p\leq0.01$ coupled with a reduction and redistribution of histone H3K9me3 and H3K27me3. We show that the alteration of repressive histone levels is required for the observed transgenerational 43% increase in germline apoptosis with $p\leq0.01$ and 85% increase in embryonic lethality with $p\leq0.001$. An increase in apoptosis suggest possible perturbations in the germline checkpoint machinery. We show that BPA exposure transgenerationally induces untimely single-stranded DNA invasion with $p\leq0.001$, 2.5-fold increase in incorrect crossover formation with $p\leq0.001$, and 67% increase in missgregation of the X chromosome. To understand which checkpoint BPA perturbs to cause the increase in apoptosis, we used mutants of each checkpoint to rescue the effect. This revealed that BPA perturbs the synapsis checkpoint because a *pch-2* mutant decreased BPA induced apoptosis by two-fold with $p\leq0.0001$ but not the DNA damage checkpoint. Similar to that of BPA, ethanol exposure at human-relevant doses also causes transgenerational chromatin desilencing and germline dysfunction, although to a lesser extent than BPA's. This project identified BPA's and ethanol's transgenerational effect on the germline machinery and reproductive health. We hope to further understand how it induces germline dysfunction, carrying important implications for human reproductive health in the context of environmental exposures.

PS 1280 Synthetic Progestins and Progesterone Induce Similar Proliferative Transcriptomic Profiles in the T47D Breast Cancer Cell Line

E. M. Martin, S. Grimm, and P. A. Wade. *NIEHS, Durham, NC.*

The use of the synthetic progestin, medroxyprogesterone acetate (MPA), during hormone replacement therapy (HRT) has been linked to increased risk of invasive breast cancer. Currently, the biological mechanism underlying this relationship is unknown. Synthetic progestins are a class of pharmaceutical compounds that bind the progesterone receptor (PR) and are predominantly used as birth control and during HRT. It is unclear whether the use of synthetic progestins other than MPA is associated with invasive breast cancer. The goal of this study is to understand whether breast epithelial cells have the same physiological and transcriptional response to endogenous progesterone and synthetic progestins. T47D cells, a human breast epithelial cell line, were grown in culture and exposed to endogenous progesterone (P4) and four common progestins: (1) MPA, (2) etonogestrel, (3) norethindrone, and (4) levonorgestrel. First, a dose response experiment was conducted to determine the effects on cell proliferation, as growth arrest is a hallmark of progesterone exposure. Next, gene expression changes were assayed at physiologically relevant doses for both P4 (200nM) and the progestins (2nM). To determine transcriptional response, Progesterone Receptor (PGR), as well as the progesterone response sentinel gene, Zinc Finger And BTB Domain Containing 16 (ZBTB16) were assayed across the time points 2, 4, 6, 8, 10,12 and 24 hours. Based on these results transcriptomic profiles were assayed at 10 hours. Transcriptomic data show that P4 and synthetic progestins elicit the same response, with 94% of the response being conserved. Additionally, the magnitude and directionality of these changes are also conserved. Enrichment analyses demonstrate that there is an increase in cancer signaling, as well as pathways important in breast cancer development including AMPK and ERK/MAPK signaling pathways. Furthermore, enrichment of transcriptional regulators revealed that beyond hormonal regulators such as Estrogen Receptor 1(ESR1) and PR, cancer specific transcription factor, such as TP53 were enriched, as was E2F4, which has been linked to P4 associated growth. Taken together, these data suggest that activation of PR is linked to cancer related transcriptomic profiles. These findings suggest a molecular link exists between the epidemiological observations associating hormonal birth control use and breast cancer.

1281 Comparison of Toxicogenomic, Epigenomic, and Apical Points of Departure for Ketoconazole in a Developmental Toxicity Study

J. LaRocca[1], E. Costa[1], V. Anand[1], S. Sriram[1], V. Marshall[2], and K. Johnson[1]. *[1]Corteva Agriscience, Indianapolis, IN; and [2]Dow, Midland, MI.*

Toxicity testing paradigms for novel molecules take several years of investment and require extensive animal usage. There is promise that leveraging alternative techniques, such as toxicogenomics, may be able to replace traditional testing strategies for risk characterization while reducing animal use and maintaining protection for human health. The objective of this study was to generate data to support the use of a transcriptome-based point of departure (POD) for developmental and reproductive toxicity (DART) by comparing transcriptome (mRNA and miRNA) to traditional PODs. Ketoconazole, a fungicide with established embryotoxic and fetotoxic properties, was used for proof of concept in a rat developmental toxicity study. Ten rats/dose group were exposed daily to vehicle control or ketoconazole with seven dose levels ranging from 0.63 to 40 mg/kg/day from gestation day 6-21. On GD 21, embryotoxicity and fetotoxicity endpoints were evaluated, and whole-genome RNA sequencing was performed on liver and placenta samples. Benchmark dose lower confidence limit (BMDLs) were generated on apical endpoints and normalized expression data. NOELs were determined for epigenetic (miRNA) endpoints and apical endpoints that could not be determined by BMD. Dam apical BMDLs ranged from 0.4 to 23.7 mg/kg/day, with placenta histopathology as the most sensitive endpoint. Fetal apical BMDLs NOELs ranged from 6.3 to 20.4 mg/kg/day, with fetal body weight as the most sensitive effect. Dam liver and placenta transcriptome BMDLs were 0.7 and 1.8 mg/kg/day, respectively, which were similar to the most sensitive apical endpoint evaluated in the study. Liver and placenta epigenomic NOELs (0.63 and 2 mg/kg/day), were similar to transcriptomic and apical PODs. These data provide support that labor- and animal-intensive DART studies could potentially be replaced with streamlined studies that employ transcriptomic data, potentially by utilizing the liver as a sentinel organ, which would not only still be protective of human health but also reduce animal use.

1282 Gene-Specific Promoter Methylation of Lead Exposure Biomarker Genes in Environmental Lead-Exposed Children from Kabwe, Zambia

Y. B. Yohannes[1,2], S. Nakayama[1], J. Yabe[3], H. Toyomaki[1], A. Kataba[1], K. Muzandu[3], H. Nakata[1], Y. Ikenaka[1], K. Choongo[3], and M. Ishizuka[1]. *[1]Hokkaido University, Sapporo, Japan; [2]University of Gondar, Gondar, Ethiopia; and [3]University of Zambia, Lusaka, Zambia.*

Environmental exposure can alter epigenetic regulatory features, such as DNA methylation, and it is linked to impacts on human health. Among environmental contaminants, lead (Pb), a probable human carcinogen, is a prevalent toxic metal that can alter altered global and gene-specific DNA methylation and associated with various human diseases. One mechanism of Pb toxicity is its inhibition of δ-aminolevulinic acid dehydratase (ALAD) activity in heme synthesis. Another gene that is affected by Pb is the tumor suppressor gene p16, a key factor involved in the early stages of carcinogenesis. Kabwe town of Zambia is ranked among "The 10 World's most polluted places" because of the Pb-Zn mine in the town operated for almost a century (1902–1994). However, to date, no data exist regarding the influence of environmental lead exposure on DNA methylation level in children from Kabwe. Thus, we examined the frequency of hypermethylation in promoter regions of ALAD and p16 genes in the Pb exposed children using methylation-specific PCR. After obtaining permission from Ministry of Health, Zambia, blood samples (n =150) were collected at 5 clinics (3 near the dumpsite and 2 far from the dumpsite) from children aged 2 to 10 years old. Blood Pb levels (BLLs) were measured by Lead Care II analyzer. Genomic DNA was extracted using NucleoSpin Blood Kit and methylation conversion of genomic DNA was done using EpiTect Bisulfite Kit. The average BLLs were 24.0 ± 9.2 µg/dL for exposed area and 7.9 ± 4.5 µg/dL for unexposed area. Analysis of the profile of methylation in exposed area showed a significant methylation level for both ALAD and p16 genes. The methylation frequencies of ALAD CpG were 84.3% and 42.1% in exposed and unexposed areas, respectively and their associations with the risk of Pb poisoning was significant (adjusted OR = 7.84, 95% CI: 3.22-19.07; p<0.001). The incidence of p16 promoter hypermethylation for same area categories was 61.7% and 42.1%, respectively. In general, aberrant methylation of ALAD and p16 genes promoter region in the Pb exposed children might offer an effective means for earlier diagnosis of Pb poisoning.

1283 A Single Nuclei Analysis of Changes in Epigenetic Sensitivity to Chemical Exposure with Age

R. Barrere-Cain, L. Truong, B. Panter, Y. Chen, and P. Allard. *University of California Los Angeles, Los Angeles, CA.*

It is a well-known that the epigenome in early development is particularly vulnerable to chemical exposure. There is relatively little known, however, about periods of sensitivity during the aging process. Understanding how sensitivity to chemical exposure changes with age is crucial for designing thorough risk assessments. To map epigenetic sensitivity with age we are performing single nuclei RNA sequencing in adult *C. elegans*. *C. elegans*' short lifespan facilitates aging experiments and many fundamental age-related pathways are conserved between *C. elegans* and humans. Previously, we used immunofluorescence to show that regulation of certain histone marks becomes more variable with age, suggesting that older organisms may be more vulnerable to epigenetic perturbations. Single nuclei sequencing will help us further understand gene expression changes with age and chemical exposure. To assess the quality of our nuclei dissociations we used fluorescent activated cell sorting on nuclei dissociated from transgenic *C. elegans* containing GFP tagged germline nuclei. We obtain about 30% germline nuclei, suggesting we will be able to detect changes in the germline transcriptome with age and chemical exposure. After performing sequencing on day two adult *C. elegans*, we obtained 32,099 reads per cell, 1,515 genes per cell, and 10,810 nuclei sequenced, indicating that we had the sequencing depth to gain a comprehensive view of adult *C. elegans* transcriptomic changes and communication between tissues. The breadth of our sequencing enabled us to obtain rare cell types, for example roughly 5% of our nuclei were neurons. However, we had a low sequencing saturation of 31%, suggesting our samples were overly concentrated. Next, we will expose *C. elegans* to two chemicals pervasive in the environment, bisphenol A and perfluorooctanesulfonic acid, at different ages and then perform single nuclei sequencing. Subsequent chromatin immunoprecipitation sequencing will identify the upstream epigenetic changes associated with the observed gene expression changes. We will compare perturbations to the transcriptome and epitranscriptome at different ages to identify changes in chemical sensitivity with age. One benefit of our approach is that we can evaluate transcriptomic changes in specialized cell types, such as neurons, whose expression patterns are usually masked in bulk RNA sequencing. Furthermore, our research will help fuel dialogue on how to account for age when designing chemical safety assessments.

1284 Somatic Expression of piRNA in the Mouse Identifies Short, Tissue-Specific piRNA: Potential Implications for Toxicoepigenetics

B. P. Perera[1], M. L. Colwell[2], T. R. Jones[1], K. Neier[3], K. Wang[1], J. M. Goodrich[1], R. K. Morgan[1], C. Faulk[4], M. A. Sartor[1], and D. C. Dolinoy[1]. *[1]University of Michigan, Ann Arbor, MI; [2]University of Minnesota, St. Paul, MN; [3]University of California Davis, Davis, CA; and [4]University of Minnesota, Saint Paul, MN.*

Piwi-interacting RNAs (piRNAs) are a class of small non-coding RNA that associate with PIWI proteins for DNA methylation-induced retrotransposon suppression and are highly expressed from the germline. Mature germline piRNAs typically contains 24-32 nucleotides, 5′ uridine signatures, adenosine signatures at position 10, and 2′-O-methylation signatures at 3′ ends. Non-coding RNA expression is sensitive to environmental exposures, though the extent to which piRNA expression is modified by environmental toxicants is poorly understood. Traditionally, piRNAs were considered to be associated with sequence-specific *de novo* DNA methylation primarily of transposons and genic regions in germ cells. The current study overturns this accepted knowledge by revealing widespread PIWIL and piRNA expression from the mouse soma by incorporating qRT-PCR methods and next-generation sequencing of small RNAs enriched for piRNAs following sodium periodate treatment, respectively. Although *Piwil1*, *Piwil2*, and *Piwil4* were highly expressed in the germline, their somatic expression was also observed in the brain, liver, kidney, and heart. Sequencing results indicated short, tissue-specific somatic piRNA expression, with the hippocampus containing 5,494 piRNA-like peaks, followed by cortex (1,963), kidney (580), and liver (406). The study identified 26 piRNA sequence species and 40 piRNA locations exclusive to examined somatic tissues, compared to germline piRNA. Despite the lack of exposure-specific piRNA biomarker studies in the field of toxicology, cancer research has identified disease-associated piRNA biomarkers. As such, our ongoing research profiles the longitudinal tissue-specific effects of perinatal exposures on the piRNA transcriptome in mice, to reveal exposure-associated biomarkers in advancing disease interventions and therapeutics including ncRNA-based epigenome editing.

1285 Tissue- and Sex-Specific DNA Methylation Changes in Mice Perinatally Exposed to Lead

K. Wang, S. Liu, K. Neier, J. Colacino, L. Svoboda, M. A. Sartor, and D. C. Dolinoy. *University of Michigan, Ann Arbor, MI.*

Lead (Pb) is a well-known toxicant that can interfere with the development of a child's nervous and metabolic systems and increase the risk of developing diseases later in life. Although studies have investigated epigenetic effects associated with Pb exposure, knowledge of genome-wide changes with *in vivo* low dose perinatal Pb exposure in multiple tissues is limited. Within The Toxicant Exposures and Responses by Genomic and Epigenomic Regulators of Transcription (TaRGET II) consortium, we utilized a mouse model to investigate tissue- and sex-specific DNA methylation. Experiments were performed using genetically invariant mice 93% identical to C57BL/6J. Dams were assigned to control (0 ppm) or Pb-acetate (32 ppm) water, resulting in average maternal blood lead levels below the limit of detection and 32 µg/dL, respectively. Exposures started two weeks prior to mating and continued until weaning at post-natal day 21 (PND21). One target tissue (adversely affected by exposure, i.e. liver) and one surrogate tissue (easily accessible, i.e. blood) were collected from PND21 mice (N=6 male and N=6 female per group), and the DNA methylome was assessed using enhanced reduced representation bisulfite sequencing (ERRBS). Differentially methylated cytosines (DMCs) and differentially methylated regions (DMRs) were identified using methylSig with a FDR<0.05 and a methylation difference >10%. We identified tissue-specific DMCs from male (n=426 and n=690) and female (n=514 and n=602) mice in liver and blood, respectively. Among DMC-associated genes, 19 and 12 of them overlapped between sex in blood and liver, respectively. In addition, we found 15 DMC-associated genes (e.g. *CACNA1I*, *PHACTR1*, *AIFM3*) that overlapped between blood and liver in males and a distinct set of 15 DMC-associated genes that overlapped in females. In parallel, we used 50 base-pair regions to identify tissue- and sex-specific DMRs. Tissue-specific DMRs in males (n=509 and n=326) and females (n=399 and n=369) were found in blood and liver, respectively. Overall, our findings demonstrate that low dose perinatal Pb exposure can induce tissue- and sex-specific DNA methylation changes and provide information for future Pb studies in humans.

1286 Preferential Tissue Hypomethylation of the Mouse Epigenome by Low-Dose Decitabine Exposure

M. L. Colwell[1], N. Wanner[1], M. Drown[2], C. Drown[1], D. Dolinoy[3], and C. Faulk[1]. *[1]University of Minnesota, Saint Paul, MN; [2]University of Miami, Miami, FL; and [3]University of Michigan, Ann Arbor, MI.*

Decitabine (5-aza-2'deoxycytidine; DAC) is a small molecule drug commonly used to demethylate the epigenome in cell and whole animal models. However, current literature fails to identify the optimal dose of DAC to demethylate the epigenome. Additionally, many reports use imprecise measures of DNA methylation. Our preliminary data used reported doses in whole mouse models inducing high cytotoxicity with minimal to no changes in blood or somatic tissue DNA methylation. The current study aims to find the threshold of DAC to generate hypomethylation of the epigenome without causing cytotoxic effects. Mice were exposed to chronic low doses of decitabine ranging from 0 to 0.35 mg/kg over a period of 7 weeks. Testes function by weight and sperm concentration had dose response correlations along with gene expression within testes and liver, confirmed by qPCR and RNA seq. We find hypomethylation induced by DAC is locus (mLINE, IAP, IGF2, TCF3) and tissue (cortex, hippocampus, liver, testes, blood) specific, and is not uniform as previously reported. Bone marrow pathology indicates doses exceeding 0.35mg/kg during a chronic exposure prompts cytotoxic effects. Further, higher doses of DAC tend to hypermethylate rather than hypomethylate the epigenome by our WGBS analysis. Our findings indicate DAC is tissue specific, and may not be an ideal negative control for hypomethylation.

1287 Nonclinical Safety Assessment of Pharmaceutical Agents That Act Through Epigenetic Mechanisms of Action: Current Status and Industry Perspectives

V. L. Reynolds[1], P. Butler[2], M. M. Abernathy[1], L. Aschenbrenner[2], D. D. Best[1], J. Blank[3], M. Crosby[4], L. Custer[5], P. A. Escobar[6], K. Kolaja[7], J. Moggs[8], C. Snyder[9], T. VanVleet[4], J. Zhou[10], and T. K. Hart[11]. *[1]Eli Lilly and Company, Indianapolis, IN; [2]Pfizer Inc., San Diego, CA; [3]Takeda Pharmaceutical Company Limited, Boston, MA; [4]AbbVie Inc., North Chicago, IL; [5]Bristol-Myers Squibb Company, New Brunswick, NJ; [6]Merck & Co. Inc., West Point, PA; [7]Celgene Corporation, Summit, NJ; [8]Novartis AG, Basel, Switzerland; [9]Gilead Sciences Inc., Foster City, CA; [10]Janssen Pharmaceuticals Inc., Raritan, NJ; and [11]GlaxoSmithKline plc, Collegeville, PA.*

Pharmaceutic products designed to act as epigenetic modulators have been approved by regulatory authorities for treatment of advanced cancer. While the predominant effort in epigenetic drug development continues to be in oncology, nononcology indications are also garnering interest. A survey of pharmaceutical companies was conducted to assess the interest and concerns for developing small molecule direct epigenetic effectors (EEs) as medicines. Survey themes addressed the general levels of interest and activity with EEs as therapeutic agents, potential safety concerns, and possible future efforts to develop targeted strategies for nonclinical safety assessment of EEs. Thirteen companies contributed data to the survey. Overall, the survey data indicate the consensus opinion that existing ICH guidelines are effective and appropriate for nonclinical safety assessment activities with EEs. Special attention in the framework of toxicology study designs should be considered for delayed or latent toxicities, carcinogenicity, reproductive toxicity and the potential for transgenerational effects. While current guidelines have been appropriate for the nonclinical safety assessments of epigenetic targets, broader experience with a wide range of epigenetic targets will provide information to assess the potential need for new or revised risk assessment strategies for EE drugs.

1288 Epitranscriptomics of RNA Oxidation Reveals Mechanisms of Lung Toxicity and Disease

J. Gonzalez Rivera, and L. Contreras. *University of Texas at Austin, Austin, TX.* Sponsor: L. Contreras, American Society for Clinical Investigation American Society for Biochemistry and Molecular Biology

Chemical modifications of proteins and nucleic acids play critical roles in the regulation of gene expression. New evidence suggests that environmental stresses may be involved in the misregulation of the functional activities of RNA modifications and pathways during lung distress and disease. Air pollution is the major source of environmental toxicity to the pulmonary cells. Components of air pollution can generate free radicals and perturb redox homeostasis in cells, leading to formation of the prominent RNA oxidative modification 8-oxo-7,8-dihydroguanine (8-oxoG). This mark is predominantly induced in respiratory cells, and it leads to genotoxicity as it preferentially mispairs with adenosine. Given the prevalence of RNA oxidation under environmental challenges, it is critical to identify novel molecular mechanisms involving RNA oxidation toxicity to cellular physiology and disease. To address this, we developed a high-throughput sequencing method to profile 8-oxoG in mRNAs of human bronchial epithelial BEAS-2B cells. Cells were exposed for 1.5 hours to realistic air pollution mixtures derived from the reaction of ozone (100 ppb) with acrolein (100 ppb), methacrolein (97ppb) and α-pinene (44ppb), common organic volatile compounds in the atmosphere. These compounds formed a multi-component gas-phase mixture and submicron secondary organic aerosols (PM 1.0) with concentrations ~ 40 µg/m^3. Using this approach, we found 42 transcripts that are consistently oxidized by air pollution. These transcripts belong to key oxidative stress, signaling, and metabolic pathways. Importantly, one of the mRNA transcripts that is more susceptible to oxidation is FDFT1, a protein that catalyzes a regulatory step in cholesterol synthesis and free-radical scavenging. Moreover, we confirmed a ~2-fold (p-value < 0.05) decrease in expression of FDFT1 protein, and a ~1.7-fold (p-value < 0.001) decrease in cellular cholesterol levels. To further validate the involvement of misregulation of cholesterol on cellular toxicity of air pollution, we knocked down FDFT1 using anti-sense siRNA in BEAS-2B cells. We found that FDFT1 knockdown promotes distinct morphological phenotypes typically observed in studies of lung stress and inflammation. Overall, our findings indicate that air pollution influences the formation of 8-oxoG marks in transcripts of epithelial lung cells leading to alterations on cellular function and cell morphology.

1289 Detrimental Effects of Flame Retardant PBB153 Exposure on Sperm and Future Generations

K. W. Greeson[1,2], K. L. Fowler[3], P. M. Estave[4], S. K. Thompson[1], C. Wagner[5], R. C. Edenfield[1], K. M. Symosko[1,2], A. N. Steves[6], M. E. Marder[3], M. L. Terrell[3], H. Barton[3], M. Koval[3], M. Marcus[3], and C. A. Easley IV[1,2]. *[1]University of Georgia, Athens, GA; [2]Regenerative Bioscience Center, Athens, GA; [3]Emory University, Atlanta, GA; [4]Wake Forest School of Medicine, Winston-Salem, NC; [5]University of Texas McGovern Medical School, Austin, TX; and [6]University of California San Diego, San Diego, CA.*

In 1973, the Velsicol Chemical Company, which manufactured FireMaster, a brominated flame retardant, and NutriMaster, a nutritional supplement, mistakenly shipped hundreds of pounds of FireMaster to grain mills around Michigan where it was incorporated into animal feed and then into the food chain across the state. An estimated 6.5 million Michigan residents consumed polybrominated biphenyl (PBB)-laced animal products leading to one of the largest agricultural accidents in US history. To date, there have been no studies investigating the effects of PBB on epigenetic regulation in sperm, which could explain some of the endocrine-related health effects observed among children of PBB-exposed parents. Fusing epidemiological approaches with a novel *in vitro* model of human spermatogenesis, we demonstrate that exposure to PBB153, the primary component of FireMaster, alters the epigenome in human spermatogenic cells. Using our novel stem cell-based spermatogenesis model, we show that PBB153 exposure decreases DNA methylation at regulatory elements controlling imprinted genes. Furthermore, PBB153 affects DNA methylation by reducing *de novo* DNA methyltransferase activity at increasing PBB153 concentrations while reducing maintenance DNA methyltransferase activity at the lowest PBB153 concentration. Additionally, PBB153 exposure alters the expression of genes critical to proper human development. Taken together, these results suggest that PBB153 exposure alters the epigenome by disrupting methyltransferase activity leading to defects in imprint establishment causing altered gene expression, which could contribute to health concerns in the children of men exposed to PBB153. While this chemical is toxic to those directly exposed, the results from this study indicate that the epigenetic repercussions may be detrimental to future generations. Above all, this model may be expanded to model a multitude of environmental exposures to elucidate the effect of various chemicals on germline epigenetics and how paternal exposure may impact the health of future generations.

1290 Establishing Methods to Assess Epigenetic Signatures in Archived Study Tissues

M. Malloy[1], G. Carswell[2], B. Bennett[3], P. Bushel[3], L. Wehmas[2], S. D. Hester[2], and B. N. Chorley[2]. *[1]Oak Ridge Institute for Science and Education, Durham, NC; [2]US EPA, Durham, NC; and [3]NIEHS, Durham, NC.*

Revisiting archived studies using new methods on preserved samples will aid in a molecular understanding of adverse chemical effects, thereby reducing animal use, enhancing chemical hazard prioritization, and providing weight of evidence for regulatory decision making. Alterations in DNA methylation can occur with environmental chemical exposures, persist over time, and result in adverse health outcomes. In this pilot work, we tested the ability of Reduced Representation Bisulfite Sequencing (RRBS) to measure DNA methylation in formalin fixed paraffin embedded (FFPE) tissue samples relative to paired frozen controls. The 5 yr old liver tissue samples were obtained from male mice treated with 600 ppm phenobarbital (PB), a known mediator of DNA methylation changes and potential tumorigen, or vehicle control in drinking water for 28 d. Sequencing results indicate that FFPE samples contained significantly higher CpG sites relative to frozen samples (average 8.5 and 4.4 million reads, respectively with p=0.010; Kruskal-Wallis rank sum test); however, with higher read depth criteria (≥ 5X CpG site coverage), the remaining read counts for each sample type were statistically similar. In addition, read count variability in FFPE samples was significantly higher (p-value = 1.767e-11; Kruskal-Wallis rank sum test) than in frozen samples, overall indicating poorer quality sequencing data associated with FFPE. Only a few differentially methylated regions (DMRs) due to PB exposure were quantified in either sample type (4 and 1 DMRs, FDR p<0.05 for frozen and FFPE, respectively). When assessed with less stringency (uncorrected p<0.03 and methylation changes of >1%), 644 and 963 DMRs were identified for frozen and FFPE samples, respectively; however, only 30 DMRs were shared between sample types. In addition, genes linked to DMR regions overlapped less than 2% of previously published DMR genes due to short-term PB exposure in mouse liver, regardless of sample source. This indicates the study sample size (n=3 per condition) was of insufficient power to determine true DMRs. Follow-up studies in progress will address this issue. With sufficient power, we estimate that these FFPE-sourced data will accurately represent data from frozen/fresh tissue, thereby unlocking epigenetic-based data from archived tissue to refine mechanistic understanding of susceptibility to chemical-mediated toxicity. *This abstract does not necessarily reflect the policy of the US EPA.*

1291 Prenatal Lead (Pb) Exposure's Effect on DNA Methylation (5mC) and Hydroxymethylation (5hmC) in Adolescent Whole Blood

C. A. Rygiel[1], J. M. Goodrich[1], W. Perng[2], T. R. Jones[1], M. Solano[3], H. Hu[4], M. M. Tellez-Rojo[3], K. E. Peterson[1], and D. C. Dolinoy[1]. *[1]University of Michigan, Ann Arbor, MI; [2]Colorado School of Public Health, Aurora, CO; [3]National Institute of Public Health, Cuernavaca, Mexico; and [4]University of Washington, Seattle, WA.*

Gestational lead (Pb) exposure can adversely impact offspring health through multiple mechanisms, one of which is alteration of the epigenome via DNA methylation, addition of a methyl group to the 5th carbon of cytosine, and hydroxymethylation, an intermediate in oxidative demethylation that is associated with increased gene expression. Most methods collectively measure 5-methylcytosine (5mC) and hydroxymethylcytosine (5hmC) without distinguishing between the two. The aim of this study was to identify the association of prenatal Pb exposures at each trimester (T1, T2, T3) with 5mC and 5hmC levels at multiple cytosine-phosphate-guanine (CpG) sites within candidate regions of genes previously associated with prenatal Pb exposure (*HCN2*, *NINJ2, RAB5A* and *TPPP)* in whole blood leukocytes of children ages 11-18 years. Participants from the Early Life Exposure in Mexico to Environmental Toxicants (ELEMENT) birth cohorts with archived whole blood were selected (n=144) for analysis by pyrosequencing following oxidative or standard sodium bisulfite treatment. Combined, this method directly quantifies total methylation (5mC+5hmC) and 5mC only; 5hmC is obtained by subtraction. Participants are 51% male with blood lead levels (BLL) at 3.29 ± 4.44 µg/dL during collection with historical T1 maternal BLL 6.43 ± 5.16 µg/dL, T2 BLL 5.66 ± 5.21 µg/dL, and T3 BLL 5.86 ± 4.34 µg/dL. 5mC levels were measured in *HCN2* (83.5 ± 8.87%), *NINJ2* (36.3 ± 23.0%), *RAB5A* (1.48 ± 1.30%), and *TPPP* (90.8 ± 13.2%). 5hmC levels were calculated in *HCN2* (2.05 ± 4.13%), *NINJ2* (2.32 ± 5.69%), *RAB5A* (0.67 ± 1.17%), and *TPPP* (1.11 ± 6.96%), providing evidence for 5hmC presence in whole blood. Controlling for sex, current BLL, and experimental plate, T1 maternal BLL was associated with 5mC in *NINJ2* (β=-3.85, p=0.00020) and *HCN2* (β=2.33, p=0.00054); T2 BLL was associated with 5mC in *HCN2* (β=2.27, p=0.025) and 5hmC in *NINJ2* (β=2.73, p=0.0073); and T3 BLL was associated with 5mC in *HCN2* (β=2.18, p=0.031) and 5hmC in *NINJ2* (β=3.52, p=0.00063). No statistical significance was identified in *TPPP* or *RAB5A.* Future studies need to quantify gene expression to determine if 5mC/5hmC changes are promoting transcriptomic alterations and investigate epigenetic patterns in other tissues.

1292 Prediction and Analysis of Hyper- and Hypomethylated Genes Associated with Breast Cancer

K. Chitrala[1], S. Yeguvapalli[2], M. Nagarkatti[3], and P. Nagarkatti[3]. *[1]Temple University School of Medicine, Philadelphia, PA; [2]Sri Venkateswara University, Tirupati, India; and [3]University of South Carolina School of Medicine, Columbia, SC.*

Breast cancer is one of the major cancers affecting women around the world. Several reports showed that epigenetics plays a major role in cancers. Among the epigenetic modifications, DNA methylation (DNAm) is known to play a key role in breast cancer. In the present study, we aimed to analyze the epigenetic modifications in breast cancer among African Americans (AAs) and Caucasian Americans (CAs). To this end, we have downloaded the publicly available DNAm data for breast cancer among AAs and CAs from the TCGA database. Differential methylation analysis for the downloaded TCGA datasets was performed using *TCGAbiolinks*, an R/Bioconductor package for integrative analysis with GDC data. Results from 160 samples in AAs and 578 samples in CAs were available for breast cancer in TCGA database. Differential methylation analysis showed that there were statistically significantly differentially methylated positions (DMPs) between AAs and CAs. Among these DMPs, genes *MRPL28* (Mitochondrial Ribosomal Protein L28) and *PACS2* (Phosphofurin Acidic Cluster Sorting Protein 2) were identified as top five hypermethylated and the genes *RPH3AL* (Rabphilin 3A Like [Without C2 Domains]), *S100A14* (S100 Calcium Binding Protein A14) and *HOOK2* (Hook Microtubule Tethering Protein 2) were identified as top hypomethylated genes at a p-value <0.05. In conclusion, results from our study may provide further insights into the genes that influence the health outcomes in breast cancer among AA and CA populations.

1293 Morphine Sulfate Downregulates Mitotically Heritable Epigenetic Histone Modifications and Disrupts Pluripotency Phenotype in Human iPSCs

A. J. Chintalapati, and F. A. Barile. *St. John's University College of Pharmacy and Health Sciences, Jamaica, NY.*

Epigenetic (EG) manifestations and resulting genomic heterogeneity from opioid exposure is a novel and infrequent perspective to understand opioid induced toxicity. Aberrations in histone protein post-translational modifications (HP-PTMs) induce perturbations in chromatin integrity and subsequent differences in global gene expression patterns. In the current study, we hypothesized that morphine sulfate (MS) alters histone-3-protein (H3)-PTMs and pluripotency in human induced pluripotent stem cells (iPSCs). Observations of 21 global genomic H3-PTMs following exposure to 10 μM MS for 2 and 5 days suggest decreased levels of gene expression repressive H3-PTMs, H3K9me1 (2 days) and H3K27me3 (5 days). To confirm if these changes were reversible, cells were allowed to recover for 3 days in the absence of MS. Genomic levels of both H3K9me1 and H3K27me3 were not different from control, suggesting that MS induced EG effects are reversible. Furthermore, decrease in levels of H3K9me1 and H3K27me3 are concentration dependent and are not antagonized by pre-exposure of iPSCs to 10 μM naltrexone, suggesting an EG aberration in an opioid receptor independent pathway. Continuous MS exposure to 1 and 10 μM for longer durations rendered the levels of histones to initially level off, followed by another increase at 26 days, relative to control. Interestingly, shorter durations of MS exposure induced pluripotency as determined by stem cell specific nuclear transcription factor Oct-4 and cell surface marker TRA-1-60. Pluripotency stimulation was effectively inhibited when iPSCs were exposed to 10 μM naltrexone prior to MS exposure. However, except for a MS-induced decrease in TRA-1-60 following MS exposure for 29 days, pluripotency of iPSCs did not change. Together, the results indicate that MS alters pre-programmed H3-PTMs and stem-cell pluripotency according to opioid receptor independent/dependent mechanisms, respectively.

1294 Role of microRNA in Regulation of CD44 Involved in Development of Autoimmune Hepatitis

J. Zhou, Y. Zhong, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

Autoimmune hepatitis (AIH) is a rare severe liver disorder, which affects both children and adults worldwide. The incidence of AIH is increasing in the recent years. AIH may lead to develop cirrhosis and liver cancer. Studies have shown that AIH may result from the abnormal body's immune system, which attacks own liver, and causes inflammation and liver damage. However, the exact cause of AIH is unclear. Our study using concanavalin A (Con A)-induced AIH mouse model demonstrated that there was a significant increase in the plasma aspartate aminotransferase activity (AST) level, liver damage and liver-infiltrating mononuclear cells in CD44 KO mice when compared to C57BL/6 wild type mice. CD44 deficiency induced severe disease due to decreased apoptosis of liver-infiltrating cells and increased liver damage by such infiltrating cells. Our RNA sequencing data revealed that approximate 4,700 genes were up-regulated with a fold change >2.0, whereas 5,300 genes were down-regulated in liver tissues from Con A-induced AIH mice. Gene function analysis showed that the up-regulated genes such as BCL2L1, CASP3 and CASP8 in AIH mice might be responsible for hepatocyte apoptosis and liver injury, whereas the down-regulated genes such as IL-6 and SOCS1 in AIH might be associated with liver inflammation. Importantly, CD44 was up-regulated in AIH mice which could target BCL9 and β-catenin, suggesting that the expression and functions of CD44 may play a role in the regulation of Wnt/β-catenin signaling pathway, involved in autoimmune hepatitis pathogenesis. MicroRNA (miRNA) array analysis indicated that several miRNAs including miR-138-5p, miR-1911-3p, miR-1915-3p, miR-1249-5p, miR-1953 and miR-1356-3p, which could target CD44, were up-regulated in AIH mice; however, many CD44-targeting miRNAs such as miR-199a-3p, miR-328-3p, miR-471-3p, miR-483-3p, miR-708-5p and miR-1247-3p were down-regulated significantly in AIH mice. Interestingly, several up-regulated miRNAs such as miR-99a-3p, miR-503-3p, miR-6901-5p and miR-743a-5p could target β-catenin, suggesting that miRNAs may regulate Wnt/β-catenin signaling pathway and thus affect AIH pathogenesis. Moreover, the other up-regulated miRNAs such as miR-124-5p, miR-126a-5p, miR-137-3p and miR-140-5p could target CASP3, indicating that specific miRNAs may regulate cell apoptosis and thus affect autoimmune hepatitis pathogenesis. Further studies will be needed to elucidate the functions and underlying mechanisms of specific miRNAs in the regulation of CD44 involved in the development of autoimmune hepatitis. Our results suggest that CD44 may play an important role in the pathogenesis of autoimmune hepatitis. *Supported by NIH grants P01AT003961, P20GM103641, R01AT006888, R01ES030144, R01AI129788 and R01AI123947.*

1295 Epigenetic Regulation of Immune Response by Cannabidiol in Experimental Autoimmune Encephalomyelitis

X. Yang, M. Bam, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina, Columbia, SC.*

Several studies have suggested that ingredients in marijuana such as THC and CBD regulate immune response through epigenetic mechanisms. In this study we use microarray and next generation sequencing (NGS)-based approaches to determine how CBD alters histone/DNA methylation and expression of non-coding RNA (miRNA) and long non coding RNA (lncRNA) in CD4+ T lymphocytes in a mouse Experimental Autoimmune Encephalomyelitis (EAE) model. Treatment with CBD leads to attenuation in neuroinflammation and decrease in T cell proliferation in MOG induced EAE. We have found that the overall methylation levels of two histone marks, H3K4me3 which is associated with transcription activation and H3K27me3 which is associated transcription suppression, do not differ significantly in CD4+ T cells from naïve mice, EAE mice and CBD-treated EAE mice. However, histone methylation signal is enriched in the binding sites of certain transcription factors, such as ZNF143 and FoxA1, suggesting that these transcription factors may have important roles in CBD mediated immune modulation. In microarray study, we have found that the expression of protein coding transcripts as well as non-coding RNAs is altered in EAE mice compared to those in naïve mice. More importantly, the expression pattern of many transcripts is reversed by CBD treatment. A unique finding of this study is that the expression of many miRNAs and lncRNAs is dramatically affected by CBD. For example, increased expression of pro-inflammatory miR-155, -19, -210 and -223 in EAE is reversed by CBD treatment. Among those altered lncRNAs, most of them have not been validated experimentally and their functions are not known. We selected some validated lncRNAs and their expressions in CD4+ T cells from CBD and vehicle treated EAE mice are confirmed by real-time qPCR. For instance, lncRNA Neat1, which promotes cell proliferation and Mirt2, which inhibits the activation of NF-kB and MAPK pathways to limit the expression of proinflammatory cytokines are among the most significantly altered lncRNAs by CBD. In summary, this study shows that CBD regulates immune response through epigenetic mechanisms, particularly miRNA and lncRNA. *Supported by NIH grants P01AT003961, P20GM103641, R01AT006888, R01ES030144, R01AI129788 and R01AI123947.*

1296 PCB126-Induced Alterations in m6A RNA Modifications in Zebrafish Embryos

N. Aluru, and S. I. Karchner. *Woods Hole Oceanographic Institution, Woods Hole, MA.*

Chemical modifications of proteins, DNA and RNA moieties play critical roles in regulating gene expression. Emerging evidence suggests these RNA modifications (epitranscriptomics) have substantive roles in basic biological processes. One of the most common modifications in mRNA and noncoding RNAs is N^6-methyladenosine (m6A). In a subset of mRNAs, m^6A sites are preferentially enriched near stop codons, in 3' UTRs, and within exons, suggesting an important role in the regulation of mRNA processing and function including alternative splicing and gene expression. Very little is known about the effect of environmental chemical exposure on m6A modifications. As many of the commonly occurring environmental contaminants alter gene expression profiles and have detrimental effects on physiological processes, it is important to understand the effects of exposure on this important layer of gene regulation. Hence, the objective of this study was to characterize the acute effects of developmental exposure to PCB126, an environmentally relevant dioxin-like PCB, on m6A methylation patterns. We exposed zebrafish embryos to PCB126 for 6 hours starting from 72 hours post-fertilization and profiled m6A RNA using methylated RNA immunoprecipitation followed by sequencing (MeRIP-seq), as well as assessing changes in mRNA splicing. We observed 6,983 and 11,315 m6A peaks in DMSO and PCB126 exposure groups (FDR 5%), respectively. The majority of the peaks are preferentially located around the 3'UTR and stop codons. Pathway analysis of m6A marked transcripts induced by PCB126 exposure revealed that these transcripts are associated with important developmental pathways (MAPK, Hedgehog, Notch and Wnt). These results suggest that PCB126 could affect developmental gene expression patterns by altering m6A levels. Gene expression analysis revealed upregulation of classical aryl hydrocarbon receptor (AHR) target genes such as cytochrome P450s in response to PCB126 exposure. Interestingly, none of the AHR target genes overlapped with the m6A altered transcripts, suggesting that xenobiotic metabolism may not be under m6A regulation. Further studies are necessary to understand the functional consequences of exposure-associated alterations in m6A levels. *This work is supported by NIEHS ES024915.*

1297 Single Cell Analyses Identify NK-Like T Cells in Peripheral Blood Affected by Tobacco Smoke Exposure

M. R. Campbell, S. N. Martos, O. A. Lozoya, M. Wan, G. S. Pittman, and D. A. Bell. *NIEHS, Research Triangle Park, NC.*

Exposure from tobacco smoke has been found to impact immune response, leukocyte subtypes, DNA methylation, and expression from human whole blood. Analysis with single cell technologies will resolve smoking associated (sub)population compositions, gene expression differences, and identification of rare subtypes masked by bulk fraction data. Single cell RNA sequencing (scRNAseq) from primary peripheral blood mononuclear cells (PBMCs) identified shifts in subtype distributions within the CD4 T and CD8 T cell populations between smokers (n=4) and nonsmokers (n=4). In order to confirm and immunotype the PBMC populations, we used CyTOF with a 26-marker phenotypic panel to evaluate ~ one million viable cells from the same individuals profiled in scRNAseq. Major cell type population frequencies showed strong correlation between scRNAseq and CyTOF (Pearson r=0.99, p<0.0001). Using the VorteX Clustering Environment and the X-shift algorithm in combination with manual gating (Cytobank) for CyTOF analysis, we found no changes (Mann-Whitney, p=0.69; p=0.42) in the total number of CD8 T cells and Natural Killer T (NKT) cells, which was consistent with scRNAseq analysis. From the CD8 T cells, CyTOF found a significant increase (p=0.03) in the frequency of $CD16^+$ CD8 T cells in smokers. CD16 is commonly associated with nonclassical monocytes and Natural Killer (NK) cells. In NK cells, CD16 acts as a receptor that binds IgG antibodies to activate antibody-dependent cellular cytotoxicity (ADCC) processes. Using manual gating, the majority of this NK-like $CD16^+$ CD8 T cell subtype was CD45RA positive for both smokers and nonsmokers, indicating that this CD8 T cell subtype effector memory T cells re-expressing CD45RA (T_{EMRA}) cells. To demonstrate reproducibility and further phenotype smoking-altered T cell subpopulations, we designed a 36 antibody CyTOF panel containing markers to differentiate among naïve, central memory, effector memory and end-stage effector memory T subsets. We also quantified expression of cytolytic effector proteins (GZMB and PRF1) and exhaustion-associated proteins (PD-1, TIM-3, and CTLA-4).

1298 Epigenetic Signatures of the Past-Bisphenol A Exposure in Germ Line and Somatic Cells across Two Generations: A Transgenerational Study

X. Wang, and R. K. Bhandari. *University of North Carolina Greensboro, Greensboro, NC.*

Exposure to environmental chemicals can have far reaching health effects especially when it occurs during the sensitive windows of embryonic development. Some chemical exposures have been found to be inherited by subsequent generations even after the exposure was ceased several generations ago. The effects that develop in absence of exposure but due to the past exposure of their ancestors is called transgenerational health effects. Transgenerational health effects in humans are not clearly understood; however, the studies from non-human studies suggest that chemicals can leave some exposure-specific epigenetic marks on germ stem cells that are transmitted to subsequent generations resulting in adverse health outcomes. The health effects developed at the multigenerational (in presence of direct contact with the chemical) seem to be different from transgenerational health effects. No epigenetic biomarkers have been identified that can reliably identify the past exposure and predict future health outcomes. The epigenetic marks are cell type and developmental stage specific. The transgenerational epigenetic marks that are resistant to epigenetic reprogramming are thought to be consistent across generations; however, very little is known about their specificity and role in development of predicted phenotypes. We are trying to identify epigenetic signatures of past bisphenol A exposure (10 ug/L) in medaka fish germline and somatic cells. We exposed medaka fish embryo from the day of fertilization to 12 days post fertilization and studied the dynamics of DNA methylation and gene expression across various stages of germ cells and across generations. Our results demonstrate that: a) the BPA-induced epigenetic marks escape epigenetic reprogramming (the process of erasure of parent-derived epigenetic marks and establishment of offspring cell/sex specific epigenetic marks) in germ stem cells (primordial germ cells, PGCs); b) some new epigenetic marks are established in germ cells during spermatogenesis in males; and c) majority of the BPA-specific epigenetic marks are *de novo* established past gametogenesis and are maintained by sperm. Approximately 30% reduction in fertility observed in males due to ancestral BPA exposure (past three generations). In this talk, we will present epigenetic marks of the past BPA exposure that are transmitted to offspring across two subsequent generations, and transcriptional pathways linked to these epigenetic alterations, which are potentially useful for prediction of adverse health outcomes. *Supported by fundings from National Institute of Environmental Health Sciences (NIEHS) R21ES027123, R21ES027123-02S1.*

1299 Arsenic-Induced Polyadenylation of Canonical Histone H3.1 mRNA Facilitates Cell Transformation through Inhibition of Variant Histone H3.3 Assembly

D. Chen[1], Q. Chen[1], Z. Wang[2], Y. Zhu[1], T. Kluz[1], C. Zang[2], M. Costa[1], and C. Jin[1]. *[1]New York University School of Medicine, New York, NY; and [2]University of Virginia School of Medicine, Charlottesville, VA.*

Arsenic is the number one global carcinogenic contaminant, affecting more than 150 million people worldwide. Our previous study revealed that exposure to arsenic reduces cellular levels of the stem-loop binding protein (SLBP), which is critical for canonical histone pre-mRNA processing, resulting in the generation of polyadenylated H3.1 mRNA *in vitro*. This is intriguing because in general canonical histone mRNAs, unlike most other genes in multicellular organisms, do not possess a poly(A) tail. In the current study, we investigated the role of arsenic-induced H3.1 mRNA polyadenylation in carcinogenesis and the underlying mechanisms. The soft agar colony formation assay and xenograft assay demonstrate that ectopic expression of polyadenylated H3.1 mRNA promotes anchorage-independent cell growth and tumor formation in nude mice. Moreover, RNA-seq, flow cytometry cell cycle analysis, and chromosome spread assays display that polyadenylation of H3.1 mRNA causes transcriptional deregulation, G2/M cell cycle arrest, chromosome aneuploidy and aberrations. Notably, the ChIP-seq results reveal that induction of polyadenylated H3.1 mRNA results in displacement of the variant H3.3 from critical gene regulatory elements such as active promoters, insulators, and enhancers. H3.3 displacement appears to be critical for arsenic-induced carcinogenesis, since knockdown of H3.3 by siRNA induced cell transformation, whereas overexpression of H3.3 rescued cells from arsenic-induced transformation. Importantly, arsenic was capable of inducing high levels of H3.1 mRNA polyadenylation and marked loss of the SLBP in lung tissues of A/J mice exposed to arsenic (0, 100, and 200 μg/L) by inhalation for one week. This study uncovers polyadenylation of H3.1 mRNA and resulting displacement of H3.3 from regulatory elements as a potential mechanism for carcinogenesis. In addition, our findings add new insight not only into the oncogenic role for histone variant H3.3 but also into genomic instability induced by imbalance in histone stoichiometry. *This work was supported by National Institutes of Health grants R01ES026138, P30ES000260, R01ES029359, R01ES022935, and K22CA204439.*

1300 The Organophosphate Pesticide Methyl-Parathion Modulates the Expression of DNA Methylation-Demethylation Genes Through Oxidative Stress in Mice Testicular Cells

C. Zamora-Gonzalez, M. Solis-Heredia, R. Bonilla-Moreno, G. Martinez-Aguilar, I. Camacho-Hernandez, I. Poblete-Naredo, and B. Quintanilla-Vega. *Cinvestav, Mexico City, Mexico.*

DNA methylation-demethylation (DNA-M/D) is an epigenetic mechanism, which is associated with gene expression. DNA methylation involves the covalent transfer of methyl groups to cytosine from cytosine-guanine (CpG) sites, forming 5-methylcytosine (5-mC); this process is catalyzed by DNA-methyltransferases (DNMTs). Active DNA demethylation, catalyzed by ten-eleven translocation enzymes (TETs), consists in the sequential oxidation of 5-mC to finally be repaired to cytosine. The regulation of this process is not fully known; however, it has been proposed that reactive oxygen species (ROS; either endogenous or exogenous) can regulate DNA-M/D. The organophosphate pesticide methyl-parathion (Me-Pa), despite its highly toxicity, is employed in developing countries and it produces oxidative damage in macromolecules of sperm cells, as well as DNA alkylation. Recently, we reported that Me-Pa exposure generates promoter-specific hypermethylation in antioxidant response and DNA repair genes in sperm cells, but the mode of action is unknown. The objective of this study was to evaluate the *DNMTs* and *TETs* expression and methyl-purine DNA glycosylase (*MPG;* alkylation repair gene) expression in sperm cells of mice exposed to Me-Pa (6 mg/kg/day/5 days) and co-exposed with Me-Pa (same dose)-Vitamin E (50 mg/kg/day/5 days) to evaluate ROS participation. The exposed group to Me-Pa showed an increase in *DNMT3B* (*de novo* methylation), *DNMT1* (maintenance of methylation), *TET1*, and *TET2* expression and a decrease in *MPG* expression. On the other hand, the co-exposed group showed lower expression of *DNMTs* and *TETs* genes comparing with Me-Pa treated animals, suggesting that ROS may modulate the expression of DNA-M/D genes. Moreover, we observed an increased in *MPG* expression in the co-exposed group, suggesting that Me-Pa could be generating direct methylations in DNA and thereby activating the alkylation repair. In summary, these results suggest that the modulation of DNA-M/D genes expression, which was related to oxidative stress generated by Me-Pa exposure may partially explain the promoter-hypermethylation and low expression of antioxidant and DNA repair genes previously observed after Me-Pa exposure.

1301 Understanding Environmental Impact on Germ Cell Differentiation Trajectories Using scRNA-Seq

P. Allard. *University of California Los Angeles, Los Angeles, CA.*

While the intricate steps of germ cell development have long been hypothesized to provide unique windows of sensitivity to environmental insults, little is known of the effect of chemical exposure on the epigenome of germ cells and of the mechanisms of inheritance of these effects. This gap is particularly significant as embryonic germ cells undergo an extensive remodeling of their chromatin which includes genome-wide demethylation and the establishment of a complex pattern of histone modifications. The failure to properly regulate these histone marks leads to spurious repetitive element expression, germ cell death and infertility. Here, we use *in vitro* generated mouse and human germ cells termed Primordial Germ Cell-Like Cells (PGCLCs), to conclusively show that their epigenetic remodeling period constitutes a period of high sensitivity to environmental exposure. To this aim, we exposed their precursors, epiblast-like cells (EpiLCs) as well as PGCLCs for various lengths of time to (1) known chemical inhibitors of specific histone marks and (2) a model environmental chemical: BPA. We examined the impact of these exposures on survival/viability as well as the levels of repressive histone marks such as H3K9me3 and H3K27me3. By using targeted chemical inhibitors, we show that the tight regulation of both repressive histone marks H3K9me3 and H3K27me3 is essential for survival of differentiating PGCLCs. We also show that low BPA concentrations (1 and 10uM) disproportionately affect PGCLCs survival but not EpiLCs. These effects correlate with a marked decrease of both repressive marks H3K9me3 and H3K27me3. Finally, by using scRNA-seq, we show that exposure of human PGCLCs to low BPA levels doses alters the developmental trajectory of PGCLCs and affects precursors of PGCLCs disproportionately compared to PGCLCs themselves. We expect this research to provide a much-needed examination of the pathways implicated in the sensitivity of early germ cells to environmental insults and at the root of infertility.

1302 Genome-Wide DNA Methylation Changes in MutaMouse Lung and Liver Tissue following Subchronic Exposure to Benzo[*a*]pyrene

V. P. Tryndyak[1], A. S. Long[2,3], P. A. White[2], V. M. Arlt[4], F. A. Beland[1], and I. P. Pogribny[1]. *[1]US FDA/NCTR, Jefferson, AR; [2]Health Canada, Ottawa, ON, Canada; [3]University of Toronto, Toronto, ON, Canada; and [4]King's College London, London, United Kingdom.*

Benzo[*a*]pyrene (B[a]P), a representative polycyclic aromatic hydrocarbon and Group 1 human genotoxic carcinogen, is found in coal tar, tobacco smoke, indoor and outdoor air, and broiled meats. Accumulated evidence indicates that, in addition to having exposure-induced genotoxic effects, genotoxic carcinogens such as B[a]P can induce epigenetic alterations associated with carcinogenesis. It was previously reported that subchronic MutaMouse exposure to B[a]P resulted in the greater level of DNA adducts in the lungs, a target organ for B[a]P carcinogenicity in mice, relative to livers, a non-target organ; however, the frequency of induced *lacZ* mutations was comparable in both organs. The goal of this study was to investigate the effect of B[a]P exposure on epigenetic alterations in MutaMouse lung and liver tissue following subchronic exposure. Adult male MutaMouse were treated with 75 mg B[a]P/kg body weight/day via oral gavage for 28 consecutive days, and the status of DNA methylation investigated by reduced representation bisulfite sequencing (RRBS). Exposure to B[a]P produced a comparable number of treatment-related differentially methylated regions (DMRs) in both organs. A combined analysis of gene-specific DNA methylation and differentially expressed genes (DEGs) showed that among 3390 DMRs and 368 DEGs in the lungs and 3007 DMRs and 315 DEGs in livers, only 32 and 20 genes in the lungs and livers, respectively, displayed an inverse correlation between DNA methylation and gene expression. Despite there being no differences in the number of treatment-related DMRs in the lungs and livers of B[a]P-exposed mice, there were marked differences in the pattern of organ-specific DNA methylation. Treatment with B[a]P resulted in a profound loss of genome-wide DNA methylation in the lungs, an epigenetic carcinogenesis-related event associated with genomic instability. This was evidenced by a 2-fold greater number of hypomethylated DMRs than hypermethylated DMRs. In contrast, no substantial difference between the number of hypomethylated and hypermethylated DMRs was found in the livers. The results indicate that, in addition to genotoxic alterations, the carcinogenic effect of B[a]P may be associated with both cancer-related genotoxic and epigenetic alterations in the target organ.

1303 Low-Level Sodium Arsenite Exposure Decreases Histone H3 Lys36 Trimethylation in Human Liver HepaRG Cells

B. Borowa-Mazgaj, V. Tryndyak, F. A. Beland, and I. P. Pogribny. *US FDA/NCTR, Jefferson, AR.*

Inorganic arsenic exposure is a worldwide environmental health problem. The underlying mechanisms of arsenic toxicity and tumorigenicity are still not completely clarified; however, the involvement of epigenetic alterations has been suggested in the arsenic-induced tumorigenic process. Previously we showed that exposure of mature liver HepaRG cells to a low concentration of sodium arsenite for 14 days induced prominent gene expression and genome-wide DNA methylation alterations. Here, we investigated the effect of inorganic arsenic on histone modifications in differentiated HepaRG cells. Treatment of HepaRG cells with sodium arsenite for the 14 consecutive days resulted in a marked decrease of global histone H3 lysine 36 trimethylation (H3K36me3). Mechanistically, the loss of H3K36me3 in sodium arsenite-treated cells was accompanied by down-regulation of the histone methyltransferase *SETD2* gene, which is involved in histone H3K36 trimethylation. In addition to a global loss of histone H3K36me3, the sodium arsenite treatment caused an extensive reduction in gene-specific histone H3K36me3, as detected by ChIP-seq analysis. Interestingly, 69.5% of gene-specific histone H3K36me3 peaks were in the exon/intron regions, while only 1.4% was associated with gene promoters. Furthermore, by using combined gene expression and ChIP-seq analysis, we identified 203 genes, which expression positively correlated with histone H3K36me3 enrichment. The expression of most of these genes, 160 genes or 79%, was associated with the loss of histone H3K36me3. These genes belong to several pathways, crucial for cellular function and homeostasis, among which were: lipid homeostasis, xenobiotic, bile, carboxylic acids, steroid metabolism, and epithelial to mesenchymal transition. These findings emphasize the importance of epigenetic alterations as one of the key molecular events in the pathogenesis of arsenic-associated tumorigenesis.

1304 Scoping Review of Polycyclic Aromatic Hydrocarbons (PAH) Human and Experimental Animal Cancer Studies

A. Wang[1], A. Ewens[2], W. Arroyave[2], P. Schwingl[2], S. Atwood[2], and R. Lunn[1]. *[1]NIEHS, Research Triangle Park, NC; and [2]Integrated Laboratory Systems Inc., Research Triangle Park, NC.*

The carcinogenicity of some, but not all, PAH are known. To gauge feasibility of a potential systematic review of PAH cancer hazard, we conducted a systematic literature search of PAH human and animal cancer studies. We screened studies and categorized exposure and cancer exanimated. Study quality was not evaluated. Human cancer studies included studies with occupational exposure, environmental exposure, and biomonitoring. Occupational studies usually assessed PAH exposure via expert developed job exposure matrices or expert classified exposure, and some studies used semiquantitative exposure matrices created from measured workplace ambient air. Lung cancer was reported on most; bladder, breast, pancreatic, laryngeal, prostate, and childhood brain cancers were also reported. Environmental studies used PAH in ambient air, traffic pollution, and household dust for exposure and reported on childhood leukemia and breast cancers. Studies of PAH urinary biomarkers reported on lung and breast cancers, while many PAH DNA adduct studies, some including gene-environment interaction, reported on lung, breast, and liver cancers. Measurements of individual PAH can be used as surrogates of PAH mixture, the real life human exposure. Multiple exposure types with overlapping cancer endpoints reported will be a strength in future assessments. Animal cancer studies were searched for PAH in general and 35 specific PAH names, which did not include PAH listed in the current Report on Carcinogens. Animal carcinogenicity, co-carcinogen, or initiation/promotion studies, published in English, with some physiologically relevant exposures (oral, dermal, inhalation, intratracheal instillation, or i.p. injection) were included. Nearly all studies were published before the year 2000. Among 24 PAH categorized, chrysene, benzo[*e*]pyrene, cyclopenta[*cd*]pyrene, pyrene, and anthracene were the most studied. Most studies were in mice with dermal application, and many reported skin neoplasms. Lung and liver, but not skin, tumors were reported in i.p. studies. Other exposure routes or report on other tumor sites were rare. Some dermal and non-dermal exposure studies reported no increase in tumors, while anthracene, benzo[*ghi*]perylene, chrysene, cyclopenta[*cd*]pyrene, fluoranthene, and pyrene had increased tumors at two or more sites. While most studies being on skin cancer of dermally exposed mice is a limitation, the highly similar design can be a strength in comparing PAH.

1305 Carcinogenic Susceptibility Comparative Study on rasH2 Mice Produced by Two Breeding Facilities

R. Inoue, M. Yasuda, E. Nishinaka, C. Nishime, H. Haga, M. Mochizuki, K. Kawai, and K. Urano. *Central Institute for Experimental Animals, Kawasaki, Japan.*

CByB6F1-Tg(HRAS)2Jic mice (rasH2 mouse) are produced at two breeding facilities, CLEA Japan, Inc. (Fuji, Shizuoka, Japan) and Taconic Bioscience (Germantown, NY, USA), and are supplied worldwide. The rasH2 mouse produced from cross-breeding by BALB/cByJJic female and C57BL/6JJic-Tg(HRAS)2Jic hemizygous male, in order to prevent genetic drift, both CLEA and Taconic colony has been renewed within 10 generations by rederivation from frozen embryos preserved in the Central Institute for Experimental Animals (CIEA, Kawasaki, Japan). After the breeding colonies renewed, we regularly perform a carcinogenic susceptibility study to confirm the homogeneity of rasH2 mice produced by the two facilities. In this study, we investigated the carcinogenic susceptibility of rasH2 mice derived from the breeding colonies replaced in 2016-2017. A total of 120 mice obtained from the two facilities (60 from each colony) were divided into vehicle (citrate buffer) and MNU (*N*-methyl-*N*-nitrosourea, 75 mg/kg) groups. Fifteen mice of each sex were assigned to each group, injected intraperitoneally with vehicle or MNU (week 0), and observed for 26 weeks. When mice were identified as moribund during the study period, they were sacrificed, and almost all organs were investigated histopathologically. The survival rates of the MNU and Vehicle group at week 26 were 0.0-6.7% and 86.6-93.3%, respectively. In MNU group, the incidence of forestomach papilloma/squamous cell carcinoma, typical MNU-induced tumors, was 100.0% in mice produced at two facilities. The incidence of malignant lymphoma of mice produced at CLEA and Taconic were 73.3-93.3% and 66.7-73.3%, respectively. Lung adenoma and skin papilloma/keratoacanthoma, major MNU-induced tumors in this strain, were observed in several mice in the MNU groups from both facilities. No significant differences were found in the tumor incidences between the two facilities. Consequently, Carcinogenic conformity of rasH2 mice derived from the replaced breeding colonies in two facilities was confirmed in the present study. Furthermore, as a result of comparison of tumor incidences in the similar study performed in past, we judged that the carcinogenic susceptibility of the rasH2 strain has been well maintained for more than two decades.

1306 Evaluation of Dietary E171, a Food Grade TiO_2, on the Rat Intestine

S. M. Cohen[1], L. L. Arnold[1], K. L. Pennington[1], N. P. Souza[1], L. K. Blevins[2], R. B. Crawford[2], A. P. Bach[2], M. D. Rizzo[2], J. Zhou[2], J. E. Henriquez[2], D. Khan[2], S. Sermet[2], and N. E. Kaminski[2]. *[1]University of Nebraska Medical Center, Omaha, NE; and [2]Michigan State University, East Lansing, MI.*

E 171, a food grade titanium dioxide (TiO_2), is a common additive in foods. We evaluated its possible effects on the gastrointestinal tract administered as 0, 40, 400, or 5,000 ppm of the diet for 100 days following pretreatment with IP injection of dimethyl hydrazine (DMH) or with vehicle only. There was no effect on survival, body weight gain or food or water consumption. Histopathology of the small intestine, spleen, liver, lungs, and testes showed no differences between groups. Large intestinal tumors were diagnosed in a few rats pretreated with DMH (one rat each in DMH+control, DMH+low dose, and DMH+mid-dose groups). Otherwise there were no histologic abnormalities of the large intestines. Aberrant crypt foci (ACF) were not significantly increased in animals fed E171 either alone or after DMH administration. As expected, there was an increase in ACF in rats pretreated with DMH compared to those not pretreated. Furthermore, there was no increase in goblet cell numbers per gland, length of intestinal glands, or goblet cells per unit length of glands in the distal colon. Our results indicate no effect of food grade E171 on the rat intestine whether administered alone or after pretreatment with DMH. This supports the lack of carcinogenic activity reported in a NCI 2-year bioassay involving dietary administration of TiO_2 up to 50,000 ppm.

1307 Cancer Risk Estimates for Carcinogenic Nitrosamine Contamination in Drugs

F. Tsai, C. Hsieh, K. Ricker, K. Li, M. Sun, S. Elmore, and M. S. Sandy. *California EPA, Sacramento, CA.*

A number of nitrosamines are recognized as potent genotoxic carcinogens, and more than 30 nitrosamines are listed as carcinogens under California's Proposition 65. Nitrosamines are present in tobacco smoke, and may occur as environmental contaminants in water, food, and personal care products. Nitrosamine contamination of several commonly used drugs, such as histamine-2 blockers and angiotensin II receptor blockers, has prompted several recent US FDA recalls. Nitrosamines identified in these recalled drugs include NDMA (N-nitrosodimethylamine), NDEA (N-nitrosodiethylamine) and NMBA (N-nitroso-N-methylamino butyric acid). Both NDMA and NDEA are classified as probable human carcinogens by IARC. NDMA is one of 13 N-nitrosomethyl-N-alkylamines (NMAs) that are listed as carcinogens under Proposition 65. NMBA is a metabolite of N-nitrosomethyl-N-butylamine (NMA-C4), one of the 13 NMAs carcinogens. Carcinogenic evidence of the NMAs is summarized briefly, including animal bioassays, genotoxicity and structure activity comparisons. Positive findings from genotoxicity and DNA adduct studies indicate that NMAs are likely to operate through genotoxic mechanisms. Structure activity comparisons with carcinogenic N-nitrosodialkylamines reveal common genotoxic and tumorigenic activities, with shared target tumor sites amongst chemicals and test animal species. For the cancer risk estimation, we applied the maximum concentrations of contaminated NDMA (20.2 µg per tablet) and NDEA (1.3 µg per tablet) in these drugs to assess the chemical-specific cancer risk. Higher cancer risk is associated with patients taking the drugs with NDMA contamination than with NDEA contamination. For patients taking the drugs with maximum NDMA dose per tablet every day for four years, the cancer risk was estimated to be 29 cancer cases per 100,000 patients. Using the same exposure scenarios, the cancer risk associated with NDEA contamination is estimated to be four cancer cases per 100,000 patients.

1308 Urinary Bladder Carcinogenicity of Acetoaceto-*o*-Toluidide in F344 Rats

M. Gi, N. Yukimatsu, T. Okuno, S. Suzuki, A. Kakeshita, and H. Wanibuchi. *Osaka City University Graduate School of Medicine, Osaka, Japan.*

Recent epidemiological studies have indicated that occupational exposure to the aromatic amine acetoaceto-*o*-toluidide (AAOT) was associated with a marked increase in urinary bladder cancers in Japan. However, little is known about the carcinogenicity of AAOT. To evaluate the urinary bladder carcinogenicity of AAOT, male and female F344 rats were treated with *N*-butyl-*N*-(4-hydroxybutyl)nitrosamine (BBN) for 4 weeks followed by dietary administration of 0, 0.167, 0.5, or 1.5% AAOT for 31 weeks. The incidences and multiplicities of bladder tumors were significantly increased in the 0.5 and 1.5% groups of male and female rats in a dose-response manner. AAOT and 7 downstream metabolites were detected in the urine of the male and female rats administered AAOT with levels increasing in a dose-dependent manner. The most abundant urinary metabolite of AAOT was the human bladder carcinogen *o*-toluidine (OTD), which was at least one order of magnitude higher than AAOT and the other AAOT metabolites. In a second experiment, male F344 rats were administered 0, 0.167, or 1.5% AAOT for 4 weeks. Cell proliferative activity, and gamma-H2AX expression, which is a novel marker for the prediction of carcinogenicity, were significantly increased in a dose-dependent manner in the bladder urothelium of rats administered AAOT. Gene expression analyses revealed that expression of JUN and its downstream target genes were increased in the urothelium of male rats treated with 1.5% AAOT. These results demonstrate that AAOT promotes BBN-induced urinary bladder carcinogenesis in rats and suggest that overexpressed of JUN and its downstream target genes may be involved the bladder carcinogenicity of AAOT. In conclusion, AAOT, like other carcinogenic aromatic amines, is likely to be a carcinogen to the urinary bladder, and OTD metabolized from AAOT is the ultimate carcinogen.

1309 Glyphosate Induces Peripheral Blood Abnormalities and Plasma Cell Neoplasms Resembling Multiple Myeloma in Mice

Y. Li. *Baylor College of Medicine, Houston, TX.*

Glyphosate is the most commercially successful and the most widely used herbicide in the United States and worldwide. It represents about 50% of United States herbicide use at ~250 million pounds annually; the annual use of glyphosate worldwide is ~1.8 billion pounds. There has been considerable debate around the carcinogenicity of glyphosate. The International Agency for Research on Cancer labeled glyphosate as "probably carcinogenic to humans". However, other agencies like the Environmental Protection Agency (EPA) have maintained that glyphosate is unlikely to pose a carcinogenic risk. In epidemiological studies on the association of cancer and glyphosate, only multiple myeloma (MM) and non-Hodgkin lymphoma have a positive and statistically significant association with glyphosate. In the present study, we employed the Vk*MYC mouse model of MM to assess the impact of glyphosate exposure on MM pathogenesis. Glyphosate induced splenomegaly and multiple peripheral blood abnormalities, including anemia and high serum immunoglobulin G (IgG) levels. In addition, glyphosate triggered bone lytic lesions and kidney damage in Vk*MYC mice. Even in wild-type C57BL/6

mice, glyphosate increased serum IgG levels, induced anemia, and increased plasma cell presence in the spleen and bone marrow, hallmarks of benign monoclonal gammopathy. Lastly, glyphosate upregulated the expression of the activation-induced cytidine deaminase (AID) in the spleen and bone marrow of both C57BL/6 and Vk*MYC mice. AID is a B-cell genome mutator and a key pathogenic player in MM and non-Hodgkin lymphoma. These data indicate that glyphosate accelerates monoclonal gammopathy development and promotes progression to MM in genetically-predisposed mice. This work offers the first direct experimental evidence establishing glyphosate as an environmental risk factor for monoclonal gammopathy of undetermined significance and MM. It reveals the underlying mechanisms of glyphosate-mediated MM pathogenesis and potentially benefit over millions with MGUS worldwide. This study also directly contribute to the science needed to inform EPA and other agency regulations of current and emerging glyphosate-based herbicidal products.

PS 1310 Differential Gene Expression in Bladder Tumors from Arylamine-Exposed Workers

R. Kolli, Z. Xu, V. Panduri, and J. Taylor. *NIEHS/NTP, Research Triangle Park, NC.* Sponsor: X. Wu

Bladder cancer is the sixth most common type of cancer in the United States. Although smoking is the most common risk factor, occupational exposure to benzidine and β-naphthylamine have been shown to increase bladder cancer risk 40-100 fold. Benzidine and β-naphthylamine are aromatic amines that were used in the production of azo dyes predominantly for paper, textile and leather industries. To our knowledge, there have not been any toxicological studies in cancer epidemiology with a case-case study design, comparing the molecular signatures of tumors from people with exposure to chemical carcinogens to those from people without such exposure. Here we compare gene expression in 22 formalin-fixed paraffin-embedded (FFPE) bladder tumors from people with high-level occupational exposure to arylamines to that in 26 FFPE bladder tumors from people without such exposure. Our study subjects were from a cohort of workers employed at the DuPont Chambers Works (Deepwater, NJ), a major producer of β-naphthylamine and benzidine until the 1960s. Bladder tumors from unexposed subjects were from the Roswell Park Cancer Institute (Buffalo, NY). The tumor samples comprised of old, hard-to-extract fixed tissue ribbons from surgeries between 1950–1990. RNA was extracted from these ribbons and was analyzed for fragment sizes. All of the 48 samples contained RNA fragments with a minimum length of 300 nucleotides (nt), essential for reliable quality determination of FFPE-derived RNA. Samples were normalized to contain 200 ng of 300 nt or longer RNA fragments. Gene expression was analyzed on Nanostring nCounter system using two panels, PanCancer Progression panel and a custom-panel. The analysis comprised of 770 cancer progression-related genes and 69 custom-designed arylamine- and bladder cancer-related genes. Preliminary analysis showed a differential gene expression pattern in bladder tumors from arylamine-exposed versus unexposed subjects. Further investigation is underway to estimate arylamine-associated gene enrichment and pathway scoring. These findings would provide insights into the mechanisms underlying pathologies associated with arylamine exposure.

PS 1311 Evidence Relating to the Carcinogenicity of Acetaminophen in Human Epidemiological Studies and Long-Term Animal Bioassays

N. Guha, G. Osborne, S. Elmore, K. Li, M. S. Sandy, and M. Sun. *California EPA, Sacramento, CA.*

Acetaminophen is one of the most widely used analgesic and antipyretic drugs and is available in many prescription and over-the-counter medications. Concerns over the carcinogenicity of acetaminophen arose because it is the major metabolite of phenacetin, a recognized carcinogen that causes cancer of the renal pelvis. Acetaminophen has been classified as 'not classifiable as to its carcinogenicity to humans' with inadequate epidemiologic evidence in both of the previous reviews by the International Agency for Research on Cancer (IARC) in 1990 and 1999. Numerous studies have been published since. OEHHA reviewed the complete peer-reviewed, published literature on the carcinogenicity of acetaminophen. For the human epidemiology studies, the strongest evidence was for kidney cancer (renal cell carcinoma and cancer of the renal pelvis); the majority of these epidemiologic studies reported risk estimates above one, although not all were statistically significant. Positive dose-response trends were also observed. Several studies controlled for important confounders and a few assessed exposure through databases of prospectively collected prescriptions, minimizing the possibility of information bias. For lymphohematopoietic cancers as a group, the majority of epidemiologic studies reported positive associations, some statistically significant, with acetaminophen use. The results were the most consistent for leukemia/lymphoma combined, myeloid leukemias (including AML), NHL, and multiple myeloma. For liver cancer, positive associations were reported in the two well-conducted large cohort studies, although one study could not control for alcohol and tobacco use. For cancers of the breast, ovary, uterine endometrium, and prostate, the association with acetaminophen use was either decreased or null. The data for a number of other cancer sites were either sparse (e.g., brain, respiratory tract, gastrointestinal tract, pancreas, cervix, and all cancers combined) or inconsistent (e.g., skin and colorectum). In long-term animal carcinogenicity studies, tumor findings were observed in three of 10 studies in mice and three of seven studies in rats. Liver tumors were observed in male and female mice and rats, pituitary gland tumors were observed in female mice, bladder tumors were observed in male and female rats, and mononuclear cell leukemia was observed in female rats.

PS 1312 Exploring the Potential Carcinogenic Activity of Per- and Polyfluorinated Alkyl Substances (PFASs) Using High-Throughput Toxicity Screening Data

C. Hsieh[1], N. Singh[1,2], M. S. Sandy[1], and L. Zeise[1]. *[1]California EPA, Sacramento, CA; and [2]University of California Davis, Davis, CA.*

Per- and polyfluorinated alkyl substances (PFASs) are ubiquitous, persistent and toxic chemicals that pose public health concerns. More than 4,700 PFASs exist; however, current scientific understanding of the toxicity of these compounds is informed by studies of a select few, primarily perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). Carcinogenicity concerns have arisen based on limited evidence from epidemiological studies for PFOA and animal tumor findings and mechanistic data for PFOA and PFOS. We explored the carcinogenicity potential of other PFASs using the computational, high throughput screening tool, the US EPA CompTox Chemical Dashboard's ToxCast (https://comptox.epa.gov/dashboard). ToxCast screening has produced toxicity data for thousands of chemicals, including a number of PFASs. A number of the ToxCast assays can be mapped to the IARC ten key characteristics of carcinogens (Smith et al., *EHP*, 124:713, 2016). Results for PFASs screened in the ToxCast assays and visual analytics software, Toxicological Prioritization index (ToxPi, http://toxpi.org/) were used to describe the carcinogenic potential of PFASs. A comprehensive literature search was also conducted to check the consistency of our analyses with other mechanistic data streams. Twenty-three PFASs that had sufficient ToxCast data and covered a range of structural subclasses were selected for analysis. PFASs were active in several of the carcinogenicity realms identified by IARC, the most significant being receptor-mediated effects, oxidative stress induction and alterations in cell proliferation. Patterns observed varied by length of fluorine-bonded chains and/or functional group within and between each key characteristic, suggesting structure-based variability in activity. A vast range of biological perturbations suggested that PFASs are potentially active in a number of mechanistic pathways associated with carcinogenic potential. In general, the key characteristics associated with the ToxCast findings are also supported by literature from other mechanistic data streams. Additionally, we explore how this approach might be integrated in a read-across context to infer carcinogenicity for a subset of the data-poor PFASs.

PS 1313 Cotinine, a Major Nicotine Metabolite, Induces Cell Proliferation in Urothelium *In Vitro* and *In Vivo*

S. Suzuki[1,2], S. M. Cohen[3], L. L. Arnold[3], K. L. Pennington[3], A. Naiki-Ito[2], H. Wanibuchi[1], and S. Takahashi[2]. *[1]Osaka City University Graduate School of Medicine, Osaka, Japan; [2]Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; and [3]University of Nebraska Medical Center, Omaha, NE.*

Tobacco smoking is a major risk factor for various human cancers including urinary bladder carcinoma. In a previous study, nicotine enhanced urinary bladder carcinogenesis using a rat two-stage model. In the present study, we examined the effects of cotinine, a major metabolite of nicotine, on urinary tract carcinogenesis. Cotinine induced cell proliferation in bladder cancer cell lines. By western blot analysis, cotinine induced phosphorylation of Stat3 and expression of cyclin D1 in UMUC3 cells. The cell proliferation induced by cotinine was blocked by inhibitors of both nicotinic receptors and Stat3. In an *in vivo* study, cotinine in drinking water also induced cell proliferation and simple hyperplasia in urinary bladder and renal pelvis urothelium of rats, but to a lesser degree compared to nicotine. Cytotoxicity detected by scanning electron microscopy and apoptosis evaluated by caspase immunohistochemistry in the bladder urothelium were induced by nicotine but not cotinine.

These data suggest that cotinine enhances urothelial cell proliferation both *in vitro* and *in vivo*, and cotinine is considered to be partly involved in urinary tract carcinogenesis by nicotine.

1314 Comparative Toxicity and Carcinogenicity of Di(2-ethylhexyl) Phthalate (DEHP) in Perinatal versus Adult Exposed HSD: Sprague-Dawley SD Rats

T. D. Hubbard[1], S. Elmore[1], M. D. Stout[1], K. R. Shockley[1], T. Crabbs[2], H. Cunny[1], S. McBride[3], B. Sparrow[4], H. Toy[4], and C. Blystone[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; [2]EPL Inc., Durham, NC; [3]S3 Inc., Durham, NC; and [4]Battelle Memorial Institute, Columbus, OH.*

Di(2-ethylhexyl) Phthalate (DEHP) is a plasticizer known to produce adverse effects on the developing male reproductive tract and on fertility via an anti-androgenic mechanism. Increased incidence and severity of male reproductive tract malformations occurs in rodents following exposure during critical developmental windows. DEHP is a known rodent carcinogen which induces hepatic, pancreatic, and testicular tumors in chronic studies. To date, no previous cancer assessments of DEHP have utilized a lifetime exposure paradigm that includes the perinatal and prepubertal periods. Currently, it is not clear if developmental exposure would alter lifetime DEHP-associated carcinogenic risk. To address this concern, the National Toxicology Program (NTP) evaluated if perinatal + lifetime DEHP exposure would impact the dose response, incidence and/or severity of the carcinogenic response in rodents relative to chronic exposure initiating in adulthood. Two cancer bioassays were conducted, in which 50 Sprague-Dawley rats per sex/group were exposed to 0, 300, 1000, 3000 or 10000 ppm of DEHP via dosed feed for 2 years, with differing exposure paradigms: adult only or perinatal + lifetime exposure. No effect on overall survival was attributed to DEHP in either study. Body weights of rats in the 300, 1000, and 3000 ppm groups were commensurate with controls in both studies. At study termination, lower body weights associated with decreased body weight gains throughout the study duration were observed in 10000 ppm groups in both perinatal (males -30%, females -32%) and adult (males -16%, females -22%) cancer bioassays, relative to controls. Identified tumor types in the liver and pancreas were consistent between studies. Higher incidences of pancreatic acinar and hepatocellular adenomas/carcinomas were noted in perinatally-exposed males and females, respectively, relative to adult-only exposures, although this finding was restricted to the 3000 ppm exposure groups. In contrast to previous reports, a higher incidence of testicular adenomas was observed in 10000 ppm adult-only exposures, relative to perinatally-exposed animals. In summary, these findings suggest that perinatal + lifetime exposure may alter the DEHP carcinogenic response in rodents relative to adult-only exposure.

1315 Alternative Splicing as a Key Mechanism in Arsenic-Induced Squamous Cell Carcinoma: Evidence from RNA-Seq and Proteomic Analysis

A. P. Ferragut Cardoso[1], M. Banerjee[1], D. W. Wilkey[1], L. Al-Eryani[2], M. A. Sayed[1], J. W. Park[1], M. Merchant[1], and J. C. States[1]. *[1]University of Louisville, Louisville, KY; and [2]National Cancer Institute, Bethesda, MD.*

Chronic exposure to arsenic, a group I carcinogen, leads to multi-organ cancers, skin being the primary target, although, the molecular etiology remains elusive. Arsenic exposure has been reported to induce differential mRNA splicing. Abrogation of normal alternative splicing patterns have been linked to several cancers, as the expression of many cancer-related genes are regulated by alternative splicing. We hypothesized that differential mRNA splicing in protein coding genes could be a driving force in an established cell line model of arsenic-induced skin carcinogenesis. HaCaT cells exposed to 0 (As-) or 100 (As+) nM $NaAsO_2$ were maintained for 7 weeks in independent quadruplicates. RNA and proteins were isolated from each sample. RNA-seq was carried out followed by analysis of the data by rMATS algorithm to identify significant differential splicing events between the As^- and As^+ samples. In addition, we performed ESI tandem mass spectrometric analysis to quantify differential proteome expression in whole cell lysates of the same samples. 1,149 skipped exon events were significantly different between As^- and As^+, of which 61.5% resulted in the protein coding changes. From proteomic analysis, 227 differentially expressed proteins were found. Gene ontology (GO) analysis on the alternatively spliced genes found enrichment in several splicing related pathways (83 unique genes). In accordance, GO analysis of the proteomic profile also showed splicing as a major enriched category (37 unique proteins). Comparison of over-represented pathways from alternative splicing and proteomic data revealed 3 common molecules: Splicing Factor SWAP (*SFSWAP*), DEAD-Box Helicase 42 (*DDX42*) and Serine/Arginine Repetitive Matrix 2 (*SRRM2*). These genes are related to mRNA splicing and are associated with cancer. Presence of overlapping unique genes/proteins in the two datasets that are involved in the same splicing regulation pathways suggests that global modulation of mRNA splicing by arsenic exposure plays a role in arsenic-induced carcinogenesis. *Funding: NIH grants R01ES027778, R21ES023627, P20GM103436, R15GM126446, P20GM113226, P30GM106396.*

1316 Bis-Indole Derived Nuclear Receptor 4A1 (NR4A1) Antagonists Inhibit TGF-β-Induced Invasion of Embryonal Rhabdomyosarcoma Cells

R. Shrestha, K. Mohankumar, and S. Safe. *Texas A&M University, College Station, TX.*

Transforming growth factor β (TGFβ) enhances invasion of breast and lung cancer cells through phosphorylation-dependent nuclear export of the nuclear receptor 4A1 (NR4A1, Nur77). This response is inhibited by the NR4A1 antagonist 1,1-bis(3'-indoly)-1-(phydroxyphenyl)methane (CDIM8) and we hypothesized that similar effects would be observed in Rhabdomyosarcoma (RMS) cells. Although some kinase inhibitors block TGFβ-induced invasion of embryonal RMS (ERMS) cells, the mechanism differs from breast and lung cancer cells since NR4A1 is extranuclear in ERMS cells. However, CDIM8 blocks basal and TGFβ-induced invasion of RD and SMS-CTR ERMS cell lines but not Rh30 alveolar rhabdomyosarcoma cells. Moreover, the response in ERMS cells was independent of SMAD7 degradation or activation of SMAD2/SMAD3. β-catenin silencing decreased ERMS cell invasion and CDIM8 induced proteasome-independent downregulation of β-catenin. The novel mechanism of CDIM8-mediated inhibition of basal and TGFβ-induced ERMS cell invasion was due to activation of the bcl-2-NR4A1 complex, mitochondrial disruption, induction of the tumor suppressor-like cytokine interleukin-24 which in turn downregulates β-catenin expression. Thus, the NR4A1 antagonist inhibits TGFβ-induced invasion of ERMS cells through initial targeting of cytosolic NR4A1.

1317 Assessment of the Carcinogenic Potential of Pretomanid in Transgenic Tg.rasH2 Mice

J. L. Ambroso[1], J. E. Dillberger[2], R. S. Barry[1], and T. J. Yang[3]. *[1]RTI International, Research Triangle Park, NC; [2]J. Dillberger LLC, Nashville, IN; and [3]TB Alliance, New York, NY.*

The nitroimidazole pretomanid (PA-824) was recently approved by FDA for treatment of extensively drug resistant tuberculosis (XDR TB). Nitroaromatic compounds as a class carry a risk of being genotoxic and potentially carcinogenic based on reactive metabolite formation. Pretomanid was found to be nongenotoxic in a series of *in vitro* and *in vivo* studies (with and without liver S9 fraction), but a minor metabolite known as M50 was found to be positive in an Ames assay. To assess the *in vivo* carcinogenic potential of pretomanid, hemizygous Tg.rasH2 mice were administered the compound once daily by oral gavage administration for 26 weeks. Male mice were given pretomanid in vehicle at doses of 0, 5, 15 and 40 mg/kg/day. Female mice were given pretomanid in vehicle at doses of 0, 10, 30 and 80 mg/kg/day. Positive control mice of both sexes received intraperitoneal injections of urethane at 1000 mg/kg on Days 1, 3 and 5. There were no pretomanid-related early deaths, tumors, non-neoplastic microscopic findings, or gross necropsy findings at any dose level. The positive control gave the anticipated response. Oral administration of pretomanid to mice produced plasma exposure to both parent compound (high dose AUC was 2 to 3 times the clinical AUC at the maximum recommended human dose) and its M50 metabolite, with exposure to pretomanid more than 10 times the exposure to the M50 metabolite at all dose levels in both sexes. These data show that pretomanid was not carcinogenic in a transgenic mouse model.

1318 A Retrospective Analysis of Transgenic Mouse Carcinogenicity Studies for Pharmaceuticals in Japan

M. Nonaka[1], M. Naota[1], J. Nishimura[1], K. Ogawa[2], and A. Nishikawa[2]. *[1]Pharmaceuticals and Medical Devices Agency, Tokyo, Japan; and [2]National Institute of Health Sciences, Kawasaki, Japan.*

Rat 2-year carcinogenicity studies of 182 compounds were retrospectively analyzed by PhRMA (*Toxicol. Pathol.* 39, 716-744, 2011). Taken together with retrospective analyses for the various datasets (PhRMA, FDA, JPMA, and EU + FDA), it has been hypothesized that based on evidences for pharmacology,

genotoxicity, and chronic toxicity the outcome of a 2-year rat carcinogenicity study can be predicted. In the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH), S1 (carcinogenicity study) Expert Working Group proposed a prospective evaluation period to verify the possibility of waiving rat 2-year carcinogenicity studies by integrative analysis of Weight-of-Evidence (WOE) factors such as pharmacological action, genotoxicity, tumor-related lesions in rat 6-month toxicity studies and hormonal perturbation. Meanwhile, in the ICH S1B guideline a mouse study is also required to assess carcinogenic potential of a pharmaceutical in addition to the rat study. According to the current S1B guideline, medium-term transgenic (Tg) mouse carcinogenicity studies can be used instead of the long-term mouse studies. Depending on the ongoing ICH S1 prospective evaluation, the rat 2-year study can be waived. In such cases, the Tg mouse study will increase its weight. In this context, a comprehensive survey on Tg mouse carcinogenicity studies should be important in revising S1 guidelines. Here we retrospectively analyzed Tg mouse carcinogenicity studies (about 40 studies) for pharmaceuticals approved in Japan since 2007. The current S1B guideline has proposed several Tg mouse assays including p53+/- deficient, Tg.AC, Tg rasH2 and XPA deficient models. Recently, the use of Tg rasH2 mouse studies is readily increased to assess carcinogenic potential of pharmaceuticals. In this session, the implementation status of carcinogenicity studies using Tg mice, and the exposure margin of clinical dose with the highest dose and the tumor outcomes in carcinogenicity studies using rasH2 mice will be presented.

1319 Phenotypic Alterations and Cancer Progression in Human Uterine Leiomyoma Cells following Continuous Cadmium Exposure

A. Lawrence[1,2], Y. Yan[1], M. Dykstra[1], L. Yu[1], L. Castro[1], J. Liu[1], and D. Dixon[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; and [2]North Carolina Central University, Durham, NC.*

Cadmium (Cd) is a ubiquitous heavy metal found in the environment and poses serious health risks. Cd exposure has previously been linked to lung and prostate cancer. Cd has also been identified as a "metalloestrogen", or estrogen-mimic. In women with benign estrogen-responsive uterine fibroids, elevated blood Cd levels have been correlated with increased fibroid tumor growth. In this study, cadmium exposure was used *in vitro* to analyze if human uterine leiomyoma (ht-UtLM; fibroid) cells could be transformed into a malignant phenotype. Fibroid cells were exposed to 10 μM $CdCl_2$ for 8-weeks and analyzed by time-lapse confocal imaging, flow cytometry, transmission electron microscopy, Ki-67, and soft agar assays. Total RNA was extracted from fibroid cells for differential gene expression analysis using NanoString PanCancer Progression/Pathways Panels. We found that after 8 weeks of Cd exposure, a robust and fast-growing Cd Resistant Leiomyoma culture (CR-LM) was established. CR-LM cells showed changes in nuclear and cytoplasmic morphology and had significantly enhanced cell motility and cell proliferation compared to passage-matched ht-UtLM controls. CR-LM cells were able to form viable colonies in soft agar thus exhibiting anchorage-independent growth. NanoString analysis showed a significant downregulation of genes encoding for extracellular matrix (ECM) proteins; whereas matrix metalloproteinase (MMP) genes, involved in ECM degradation, were dramatically upregulated. A human MMP antibody array analysis confirmed increased protein expression of several MMPs in the CR-LM cells. Ingenuity Pathway Analysis (IPA) of the dataset predicted inhibition of the TGFB1 pathway network which could activate cancer cell proliferation. Overall, these data suggest that continuous Cd exposure induces progression towards a malignant phenotype in human fibroid cells *in vitro* and that chronic environmental cadmium exposures may pose a cancer risk for women with uterine fibroids.

1320 Cytotoxicity Assessment of Zinc Oxide Nanofibers in K562 Cells

B. Kincaid[1], W. E. Gato[2], J. Wu[2], and A. Perez[1]. *[1]Columbus State University, Columbus, GA; and [2]Georgia Southern University, Statesboro, GA.*

Zinc oxide (ZnO) nanofibers (NFs) are used for water and air cleaning as well as in cosmetic products such as sunscreen. This functionality can be attributed in part to their wide band gap energy and propensity for photocatalytic activity. They are also being considered for medical devices and novel drug delivery. Therefore, research is needed to examine the toxic effects from exposure to these nanofibers and their metal oxides. Previous studies have found exposure to cause reactive oxygen species (ROS)production which induced apoptosis and oxidative stress as well as cellular inflammatory response. The goal of this study was to examine the cytotoxic effect of ZnO NFs on K562 cells, a human myelogenous leukemia cell line. The ZnO nanofibers were synthesized from polyvinylpyrrolidone and zinc acetylacetonate hydrate in ethanol with the typical electrospinning technique. The fibers were then characterized with scanning electron microscopy (SEM), FT-IR, powder X-Ray diffraction, and Raman spectroscopy. The K562 cells were maintained and exposed to ZnO nanofibers at varied concentrations and time points. Cell proliferation, oxidative stress and inflammatory response were measured using MTT assay, LDH leakage assay, and quantitative real-time polymerase chain reaction (qRT-PCR). Upon ZnO NF exposure, K562 cells did not indicate significant cell death as evidenced by MTT and LDH leakage assay. Inflammatory response and oxidative stress were observed by gene expression. The most toxic concentration was 1 ug/mL. A possible explanation for the low cytotoxicity observed could be the non-adherent characteristic of K562 cells. This is due to a proposed mechanism that ZnO NFs attack the plasma membrane and then penetrate the cells.

1321 Locally Administered HB-EGF Reduces Radiation-Induced Oral Mucositis in Mice

J. Chen. *Stanford University, Stanford, CA.*

There is an unmet medical need for oral mucositis, which can occur with chemo radiation treatment of non-head and neck cancer. We investigate the efficacy of locally administered heparin-binding epidermal growth factor-like growth factor (HB-EGF) to the oral mucosa as a potential therapy to treat radiation induced oral mucositis. Using a single dose (20Gy) of X-ray irradiation to the heads of female C57BL/6J mice, we evaluated the efficacy of post irradiation treatment of HB-EGF (5 μl of 10 μg/ml) solution. The results shown that HB-EGF delivered post radiation significantly increase area of epithelial thickness and cell division of both tongue and buccal. This data provides the proof of concept that local administration of HB-EGF has the potential application to mitigate oral mucosal following radiation and shows promise for developing an effective local treatment.

1323 Investigating the Effects of Elevated Reactive Carbonyl Species Due to Glyoxalase 1 Knockdown and Inhibition in Cancer Cells

J. Anderson, S. Kenney, S. Ahmad, B. Cordova, and D. Tamae. *California State University Northridge, Northridge, CA.* Sponsor: J. Murray

The accumulation of reactive carbonyl species has been implicated in the pathology underlying diabetes, aging, and cancer. Glyoxalase 1 (Glo1) is over-expressed in tumor biopsies relative to adjacent tissue in breast and prostate cancer patients. Glo1 is part of a two enzyme, glutathione dependent detoxification system of the reactive carbonyl species, methylglyoxal (MG) and glyoxal. MG is a by-product of glycolysis that can form advanced glycation end-products (AGEs) and result in protein, RNA and DNA damage. MG accumulation can lead to DNA adducts that cause mutations and single strand breaks. The purpose of this study is to investigate the relationship between DJ-1, Nrf2, and the Glyoxalase 1/2 (Glo1/2) detoxification pathway. We knocked down Glo1 using siRNA in a panel of breast and prostate cancer cell lines. We also used the glutathione analogue, S-p-bromobenzylglutathione cyclopentyl diester ($pBrBzGSH(Cp)_2$) to inhibit Glo1. In cancer cells, DJ-1 is over expressed. DJ-1 has been found to have deglycase activity and may provide defense against reactive carbonyl species induced AGEs that are formed as a by-product of cellular metabolic activity such as glycolysis and lipid peroxidation. We have conducted western blots and quantified Glo1, Glo2, DJ-1, Nrf2 and beta-actin expression levels in the Glo1 knockdown (KD) and siRNA scrambled control cells. We did not observe any significant differences in DJ-1 expression in the Glo1 KD cells relative to the controls. We are currently investigating the relationship between Glo1 KD and Nrf2 stabilization and the elevation of members of the aldo-keto reductase (AKR) superfamily. Additionally, the upregulation of GSH due to the Keap1-Nrf2 pathway is being investigated by probing for two essential enzymes found in the GSH biosynthesis pathway, gamma-glutamylcysteine synthetase and glutathione synthetase. *This work was supported by a CSUPERB New Investigator Award and an NIH SCORE SC2 award to D.T.*

1324 Effects of Dietary Fish Oil and Omega-3 Fatty Acids on the Carcinogenic Polycyclic Aromatic Hydrocarbon (PAH)-DNA Adduct Levels in Mouse Lung *In Vivo*

G. Zhou. *Institute of Biosciences and Technology, Texas A&M University, Houston, TX.*

Many epidemiological studies and animal experiments have shown positive correlation between levels of carcinogen-DNA adducts and tumor incidence. Therefore, decrease in DNA adduct levels is expected to attenuate tumor formation. In this study we report that dietary fish oil (FO) and omega-3 fatty acids attenuate the formation of DNA adducts mediated by polycyclic aromatic hydrocarbons (PAHs). B6C3F1 male mice were pre-fed a FO or corn oil (CO) diet for 30 days, or A/J male mice were pre-treated with omega-3 fatty acids eicosapentaenoic acid (EPA, 50 mg/kg and 100 mg/kg) and/or docosahexaenoic acid (DHA, 30 mg/kg and 60 mg/kg) for 3 days. The B6C3F1 mice were then treated with a mixture of seven carcinogenic PAHs including benzo(a)pyrene (BaP) with two doses. A mixture of high dose PAHs mixture contained BaP, 1.72 µg; BA, 5.25 µg; chrysene, 5.25 µg; BbF, 2.15 µg; BkF, 1.33 µg; DBA, 0.11 µg and IP, 0.67 µg for 20 g body weight. These chemicals and their concentrations were similar to the residues extracted from contaminated soils of SuperFund sites. The low dose PAHs were proportionally reduced by 2.5 fold from high dose PAHs mixture. Animals were terminated at 1, 3, or 7d after treatment of PAHs or BaP. A/J mice were treated with pure BaP (25 mg/kg) via a single intraperitoneal injection. Animals were sacrificed 48 h after BP treatment. The levels of DNA adducts were analyzed by the ^{32}P-postlabeling assay. Our results showed that the levels of total PAH-DNA adducts in the lungs of B6C3F1 mice at 3 and 7 d after treatment of a mixture of PAHs were significantly decreased in FO compared with CO group. A/J mice pre-treated with FO, EPA and/or DHA also showed significant decreases of total pulmonary BaP-DNA adducts and/or BPDE-dG, compared to those in mice that did not receive the omega-3 fatty acids. Interestingly, low doses of EPA and DHA, given in combination, were more efficiently and significantly attenuated the levels of total pulmonary DNA adducts by 42% and levels of BPDE-dG by 45%. Furthermore, western blot analysis showed that EPA and DHA significantly inhibited the expression of CYP1B1 that plays a key role in the bio-activation of BP to DNA-binding metabolites. Reverse phase protein array (RPPA) analysis suggested a possible mechanistic link between detoxification of PAHs by omega-3 fatty acids and DNA adduct formation.

1325 Regulation of Basic Fibroblast Growth Factor (bFGF)-Induced Angiogenesis by the Small GTPase RhoA

F. Zahra[1], M. Sajib[1], V. Oikonomou[2], R. Akwii[1], P. Tullar[1], M. Lionakis[2], and C. Mikelis[1]. *[1]Texas Tech University Health Sciences Center, Amarillo, TX; and [2]National Institutes of Health, Bethesda, MD.*

Tumor vessels display abnormal structure and function due to imbalanced angiogenesis. Vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) are the best known pro-angiogenic factors in this process. The goal of antiangiogenic therapy is to inhibit tumor growth by oxygen and nutrient deprivation. Current antiangiogenic therapies target VEGF/VEGFR signaling pathways. However development of resistance due to upregulation of bFGF remains a serious disadvantage of current approaches, leading to efforts of simultaneous targeting of both VEGF and FGF pathways. A small GTPase RhoA has been reported to regulate VEGF-induced angiogenesis. In the present study we investigate the role of endothelial RhoA in bFGF-induced angiogenesis to identify whether RhoA can be considered a target for both VEGF- and FGF-induced angiogenesis. We performed RhoA pulldown assays to identify RhoA activation downstream of bFGF treatment. We used Boyden chamber cell migration assay, 2D tube formation assay using matrigel and 3D sprouting assay with collagen to assess angiogenic potential. Endothelial RhoA was knocked down by siRNAs or blocked by pharmacological inhibitors. Biochemical assays were performed to identify the molecular mechanism of bFGF-induced RhoA activation. *In vivo*, endothelial-specific inducible RhoA-deficient mice with a fluorescent reporter were used in a newly modified matrigel plug angiogenesis model allowing identification of endothelial RhoA excision efficiency. bFGF treatment activates RhoA in human umbilical vein endothelial Cells (HUVEC). RhoA inhibition with C3 toxin or RhoA knockdown abrogated bFGF-induced endothelial cell migration and tube formation *in vitro*. *In vivo*, endothelial RhoA deficiency blocked bFGF-induced angiogenesis in matrigel plug assay. Among the bFGF receptors, FGFR1 is predominantly expressed in HUVECs and FGFR1 knockdown abrogated bFGF-induced RhoA activation and angiogenesis. RhoA inhibition partially blocked bFGF-induced JNK phosphorylation but did not affect ERK and p38 activation. Ongoing experiments are aiming to delineate the precise role of endothelial RhoA in the FGF downstream pathway. Collectively, our data suggest that RhoA pathway participates in bFGF-induced angiogenesis and can be a potential target for anti angiogenic therapy.

1326 Sulforaphane Inhibits Colon Adenoma Organoid Formation and Induces Differentiation in a Dose-Dependent Manner

E. M. Hill[1], J. Burnett[2], A. Tapaswi[1], M. K. Dame[3], J. R. Spence[3], M. S. Bohm[3], C. L. McCarthy[3], K. Karpoff[3], D. Sun[2], G. Chen[3], and J. A. Colacino[1]. *[1]University of Michigan Public Health, Ann Arbor, MI; [2]University of Michigan, Ann Arbor, MI; and [3]University of Michigan Medical School, Ann Arbor, MI.*

Colorectal cancer ranks as the 2nd leading cause of cancer mortality in the United States. Preventive strategies for individuals with familial colon cancer syndromes remain limited. Sulforaphane (SFN), an isothiocyanate in cruciferous vegetables and potent activator of the Nrf2 transcription factor, has chemopreventive effects *in vitro* and *in vivo*, including inducing growth arrest and/or apoptosis. We have previously demonstrated that SFN inhibits breast cancer stem cells, which are the hypothesized cells of origin for carcinogenesis responsible for cancer invasion and metastasis. Whether SFN can act as a cancer preventive agent through targeting colon stem cells is unknown. To investigate this, we treated APC-mutant patient-derived human colon adenoma organoids with 4 doses of SFN (1.5, 3.1, 6.25, and 12.5 µM) or DMSO-control for 6 days and quantified the number and size of organoids formed. Additionally, we performed RNAseq on each treatment group and calculated benchmark doses for pathway alterations using BMDExpress2. Organoid formation decreased with SFN treatment in a dose-dependent manner and the highest dose decreased organoid formation by 80% compared to control. The number of differentially expressed genes also increased in a dose-dependent manner. Organoids treated with the lowest SFN dose had 254 differentially expressed genes (83 down-regulated and 171 up-regulated) compared to control while 7099 genes (3478 down and 3621 up) were differentially expressed in the highest dose. Increasing doses of SFN increased transcription of many Nrf2 target genes, including *NQO1*, *HMOX1*, and *ALDH3A1*. Increasing doses of SFN also increased the expression of colon differentiation genes, including *KRT20*, *AQP3*, and *ALPP*, and decreased the expression of colon stem cell genes *LGR5*, *OLFM4*, and *EPHB2*. BMDExpress2 analysis estimated the median benchmark dose for the gene ontology "stem cell proliferation" pathway at less than 1µM. Ongoing work is characterizing the stem cell specific effects of SFN in a mouse model of colorectal carcinogenesis. These results provide evidence that SFN induces a differentiation-associated phenotype in colon adenoma cells at physiologically relevant doses.

1327 The Importance of the Aryl Hydrocarbon Receptor Signaling Pathway on Mammary Tumorigenesis

C. Sweeney[1], S. Kado[1], C. Dahlem[1], F. He[1], G. Lazennec[2], T. Haarmann-Stemmann[3], and C. F. Vogel[1]. *[1]University of California Davis, Davis, CA; [2]CNRS Sys2Diag, Montpellier, France; and [3]IUF—Leibniz Research Institute for Environmental Medicine, Duesseldorf, Germany.*

The aryl hydrocarbon receptor (AhR) is known for mediating the toxicity of environmental pollutants such as dioxins and numerous dioxin-like compounds. Due to the widespread occurrence in our environment and the high toxic potential, these contaminants are of concern to promote breast cancer. Several studies have shown that the AhR is critically involved in mediating defects of the mammary gland differentiation and suppresses mammary gland development. More recently it has been found that the AhR may also act as a critical receptor protein in tumor promotion independent from exogenous ligands, which is based on its role in immune tolerance and increased survival in cancer cells. Consequently, the AhR may serve as an attractive target for new drugs in breast cancer therapy. AhR's action is restricted by a specific repressor protein, the AhR Repressor (AhRR). Interestingly, a recent report found that breast cancer patients who had low AhRR expression also had shorter metastasis-free survival and identified AhRR as an independent prognostic factor. While AhRR effectively blocks AhR, the role of AhRR as a tumor suppressor gene is only poorly understood. We hypothesize that AhRR will oppose AhR-mediated mammary tumorigenesis. Results: We established a transgenic mouse (AhRR Tg mice) that overexpresses AhRR and discovered that these mice were protected from tumor promoting effects induced by dioxin. To test the tumor-suppressive action of AhRR *in vivo*, we used a syngeneic murine tumor model in which E0771 mammary tumor cells are engrafted in the mammary fat pad. Results indicate a significantly suppressed tumor growth of E0771 cells in AhRR Tg mice compared to control B6 mice. Tumor growth was enhanced in dioxin-treated wt mice, as expected, but was significantly suppressed in AhRR Tg mice, supporting our hypothesis. Moving forward, we plan to examine the impact of AhRR overexpression in other mammary tumor models. The polyoma middle T antigen (PyMT) mouse model is a well-accepted model of ER-negative, metastatic breast cancer. Our data show, that the expression of AhR increases significantly in mammary tumors during progression in PyMT mice. In contrast, the expression of AhRR

decreases. Furthermore, expression of inflammatory markers (e.g. COX-2 and C/EBPβ) increases during tumor progression. The preliminary results indicate that the PyMT mouse is a suitable model to study the role of AhR and AhRR in breast tumorigenesis since it reflects a similar expression pattern found in human breast cancers. Our data indicate that AhRR restricts AhR-dependent expression of pro-inflammatory cytokines and acute toxicity. We also show that the AhRR represses the PKA-C/EBPβ inflammatory axis, induced by AhR activation, supporting its role as a tumor suppressor. Furthermore, AhRR opposes AhR-driven tumor cell survival. In summary the results show that AhRR suppresses mammary tumor cell growth *in vivo* and regulates genes involved in inflammation and apoptosis. The results will help us to understand AhRR's function as a tumor suppressor gene and the potential biomarkers of mammary tumorigenesis mediated by AhR and environmental toxicants.

1328 Drinking Water Bromate May Promote Carcinogenesis through Both Genotoxic and Nongenotoxic Mechanisms at Low Dosages

A. J. Brown, S. Sylvester, and D. Bull. *Washington State University Vancouver, Vancouver, WA.*

Bromate is a by-product of currently implemented disinfectants for drinking water in many countries, including the US. While linear extrapolation of male rat tumor data has been used to set the Maximum Contaminant Level (MCL), this is largely based on the assumption that direct oxidation of DNA is the responsible carcinogenesis mechanism. However, immunohistochemical and mass spectroscopy methods previously found that bromate can brominate tyrosines *in vivo*. Our data likewise suggests that bromate can brominate proteins at tyrosines *in vitro* and *in vivo,* which in turn potentially activates well characterized carcinogenesis pathways. Furthermore, bromination appears to change gene expression across several tissues and modulates serum and cellular free iron concentrations by modifying transferrin. The change in free iron would be expected to increase oxidative stress and is an alternative mode of action to the formation of 8-oxoG adducts in DNA. As the increase in free iron begins at the lowest dose we administered to rats for 28 days (5 mg/L vs the previously observed 250 mg/L in drinking water required to increase 8-oxoG), our data suggest this mechanism is more likely to occur at low doses.

1329 Comparison of NOAEL, ETD_{10}, and $BMDL_{10}$ Values for Nongenotoxic Carcinogens: Which Point of Departure Is Most Sensitive?

M. Batke[1], H. Hollnagel[2], M. T. Cronin[3], C. Yang[4], J. Rathman[5], and S. E. Escher[1]. *[1]Fraunhofer Institute for Toxicology and Experimental Medicine, Hanover, Germany; [2]Dow Europe GmbH, Horgen, Switzerland; [3]Liverpool John Moores University, Liverpool, United Kingdom; [4]Molecular Networks GmbH, Nuremberg, Germany; and [5]Altamira LLC, Columbus OH, Columbus, OH.* Sponsor: C. Dasenbrock

Human carcinogens may act by different modes of action, but generally can be classified as genotoxic and non-genotoxic carcinogens. The aim of this study was to better understand which endpoints and/ or point of departures are the most sensitive after chronic oral exposure for non-genotoxic carcinogens. 232 compounds which were classified as non-genotoxic carcinogens, using a simple decision tree, were identified. Following a detailed review of all available peer-reviewed literature, experimental and predicted data, this dataset was reduced to 223 organic compounds. NOAEL values were derived for these 223 compounds from chronic and (if required) subchronic studies following oral application using well established high quality databases e.g. RepDose, ToxRefDB, COSMOS or peer-reviewed publications. As far as possible, NOAEL values were derived from the same study as used in the CPDB database for the calculation of carcinogenic potency (TD_{50} values). NOAELs were based on either the most sensitive i) adverse apical effect in the entire study; ii) non-neoplastic lesion; or iii) neoplastic lesion. Study quality was considered as one potential confounder. These NOAELs are compared to the effective tumour dose (ETD_{10}) and the benchmark dose level ($BMDL_{10}$) calculated by model averaging, where a tumor-related effect is expected to be observed in 10% of the animals tested. The comparative analysis of the correlations between NOAEL/EDT/BMDL values revealed that compounds with a concern for bioaccumulation were found among the 5% most toxic compounds. After exclusion of these compounds, the 5th percentile of the chronic NOAELs is in the same range as of $BMDL_{10}$ values, whereas the 5th percentile of the EDT_{10} is about 3 times higher than the NOAEL. These results were evaluated with regard to the current threshold of toxicological concern (TTC) threshold. *This work received funding from the CEFIC LRI B18_2 project.*

1330 Differential Cytotoxicity of Doxorubicin in Renal Cancer Cells Is Independent of VHL and p53 Status

N. Acharya, and K. P. Singh. *Institute of Environmental and Human Health, Lubbock, TX.*

Differential sensitivity of cancer to chemotherapeutic drugs is a growing concern worldwide. Although not yet clearly known, the primary basis of differential sensitivity is believed to be governed by the genetic/epigenetic makeup of the tissue bearing cancerous growth. The objective of this study was to understand the role of the genetic background of renal cancer cells on the sensitivity to chemotherapeutic drug doxorubicin. Two renal cell carcinoma cell lines Caki-1 and 786-0 with different status of tumor suppressor genes *p53* and *VHL* were used in this study. Sub-lethal concentrations of doxorubicin were used for the treatment of cells. The cytotoxicity of doxorubicin was determined by MTT cell viability assay. The effect of doxorubicin on the cell cycle was evaluated by flow cytometry. The expression of tumor suppressor genes *VHL* and p*53, as well as* the apoptosis-related genes Bax and Bcl2, were measured by quantitative real-time PCR. The MTT data revealed that 786-0 cells were more sensitive to doxorubicin as compared to Caki-1cells. Cell cycle analysis further revealed that doxorubicin caused more G2/M arrest in 786-0 cells than in Caki-1 cells. However, the expression of p53 and VHL was much greater in doxorubicin-treated Caki-1 cells than 786-0 cells. The findings of this study suggest that chemotherapeutic drug doxorubicin is more cytotoxic to primary renal cancer 786-0 cells with mutant VHL and p53 than the metastatic Caki-1 cells with wild type VHL and p53. More importantly, our data suggest that doxorubicin-induced cytotoxicity in these two renal cancer cell lines are independent of p53 expression level.

1331 Endoplasmic Reticulum Stress and P38 Signaling Pathway Contribute to the Cytotoxicity of Perhexiline in Hepatic Cell Lines

Z. Ren, S. Chen, X. Guo, L. Couch, and L. Guo. *US FDA/NCTR, Jefferson, AR.*

Perhexiline is a prophylactic antianginal agent developed in the 1970s and used worldwide. Despite its therapeutic success, its use diminished due to reports of severe side effects including hepatotoxicity in certain patients. The mechanisms underlying, however, is unclear yet. Here using HepG2 cells and HepaRG cells, we characterized the molecular mechanisms in the cytotoxicity of perhexiline. We found that perhexiline induced endoplasmic reticulum (ER) stress in HepG2 cells. Exposing HepG2 cells to perhexiline increased the gene expression level of classic ER stress markers including PERK, IRE1α, ATF6, ATF4, and CHOP. The protein levels of CHOP, ATF4, and peIF2α were also elevated. Using a *Gaussia* luciferase reporter assay, perhexiline-suppressed protein secretion was evaluated, and defects in ER function was confirmed. Pretreatment with ER stress inhibitor 4-PBA, or knockdown of ATF-4 gene attenuated the perhexiline-induced ER stress and cytotoxicity. In addition, perhexiline activated all three branches of MAPK signaling cascade, as evidenced by increased phosphorylation of P38, JNK, and ERK1/2. Inhibition of P38 by inhibitor SB239063 significantly reduced the perhexiline-induced cytotoxicity and ER stress. Taken together, our findings suggest that ER stress and the P38 signaling pathway contributes to the cytotoxicity of perhexiline in hepatic cell lines.

1332 Novel Drug Targets for Inhibiting Tumor Growth and Immunotherapy-Related Checkpoints

K. B. Karki. *Texas A&M University, College Station, TX.*

Specificity protein transcription factors (Sp1, Sp3 and, Sp4) and members of the orphan nuclear receptor 4A subfamily (NR4A1, NR4A2 and, NR4A3) are highly expressed in most solid tumors and their derived cell lines compared to corresponding non-tumor tissues. Several studies in our laboratory have shown that many anticancer agents including ROS-inducers downregulate expression of Sp TFs in multiple cancer cell lines. We have also shown that NR4A1 acts as a cofactor for Sp1 or Sp4-mediated gene expression and CDIM/NR4A1 antagonists inhibited these responses in various cancer cell lines. The highly selective killing of cancer cell lines by piperlongumine is due to ROS-dependent epigenetic repression of c-Myc, which leads to downregulation of miRs 17, 20a, 27a, upregulation of ZBTB 4 and ZBTB10 which are Sp repressors and downregulate expression of Sp1, Sp3, Sp4, and pro-oncogenic Sp-regulated gene products. Sp TFs were also shown to be vital for the growth of multiple myeloma (MM) cells and similar results were observed after treatment of MM cells with bortezomib which is clinically used for treating this dis-

ease. Subsequent studies indicate that the underlying mechanism of action of bortezomib in MM cells is due to caspase-8 dependent downregulation of Sp TFs. We also investigated the role of NR4A2 in glioblastoma cells and showed that knockdown of NR4A2 using antisense oligonucleotides inhibited growth, induced Annexin-V staining (apoptosis) and inhibited migration/invasion. Bis-indole derived NR4A2 ligands (C-DIMs) mimicked the functional responses observed in glioblastoma cells after NR4A2 knockdown indicating that NR4A2 ligands acts as NR4A2 antagonists and these compounds represent a novel approach for treating GBM. NR4A1 is overexpressed in both ER-positive and ER-negative breast cancers and high expression of NR4A1 predicts decreased patient survival and we demonstrated that NR4A1/Sp1 regulates the PD-L1 checkpoint ligand in TNBC cells and it can be decreased after treatment with CDIM/NR4A1 antagonists and enhance tumor immunity. Cl-OCH3, a buttressed CDIM 8 analog which acts as an immunotherapy mimic inhibited mammary tumor growth and decrease lung metastasis and increased T_{eff} to T_{reg} ratio compared to untreated mice. Thus CDIM/NR4A1 antagonist are novel small molecule immunotherapy mimics and checkpoint inhibitors that are being developed for clinical applications.

1333 Mitigating Toxicity through Targeted Therapy for SETBP1-Mutant Leukemia

S. A. Carratt, T. P. Braun, C. Coblentz, Z. Schonrock, and J. E. Maxson. *Oregon Health and Science University, Portland, OR.*

Chronic neutrophilic leukemia (CNL) is a rare myeloproliferative neoplasm characterized by the overproduction of neutrophils. Historically, therapeutic options for CNL were limited to stem cell transplantation or hydroxyurea, a cytotoxic agent with a low therapeutic index. The discovery of CSF3R mutations in CNL represented the first opportunity for targeted therapy. CSF3R mutations lead to ligand-independent receptor dimerization and JAK pathway activation. Ruxolitinib, a JAK inhibitor, is currently in clinical trials for CNL. However, while ruxolitinib remains a promising therapy, some patients develop co-occurring mutations and relapse. One of the genes that is frequently mutated with CSF3R is SETBP1, which mutated in 45% of CNL patients. SETBP1 mutations predict poor overall patient survival and the mechanisms of SETBP1 in disease progression and relapse are poorly understood. In order to generate a preclinical disease model to evaluate the role of SETBP1, we made a novel hematopoietic cell line co-expressing mutant CSF3R and SETBP1. When this cell line was injected into C57BL/6 mice, myeloid leukemia developed in four weeks. A second murine model was developed by transplanting primary bone marrow transduced with CSF3R/SETBP1 into Balb/c mice, which resulted in neutrophilic leukemia in 17-19 days. Finally, doxycycline-inducible cell lines were generated to study the effect of withdrawing SETBP1 or CSF3R. To identify novel therapeutic targets, we conducted a small molecule screen on our CSF3R/SETBP1 cell line with 172 inhibitors of cancer-associated pathways. Top hits were evaluated for synergy with ruxolitinib. An irreversible inhibitor of lysine-specific demethylase 1 (LSD1) identified in this screen, and targets of LSD1 were confirmed to be upregulated by SETBP1 through RNAseq profiling of our doxycycline-inducible cell lines. To assess the tolerability of the LSD1 inhibitor and ruxolitinib, we treated healthy Balb/c mice with the LSD1 inhibitor (1.5 mg/kg/day) and ruxolitinib (90 mg/kg/day) by twice-daily oral gavage for two weeks (n=5/group). The drug combination resulted in weight loss but did not produce any hematologic abnormalities (white blood cells, hemoglobin, platelets). The combination will be evaluated for efficacy and tolerability in our murine leukemia models. In summary, we developed novel preclinical models that were used to identify a new, well-tolerated therapeutic strategy for SETBP1-mutant disease. In addition to therapeutic development, these models can be utilized in future studies of gene-environment interactions, and to evaluate the role of occupational and environmental exposures in leukemia progression.

1334 Cadmium Metal Exposures as a Driver of Gallbladder Epithelial Signaling Dysfunction and Chronic Inflammation in Gallbladder Cancers

R. R. Gullapalli, T. Caldwell, M. Rivera, and P. Sharma. *University of New Mexico Health Sciences Center, Albuquerque, NM.*

Gallbladder carcinoma (GBC) is a deadly malignancy in the human gastrointestinal system (5 year survival - 3-8%). Native Americans (NA) living in New Mexico (NM) have a 5-8 fold higher incidence of GBC compared to Caucasians living in the state. We hypothesize heavy metal exposures may be responsible for the GBC incidence disparities seen here in NM and globally. Recent epidemiological data appears to support our key hypothesis. To understand GBC disparities in NM, we established a cohort of GBC patient samples and used next generation sequencing (DNA-seq) approaches to identify major driver mutational patterns. We also used primary human GB epithelial cell lines to measure effects of Cd exposure on GB cell signaling dysfunction. In particular, we focused on effects on Akt, MAPK and COX-2 signaling pathways. DNA-seq analysis results show the mutational patterns of GBC samples in NM for the first time. We observed an elevated incidence of missense mutations in the genes of Akt and MAPK pathways similar to findings in GBC patients from China. Of importance, we observed approximately 25% of NM GBC patients have a pharmacologically targetable HER2 amplification (n=6/24). In our GB epithelial cell studies, we observed a dose dependent reduction of cell viability of gallbladder epithelial cells following 24-hour Cd exposures. The measured EC50 values of gallbladder primary cells range from 11-18 μM. Importantly, we observe activation of the Akt and MAPK signaling pathways via increased phosphorylated activation. The ROS activity in GB epithelial cells is elevated due to Cd exposures with a reduction in the GSH levels. N-acetyl cysteine supplementation, in contrast, reduced the activation of Akt and MAPK signaling proving the role of Cd-induced oxidative stress in signaling disruption. A second key observation was the increased COX-2 gene expression via activation of the Akt and NF-kB pathways. Thus, our basic studies in aggregate prove two key defining and necessary features of gallbladder carcinogenesis: Akt signaling activation and chronic inflammation. Our initial studies demonstrate a role for environmental heavy metal exposures (Cd) in gallbladder carcinogenesis for the first time. Future research will seek to strengthen the role of Cd and other heavy metal exposures as drivers of gallbladder cancer disparities seen among Native American populations of NM.

1335 14-Day Nose-Only Inhalation Toxicity and Haber's Rule Study of NNK in Rats

S. Min[1], S. Hu[1], Y. Tang[1], H. Kang[1], D. Yang[1], S. M. Lewis[1], M. S. Bryant[1], E. Sepehr[1], R. Trbojevich[1], K. J. Davis[1], M. P. Maisha[1], R. Felton[1], R. H. Heflich[1], H. Rosenfeldt[2], R. P. Yeager[2], and P. C. Howard[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]US FDA/CTP, Silver Spring, MD.*

4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) is one of the key tobacco-specific nitrosamines which play an important role in humans lung carcinogenesis. However, repeated inhalation toxicity study data of NNK currently is limited. In the present study, subacute inhalation toxicity of NNK was evaluated in Sprague Dawley rats, both sexes (9-10 weeks age) exposed by nose-only inhalation of NNK in the following groups (16 rats/sex/group): air and vehicle controls, 0.8, 3.2, 12.5, and 50 mg/kg body weight (BW)/day of NNK (NNK aerosol concentration: 0, 0, 0.03, 0.11, 0.41, and 1.65 mg/L air) for 1 hour/day for 14 consecutive days. Whether the subacute inhalation toxicity of NNK follows Haber's Rule was also evaluated by exposure for additional three dose levels of 3.2, 12.5, and 50 mg/kg BW/day of NNK (NNK aerosol concentrations: 0.03, 0.11, and 0.41 mg/L air) for 4 hours/day for 14 consecutive days (7 rats/sex/group). Toxic responses were compared between the 4-hour exposure groups and the 1-hour exposure groups with the same daily exposure doses. Clinical observations, body weights, food consumption, clinical pathology, organ weights, and histopathological findings were compared with those of vehicle control. The micronucleus assay was conducted in peripheral blood and bone marrow. The results showed that there were multiple significant adverse effects in both sexes induced by NNK inhalation but no neoplasms or NNK-related deaths. NNK exposure did not increase micronucleus frequencies in the peripheral blood or bone marrow erythrocytes. The no observed adverse effect level (NOAEL) was 0.79 (male) and 0.87 (female) mg/kg BW/day or 0.03 mg/L air for 1 hour/day for both sexes, the lowest observed adverse effect level (LOAEL) was 2.96 (male) and 3.29 (female) mg/kg BW/day or 0.10 mg/L air for 1 hour/day for both sexes. The study component designed to test Haber's Rule indicated that 14-day inhalation exposure to the same dose at a lower concentration of NNK aerosol for a longer time (4 hours daily) caused greater adverse effects than exposure to a higher concentration of NNK aerosol for a shorter time (1 hour daily).

1336 KRAS-Retroviral Fusion Transcripts and Gene Amplification in Arsenic-Transformed, Human Prostate CAsE-PE Cancer Cells

B. A. Merrick[1], D. P. Phadke[2], R. R. Shah[2], S. S. Auerbach[1], R. S. Paules[1], M. J. DeVito[3], K. E. Pelch[3,4], M. P. Waalkes[3], and E. J. Tokar[3]. *[1]NIEHS, Research Triangle Park, NC; [2]Sciome, Durham, NC; [3]NIEHS/NTP, Research Triangle Park, NC; and [4]TEDX, Eckert, CO.*

CAsE-PE cells are an arsenic-transformed, human prostate epithelial line containing oncogenic mutations in KRAS. In this *in vitro* transformation model, arsenic exposure produced a highly overexpressed, mutated KRAS allele in CAsE-PE cells versus the immortalized parent cells, RWPE-1, expressing normal KRAS transcript. We previously observed increased KRAS copy number in CAsE-PE cells, supporting a process of gene amplification of unclear origin. Here, we characterized the flanking genomic and transcriptomic sequences to KRAS in CAsE-PE cells for insight into KRAS amplification. Initial comparison

of DNA-Seq and RNA-Seq reads showed coincident spikes of reads aligned to all KRAS exons in CAsE-PE cells but in RWPE-1 cells RNA-Seq showed low KRAS exon reads and an even distribution of KRAS genomic reads. We then searched for KRAS fusions in DNA and RNA sequencing data, finding some reads aligning to KRAS and viral sequences. After generating cDNA, we designed short and long probes for hybridization and then sequenced cDNA fragments by PacBio. More KRAS reads were captured from CAsE-PE cDNA compared to RWPE-1 by each probe set, and only CAsE-PE cDNA showed presence of KRAS viral fusion transcripts, primarily mapping to LTR (long terminal repeats) and endogenous retrovirus sequences on either the 5′- or 3′-end of KRAS. A majority of KRAS viral fusion transcripts contained 4 to 6 exons but some PacBio sequences showed KRAS in unusual orientations, suggesting viral insertions occurred within the gene body. In other experiments, conditioned media were extracted for retroviral particles and RNA-Seq was performed on the isolates showing KRAS retroviral fusion transcripts in CAsE-PE media only. Truncated KRAS transcripts suggest multiple retroviral integration sites may occur within the KRAS gene, producing KRAS retroviral fusions of various lengths. The CAsE-PE *in vitro* arsenic-transformation model suggests prime molecular events in arsenic-derived tumors could include an arsenic mutation signature, production of driver oncogenes such as KRAS, activation of endogenous retroviruses with potential for genomic integration, and the formation of retroviral fusion transcripts for gene amplification. These findings suggest new avenues for future research in arsenic carcinogenesis.

1337 LC-MS/MS Assay Development Quantifying Mouse Plasma DFMO Concentrations

M. A. Swanson[1], C. Szarowicz[1], S. T. Pike[1], T. C. Dowling[1], C. R. Shultz[2], and A. S. Bachmann[2]. *[1]Ferris State University, Big Rapids, MI; and [2]Michigan State University, East Lansing, MI.*

Difluoromethylornithine (DFMO), an irreversible inhibitor of ornithine decarboxylase, is being investigated for use in cancers. However, effective and safe dosing requirements based on pharmacokinetic modelling studies are needed. Accordingly, a quantitative assay using a Shimadzu triple quad LC-MS/MS, an Atlantis HILIC Silica 3µm 2.1 x 100mm column, and an isocratic mobile phase (75:25 acetonitrile and 0.2% formic acid) at a flow rate of 0.5mL/min was developed. Multiple Reaction Monitoring (MRM) quantified the precursor ion, 183m/z, using the following daughter ions: 183>120.10, 183>166.10, 183>80.05. Plasma standards and quality controls (QC) (20 uL) were processed using protein precipitation with cold acetonitrile. The lower limit of detection (LLOD) was 5ng/mL in neat solutions. Assay performance was determined from multiple runs (n=10) with standards from 250 - 50,000 ng/L and three levels of QC (500, 7500, and 40,000 ng/mL). Standard curves were linear with R2 values between 0.9960 and 0.9999. The assay was accurate and precise with a mean bias of <4% and RSD <0.5%. The assay was successfully applied to pharmacokinetic samples obtained from a DFMO pharmacokinetic (PK) study.

1338 ΔNp63α Suppresses Cell Invasion by Modulating Rac1 Activity

A. A. Aljagthmi. *Wright State University, Dayton, OH.* Sponsor: A. Aljagthmi, American Association for the Advancement of Science

ΔNp63α, a member of the p53 family of transcription factors, is overexpressed in a number of cancers and plays a role in proliferation, differentiation, migration and invasion. ΔNp63α has been shown to regulate several microRNAs that are involved in development and cancer. We identified miRNA miR-320a as a positively regulated target of ΔNp63α. Previous studies have shown that miR-320a is downregulated in colorectal cancer and targets the small GTPase Rac1, leading to a reduction in non-canonical WNT signaling and epithelial mesenchymal transition (EMT), thereby inhibiting tumor metastasis and invasion. We showed that miR-320a is a direct target of ΔNp63α. Knockdown of ΔNp63α in HaCaT and A431 cells downregulates miR-320a levels and leads to a corresponding elevation in PKCγ transcript and protein levels. Rac1 phosphorylation at Ser71 was increased in the absence of ΔNp63α, whereas overexpression of ΔNp63α reversed S71 phosphorylation of Rac1. Moreover, increased PKCγ levels, Rac1 phosphorylation and cell invasion observed upon knockdown of ΔNp63α was reversed by either overexpressing miR-320a mimic or Rac1 silencing. Finally, silencing PKCγ or treatment with the PKC inhibitor Gö6976 reversed increased Rac1 phosphorylation and cell invasion observed upon silencing ΔNp63α. Taken together, our data suggest that ΔNp63α positively regulates miR-320a, thereby inhibiting PKCγ expression, Rac1 phosphorylation, and cancer invasion.

1339 Why Do Whales Have Lower Cancer Rates? Whale Cells Avoid Particulate Chromate-Induced Homologous Recombination Repair Inhibition

H. Lu[1], C. Browning[2], and J. P. Wise[1]. *[1]University of Louisville, Louisville, KY; and [2]Brown University, Providence, RI.*

Whales are long lived species living in a complex environment that puts them at risk for long-term exposure and accumulation of environmental contaminants. However, they have low cancer rates, which may be due to better DNA protective mechanisms. How whales evade carcinogenesis is unknown. Particulate hexavalent chromium (Cr(VI)) is a human lung carcinogen. Cr(VI) induces DNA double strand breaks in human cells. Homologous recombination (HR) repair protects against these breaks by repairing them and preventing them from causing genomic instability and carcinogenesis. Prolonged particulate Cr(VI) induces DNA double strand breaks and suppresses HR repair in human lung cells. Whales are exposed to high Cr levels. This study focuses on the effect of particulate Cr(VI) exposure in whale lung cells to determine if they exhibit protective mechanisms against Cr(VI)-induced chromosome instability. Our study show Cr(VI) induced a concentration-dependent increase in DNA double strand breaks after both acute (24 h) and prolonged (120 h) exposure in whale lung cells, but did not inhibit HR repair in whale lung cells. Acute (24 h) Cr(VI) exposure caused G2/M arrest in human lung cells, but G1 arrest in whale lung cells. Prolonged (120 h) Cr(VI) exposure causes G2/M arrest in both human lung cells and whale lung cells. Future investigation of the differences in how human and whale cells respond to chemical carcinogens may provide valuable insight into mechanisms of preventing chemical carcinogenesis. *The work was supported by the National Institute of Environmental Health Sciences [ES016893 to J.P.W].*

1340 A Scoping Review of Environmental Factors Affecting Breast Cancer Risk

J. P. Stanko[1], V. Walker[1], M. A. Cawley[2], R. B. Blain[3], S. D. Holmgren[1], A. A. Rooney[1], and S. E. Fenton[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [3]ICF International Inc., Research Triangle Park, NC.*

Breast cancer is the most commonly diagnosed cancer and the second leading cause of cancer deaths in women worldwide. Although a genetic element exists, many breast cancer cases can be attributed to normal aging processes or environmental factors. Unlike age, environmental factors have the potential to be modified or avoided, and identification or characterization of these factors may aid in establishing breast cancer prevention priorities. This scoping review is being conducted to identify environmental factors that may influence breast cancer risk by categorizing published literature from humans, animals, and advanced cell models. The research collected in this review includes breast cancer and related non-cancer outcomes that indirectly alter breast cancer risk by impacting pathways related to breast and mammary gland development. PubMed was searched using a targeted search strategy to identify all relevant evidence on the mammary effects of toxicant exposure published between January 2008 and December 2018. The search strategy utilized mammary search terms to encompass breast structure, breast characteristics and processes, breast conditions and diseases, and lactation. Non-mammary sexual developmental indicator terms were also included. From the search we identified 1149 human studies, 559 animal studies, 64 *in vitro* studies involving 3D cultures or mammospheres, and 3 *in silico* studies. The studies were systematically categorized by key concepts of exposure (four domains and nine subdomains), evidence stream (human, animal, *in vitro*) and outcomes (cancer-related, breast and mammary gland developmental endpoints, and non-mammary-related) to develop an interactive evidence map. A recent update to the search retrieved 1297 articles that are currently being screened and categorized. The evidence map will provide an interactive method for individual researchers to search, sort, filter, and query published data linking environmental exposures and outcomes related to breast cancer risk. These data can also be used to develop a database of environmental risk factors potentially linked to breast cancer and provide a state of the science to inform future research decisions and systematic review themes.

1341 Estimating Acceptable Exposure Levels for Polybrominated Diphenyl Ether (PBDE) Based on *In Vitro* Models of Human Neurodevelopment and Biological Modeling

S. Bloch[1], C. Chandrasekera[2], N. I. Kramer[3], M. Bouchard[1], and M. Verner[1]. *[1]Université de Montréal, Montreal, QC, Canada; [2]Canadian Centre for Alternatives to Animal Methods, Windsor, ON, Canada; and [3]Institute for Risk Assessment Sciences, Utrecht, Netherlands.*

Current acceptable exposure levels are mostly based on animal models, which are costly, time-consuming and may poorly predict adverse outcomes in humans. There is a need for alternative testing methods that are faster, cheaper, and provide human-relevant information. Our objective was to evaluate a method using human *in vitro* data and biological modeling to calculate an acceptable exposure level through a case study on PBDE developmental neurotoxicity. Using data from a study on human neuroprogenitor cells, we derived a point of departure using benchmark dose modeling for BDE-99 induced alteration of differentiation. We calculated a lower bound for the benchmark dose (BMDL) of 0.0832 µM for a benchmark response of 10%. We subsequently translated this BMDL expressed in terms of nominal concentration into a cellular level (2819 µg/kg cells) using the empirically-derived enrichment factor (60). We estimated the acceptable maternal daily intake (105 ng/kg/d) and plasma concentration (150 ng/g lipids) associated with a concentration of 2819 µg/kg in the child brain through reverse dosimetry using a pharmacokinetic model of gestational and lactational exposure. Finally, we compared the estimated maternal plasma BDE-99 level during pregnancy to median and maximum levels measured in epidemiological studies reporting associations with child neurodevelopment. Studies reported median levels ranging from <3.3 to 4.5 ng/g lipids, and maximum levels ranging from 169 to 298 ng/g lipids. Overall, the acceptable exposure level derived from *in vitro* data was higher than median levels measured in epidemiological studies, but in the range of maximum levels. Results suggest that factors related to the duration of exposure and interindividual variability may need to be taken into account.

1342 A Systematic Analysis of Mitochondrial Perturbation in Chemical-Induced Organ Toxicity Using High Content Imaging and High Throughput Transcriptomic Approaches

W. van der Stel[1], G. Carta[2], P. Jennings[2], E. H. Danen[1], and B. van de Water[1]. *[1]Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands; and [2]Vrije Universiteit Amsterdam, Amsterdam, Netherlands.*

Mitochondrial perturbation has been recognised as a key event in the process of chemical-induced organ toxicity. Nowadays the assessment of the mitochondrial functioning in early toxicity screens is based on static measurements of various mitochondrial processes. Here we focused on the integration of concentration- and time-resolved into an AOP framework to improve biological and mechanistic understanding of the relationship between mitochondrial perturbation and toxicity. We used a panel of >20 agrochemicals that specifically target mitochondrial respiratory complex (MRC) I, II or III and assessed both mitochondrial injury and subsequent cellular perturbations using high throughput imaging and transcriptomic platforms. We assembled a mitochondrial toxicity screening platform in HepG2 assessing the effects of MRC inhibitors on possible key events in a mitochondrial-related liver toxicity AOP. The various CI and CIII inhibitors, but not CII inhibitors, were effective in depleting complex inhibition, oxygen consumption and mitochondrial membrane potential, but not viability. Differentiated 3D HepG2 spheroids improved the prediction of complex inhibitor adverse effects. To quantify the relationship between mitochondrial perturbation and cellular signalling, we used TempO-Seq targeted RNA-seq assessing >3000 genes that capture the genome wide variations in gene expression upon MRC inhibitor exposure. The TempO-Seq data revealed gene expression upregulation that typically paralleled the potency and onset of mitochondrial toxicity by the various MRC inhibitors. Furthermore, using pathway analysis and gene clustering we identified individual genes and gene clusters could improve prediction of mitochondrial toxicity and provide the mechanistic insights on the cellular adaptation upon specific MRC complex inhibition. In summary, the integrated AOP based assessment of the dynamics of mitochondrial dysfunction and cellular stress response activation provides a novel mechanism-based approach to quantitatively in-depth assess mitotoxicity liability and discriminate the effect on different MRC complexes. *This work was part of the EU-ToxRisk project and received funding from the EU's Horizon 2020 programme under grant agreement No 681002.*

1343 Diisononyl Phthalate Exposure Affects Colonic Health in Adult Female Mice

K. K. Chiu, D. D. Meling, C. Chiang, and J. A. Flaws. *University of Illinois at Urbana-Champaign, Urbana, IL.*

Diisononyl phthalate (DiNP) is a common phthalate that is used to make polyvinyl chloride flexible. DiNP is used in many end products such as toys, faux leather, and building materials. Exposure to DiNP has been shown to aggravate immune responses in humans. However, little is known about DiNP and its effects on the gastrointestinal tract. Thus, this study tested the hypothesis that subchronic exposure to DiNP alters colon histology and gene expression related to inflammation and cell cycle regulation. To test this hypothesis, 39-40 day old female CD-1 mice were orally dosed with corn oil vehicle (n=6), 20 µg/kg/day (n=6), or 200 µg/kg/day (n=6) DiNP for 10-14 days and then euthanized during diestrous immediately after dosing. Distal colons were collected for histological examination and gene expression analyses of *Ifng*, *Tnf*, *Il22*, *Il10*, *Bcl2*, *Ccnd2*, *Cdkn1a*, *Ccnb1*, *Bcl2l10*, *Ccne1*, *Cdk4*, *Ki67*, and *Pcna*. Histological analysis showed that DiNP exposure at 20 and 200 µg/kg/day increased colonic damage compared to control ($p=0.02$ and $p\leq0.05$, respectively). Colonic damage was mainly attributed to cellular infiltration and edema. However, enterocyte sloughing and aberrant colon walls were also observed in the DiNP treatment groups. Mice exposed to DiNP showed no significant differences in cytokine gene expression (*Ifng*, *Tnf*, *Il22*, *Il10*) in the colon compared to control. However, DiNP exposure increased *Ifng* and *Tnf* expression in a dose-dependent manner compared to control. Further, 200 µg/kg/day DiNP significantly downregulated *Ccnd2* compared to control. High DiNP did not alter the expression of *Bcl2*, *Cdkn1a*, *Ccnb1*, *Bcl2l10*, *Ccne1*, *Cdk4*, and *Pcna* compared to control. These data suggest that DiNP exposure causes colonic damage and may interfere with cell growth in the colon. *Supported by NIH T32 ES 007326, NIH R01 ES028661, and Vision 20/20.*

1344 Clotrimazole, a Potent PXR Agonist, Perturbs the Physiology and Metabolic Activity of the Gut Microbiome

S. L. Collins, B. Rimal, Y. Tian, and A. D. Patterson. *Penn State University, University Park, PA.*

The Pregnane X Receptor (PXR) is a master regulator of xenobiotic metabolism in mammals, controlling the expression of genes including CYP3A4, sulfotransferases, and multi-drug transporters. The large hydrophobic ligand-binding domain of PXR allows it to respond to a broad repertoire of chemicals, with a variety of pharmaceuticals, herbal extracts, steroids, environmental toxicants, and several microbial metabolites (e.g., LCA) acting as its ligands. With a growing understanding of how xenobiotics, host metabolism, and the gut microbiome interact, it is important to determine the impact that PXR ligands have on the health and metabolism of the gut microbiome. The anti-fungal clotrimazole is a PXR agonist but also has known antibacterial activity. Using flow cytometry, we have shown that clotrimazole attenuates the membrane physiology (permeability and polarization) and biochemical activity of the collective cecal microbiome of mice, in a dose-dependent manner. Furthermore, clotrimazole significantly alters the metabolic profile of cecal microbes *in vitro*, as observed using untargeted LC-MS. Future work will aim to classify the microbes affected and understand the impact this might have on the host detoxification of additional PXR ligands. Since an intact and viable gut microbiome is essential for host health and regulation of xenobiotic metabolism, an understanding of how this relationship may be perturbed is of utmost importance.

1347 Establishment and Characterization of Rat Duodenal Organoids

J. Panzica-Kelly, W. Hedrich, B. Strassle, J. Megill, C. Hasson, L. Wang, W. Chen, T. Sherry, J. Gan, and M. Davis. *Bristol-Myers Squibb Company, Princeton, NJ.*

There is a need for additional nonclinical gastrointestinal models that can accurately model human physiology, including drug metabolism and toxicologic responses. For this reason, we have developed a rat duodenal organoid culture system that can more accurately represent the molecular and physiological features of the innate gastrointestinal environment. We isolated rat adult intestinal stem cells from whole rat duodenum and optimized culture conditions to stimulate growth and differentiation of organoids. Transmission electron microscopy (TEM), immunohistochemistry, mRNA and microarrays were used to characterize the organoids during differentiation. TEM was used to assess ultrastructural differences (such as apical microvilli, cytoplasmic vacuoles, perinuclear granules, adherens, tight junctions and desmosomes).

We stained the organoids with the following differentiation and intestinal region-specific antibodies by immunohistochemistry: zonula occludens-1 (ZO-1) for tight junction formation, mucin 2 for goblet cells, chromogranin A for enteroendocrine cells, and villin for enterocytes. Relative expression of lgr5 (adult stem cell marker), sucrose isomaltase (SI), villin and cholecystokinin (adult intestinal tissue markers) was measured by RT-PCR. As expected, lgr5 levels were down-regulated as SI, villin and cholecystokinin levels were up-regulated through the organoid differentiation period. Additionally, we used probe substrates for typical phase 1 and phase 2 drug metabolizing enzymes to assess organoid metabolism ability. Significant differences on metabolism between undifferentiated and differentiated organoids were observed. We aim to develop organoid structures from different segments of the intestine from human and preclinical species to provide a platform to investigate drug absorption and metabolism, intestinal physiology and disease, host-pathogen interactions and other toxicological questions.

1348 Discrepant *In Vitro* Cytotoxicity Results Can Be Explained by Method-Specific Differential Dependency on Pentose Phosphate Pathway-Associated Metabolism

J. P. Coyle, R. Derk, M. Farcas, T. Kornberg, T. A. Stueckle, and L. W. Rojanasakul. *NIOSH, Morgantown, WV.*

Tetrazolium reduction and resazurin assays remain the mainstay of routine *in vitro* toxicity batteries. However, neglecting to verify the baseline assumption of interaction of test article with method employed can produce potentially erroneous characterization of cytotoxicity/cell proliferation for test articles. The current investigation aimed to demonstrate the results of several standard cytotoxicity and proliferation assays varies in dependence on contributions from the pentose phosphate pathway (PPP). Beas-2B cells were treated with graded concentrations of benzo[a]pyrene (B[α]P) for 24 and 48 hours prior to cytotoxicity/proliferation assessment with commonly used MTT, MTS, WST-1, and Alamar Blue assays. B[α]P caused increased transient enhancement of metabolism of each dye assessed. An inhibitor of the glucose-6-phosphate dehydrogenase, 6-aminonicotinamide (6-AN), dose-dependently reduced metabolism of each endpoint listed in order of magnitude: WST-1 > MTS > MTT > Alamar Blue without overt cytotoxicity, implicating differential sensitivity of each endpoint to the pentose phosphate pathway (PPP). Nanomolar doses of B[α]P caused increases in all endpoints to suggest an increased cell proliferation. However, B[α]P treatment increased phosphorylation of Chk-1(S345) and p-53(S15), suggesting reductions in proliferative capacity. Reduction in proliferation was confirmed upon assessment of cell doubling time, which was lengthened dose-dependently. These results demonstrate differential sensitivity of studied cytotoxicity assessments on the PPP, thus 1) decoupling "mitochondrial activity" as an interpretation of cellular formazan and Alamar Blue metabolism, and 2) demonstrating the implicit requirement for investigators to sufficiently confirm methods of cytotoxicity/proliferation in routine experimentation. The nuances of these method-specific extramitochondrial metabolism must be scrutinized to properly qualify specific endpoints employed.

1349 Novel ID3 Regulatory Gene Networks Contributing to Brain Vascular Disease

C. M. Perez, Q. Felty, and C. Yoo. *Florida International University, Miami, FL.*

Cerebrovascular disease (CBVD) often leads to cognitive impairment and is a prominent comorbidity of Alzheimer's disease (AD) observed in 60%-90% of patients. Single nucleotide polymorphism in the human ID3 gene has been associated with atherosclerosis, however, its contribution to CBVD is unknown. This study uses a machine learning-based analysis of human brain microvessel transcriptome to identify novel ID3 gene regulatory networks in AD patients. Microarray data from human brain microvessels from 20 AD patients and controls were processed for normality. Probe set identifiers were mapped to Entrez identifiers, official gene symbols and gene names. Signal intensity values for each gene with multiple probes were averaged resulting in 21,000 unique gene annotations. Differential gene expression between case and controls was calculated by the Benjamin-Hochberg t-test ($p < 0.05$). ChIP-Seq analysis identified approximately 2,834 candidate genes bound by ID3 in endothelial cells. We discovered 38 ID3 bound target genes among 417 genes showing a 2-fold change between disease and non-disease brain microvessels. For Bayesian networks analysis, ID3 target genes were discretized in cases and controls. Variables such as age, gender, and disease were included into the Bayesian networks structure learning algorithm. Nine best structures were identified from running the learning algorithm nine times with different running times (three independent runs for 2 h, 4 h, and 8 h.). A Bayesian network structure identified at 8h was selected as the best scoring network comparing Bayesian Dirichlet scoring metric of all structures. The best scoring network showed a structural ID3 gene regulatory network interacting with age, gender, and disease. We discovered five key ID3 gene targets to be most influential to diseased brain microvessels (AMFR, BEX1, PARVG, PGM2L1, PRKACB). Furthermore, the best scoring network predicted a subject will have AD with a high probability (>0.999) when only three (BEX1, PGM2L1, PRKACB) of the five key genes are downregulated, and with a low probability (<0.001) when only PARVG was downregulated in human brain microvessels. Receiver Operating Curve analysis on ID3 gene network influence on disease resulted in an area under the curve of 0.75. Data driven machine learning is a powerful approach to predict ID3 causal gene networks involved in vascular disease. Given paucity of studies on human brain microvessels and small number of subjects in this study, a future goal will be to apply this method on a larger population with the hope of identifying blood-based biomarkers of vascular dementia.

1350 Assessment of Remediation of Arsenic from Water through Measuring Environmental Stressor Transcriptomic Gene Signatures

J. C. Morales. *Florida International University, Miami, FL.*

Nuclear respiratory factor 1 (*nrf1*) is an environmental stressor gene, when exposed acutely by numerous environmental agents, such as temperature, physical activity, diet and accumulated metals it activates and regulates cellular functions. Molecular indices to measure Arsenic (As) in surface waters are currently unavailable. Here, we use the zebrafish which is a known sentinel for biomonitoring of aquatic environments. The objective in this study was to investigate *nrf1* transcription factor and its signature genes to identify orthologue signature gene networks which may be involved in the initiation and progression of cellular processes. To identify the common *nrf1* targets, we analyzed the ChIP-seq dataset from ENCODE. We then used bioinformatics and functional genomics to determine (As- *nrf1*) significant target genes comparing the treatment effects of low concentrations 15 (ppm) [As(V)] in liver hepatocytes while characterizing the cellular processes across 4 periods (8, 24, 48 and 96 h) of treatment time. The transcriptomic dataset of GSE3048 of 12 As treated and 12 control zebrafish samples was processed for normalization. A parametric *t* test, (*p*-value <0.05) between treated and control samples was used to determine differential expressed genes (DEGs) using the Benjamin-Hochberg False Discovery Rate (FDR). Dysregulated *nrf1* targets were determined based on a criterion of 2-fold change. During 8-96 h, we discovered 236 upregulated and 336 downregulated *nrf1* targets in As treated zebrafish. Furthermore, 8 h revealed 30 up and 72 down-regulated genes. A reduced number of downregulated genes were identified at 24 h, 60 up and 6 down-regulated genes. Relatively equal number up and down regulated genes occurred at 48 h with 57 up and 62 downregulated. Broadly, we found genes at 96 h most dysregulated compared to previous times including 89 up and 196 genes downregulated. Using the functional gene ontology (GO) and (KEGG) pathways using DAVID pipeline, revealed that 72.6 % of the upregulated and 69.7% of the downregulated *nrf1* target genes matched DAVID enrichment process. The most significant upregulated GO terms across 8-96 h included metabolic processing p value (2.3E-4), cellular processing *p* value (9.5E-3) and developmental processing p value (9.5E-2). Using KEGG, *nrf1* targets play a key role in cell cycle, RNA transport, p53 signaling and glycerophospholipid biosynthesis. Our results show that the altered transcriptome responds to arsenic treatment in a sensitive manner. This provides a molecular approach to supplement traditional analytical measurements detailing a comprehensive pathway framework to monitor As in surface waters.

1351 Toward Predictive Toxicology—Computable Biological Network Models of Drug-Induced Liver Injury

K. Renggli, H. Yepiskoposyan, U. Kogel, V. Belcastro, M. Talikka, M. C. Peitsch, and J. Hoeng. *Philip Morris International, Neuchatel, Switzerland.*

Drug interactions with cigarette smoke impact the absorption, distribution, metabolism, and excretion of and, consequently, the response to some drugs. The main mechanism behind drug interactions with smoke involves hepatic metabolism, where polycyclic aromatic hydrocarbons present in cigarette smoke induce cytochrome P450 isoenzymes. The induction of these enzymes results in accelerated metabolism of xenobiotics in smokers and a clinically significant decrease in the pharmacologic effect. Xenobiotic metabolism pathways are also involved in drug-induced liver injury (DILI), where high-energy conversion of compounds can lead to necrosis or apotosis in the liver. To investigate how smoking affects DILI, we created a causal biological network model that gathered available biological knowledge into a structured and computable format. The resulting model provides a connected view of the signaling crosstalk that is critical for not only prediction of drug

toxicity but also elucidation of pathophysiological mechanisms. The network model backbone consists of biological entities (nodes) and relationships between the nodes (edges). The model has an additional layer that consists of mRNAs known to be regulated by the entities in the model backbone. All model relationships are scripted in Biological Expression Language, which facilitates computation, and, instead of overlaying gene expression changes onto the model, the second layer is used to infer the activity of the backbone nodes from transcriptomic data. Each network edge was extracted from literature, annotated with the originating source (PMID) and biological context (i.e., species, tissue/cell type, and disease state). The main involved biological processes determining a cell death outcome include a combination of the following pathways: MEK/ERK, mTOR/p70-S6K, AKT and p38/MK2/HSP27. Combining our model with transcriptomic data from relevant animal and cell models exposed to a combination of smoke and DILI model compounds provides a means for mechanistic understanding and quantitative impact assessment of toxicant effects on the liver for smokers, non-smokers, and switchers to potential modified risk tobacco products. In addition, this validation process results in network models with predictive capacities that can be used in the context of predictive toxicology to investigate the impact of compounds on biological systems.

PS 1352 Utilizing Human Cell Lines for an Unbiased and Biologically Relevant Off-Target Screening to Support Different Therapeutic Modalities

X. Liu, and J. Yuan. *Amgen Inc., Cambridge, MA.*

Unintended off-target activity remains a hurdle in drug discovery. The current approach of *in vitro* secondary pharmacology screening is often performed by pharmaceutical companies to assess unexpected binding and/or activity against a panel of off-target proteins. However, incomplete target coverage with only ~50 to 200 proteins in a typical panel, lacking biological context, and inadequacy to address specificity issues for emerging modalities such as RNA interference (RNAi) as well as Proteolysis Targeting Chimera (PROTAC), where off-target effects must be assayed changes in transcript or protein level rather than evaluation of binding or activity modulation, are some major limitations of this tool. To address this unmet need, we have developed a novel platform that allows unbiased protein profiling in biologically relevant settings. This platform can be used for off-target screening to support modalities beyond small molecules. Four cell lines were selected with a 73% coverage of the human genome based on transcriptome profiling results of CCLE (Cancer Cell Line Encyclopedia) cell lines. Global proteomics and detailed characterization were then carried out on these four cell lines. We were able to quantify a total of 10,627 protein with 10501 proteins from cellular fractions and 3146 proteins from secreted fractions. We further systematically investigated the protein targets that are implicated in cardiovascular, respiratory and central nervous systems with strong genetics and pharmacological evidence. Our proteomic platform was able to quantify 1828 proteins which are considered to be important to evaluate for drug safety assessment. The species conservation of these proteins between human, rat, dog, and monkey were also calculated, which could help provide preliminary clues on the translatability between species. This proteomic platform is best suited to screen off-targets for PROTAC and RNAi therapies, and with the aid of chemical biology, for small molecules as well. The platform may provide the opportunity to broadly assess functional essential proteins and to allow better forecasting the phenotypical consequence(s) that may lead to potential drug adverse events.

PS 1353 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) Effects of Hepatic One Carbon Metabolism during the Progression of Steatosis to Steatohepatitis with Fibrosis in Mice

R. Fling, C. Doskey, K. Fader, R. Nault, and T. Zacharewski. *Michigan State University, East Lansing, MI.*

TCDD has been linked to the development of metabolic diseases including non-alcoholic fatty liver disease (NAFLD). One carbon metabolism (OCM) gene expression and metabolites levels, notably S-adenosylmethionine (SAM) and S-adenosylhomocysteine (SAH), are often altered in animal and human models of NAFLD. Changes in the SAM/SAH ratio affect methylation reactions including the biosynthesis of methylated metabolite and epigenetic marks. To investigate the dose-dependent effects of AhR activation on OCM, male mice were orally gavaged with sesame oil vehicle control or TCDD (0.01-30 µg/kg) every 4 days for 28 days. Histopathology showed increased hepatic fat accumulation, immune cell infiltration, bile duct proliferation, and collagen deposition. TCDD dose-dependently repressed adenosylhomocysteinase (*Ahcy*; ED_{50} 10.4 µg/kg), betaine-homocysteine S-methyltransferase (*Bhmt;* ED_{50} 11.2 µg/kg), cysthionine-β-synthase (*Cbs*, BMDL 0.1 µg/kg), glycine N-methyltransferase (*Gnmt*; ED_{50} 11.2 µg/kg), and methionine adenosyltransferase 1A (*Mat1a*; ED_{50} 4.5 µg/kg). Accordingly, protein levels of AHCY, BHMT, CBS, GNMT and MAT1A were decreased with increased levels of betaine, homocysteic acid, and methionine, while cystathionine, dimethylglycine, and the SAM/SAH ratio were reduced. Additionally, SAM-dependent biosynthesis pathways for polyamines and creatine were perturbed. Decreased expression of guanidinoacetate methyltransferase (*Gamt*, ED_{50} 14.6 µg/kg*)* increased guanidinoacetate in the liver and serum while decreasing urinary creatinine. Expression of ornithine decarboxylase (*Odc1;* ED_{50} 1 µg/kg) led to increased putrescine levels in spite of increased spermidine synthase (*Srm*; ED_{50} 0.35 µg/kg) expression. These results suggest AhR activation by TCDD leads to OCM disruption concurrent with the progression of steatosis to steatohepatitis with fibrosis. *This work was supported by the Superfund Research Program (NIEHS SRP P42ES04911) and the NIEHS Multidisciplinary Training in Environmental Toxicology Program (NIEHS EHS P2T32ES007255).*

PS 1354 High Content Screening of Toxic Response Phenotypes in Cells Derived from the Diversity Outbred Mouse Population

C. W. O'Connor, W. Martin, G. Keele, R. Korstanje, G. Churchill, and L. Reinholdt. *The Jackson Laboratory, Bar Harbor, ME.* Sponsor: A. Harrill

Natural genetic variation significantly influences the physiological response to chemical exposure, and studying diverse populations can help decipher the underlying mechanism of response variability. With balanced allele frequencies, small linkage blocks, and ~90% of the genetic variation found in *Mus musculus*, the Diversity Outbred (DO) mouse population combines the experimental tractability of laboratory mice with high genetic mapping resolution. To establish a platform for cellular systems toxicology, we are generating a panel of primary fibroblast cultures from DO mice for *in vitro* High Content Screening (HCS) of arsenic exposure (sodium arsenite; $NaAsO_2$). The genotoxic effects of As exposure are a by-product of increased oxidative stress and inhibited DNA repair, which can be assessed at single cell resolution using the Operetta High Content Imaging system. Combined with a parallel *in vivo* sodium arsenite exposure, our cellular response phenotypes will ultimately be correlated to physiological responses and multi-omics analysis. Here we show our preliminary assessment of broad sense heritability for a range of cellular traits influencing the response to arsenic exposure using fibroblasts derived from the 8 isogenic founder strains of the DO population. Our results show that genetic background influences arsenic cytotoxicity, with the CAST/EiJ strain being particularly susceptible. Notably, the CAST/EiJ derived allele of arsenic methyltransferase (*As3mt*) has increased expression, identified through expression quantitative trait loci (eQTL) analysis, which may relate to the arsenic sensitivity. Taken together, these data show that our *in vitro* platform is sensitive enough to detect heritable differences cellular responses to toxic exposure, and mouse genetic reference populations such as the DO can be used for high resolution mapping and validation of the loci that influence toxic response.

PS 1355 Identification and Functional Characterization of a Novel Biomarker for Aryl Hydrocarbon Receptor (AhR) Activation

P. Shankar, G. R. Garcia, J. K. LaDu, C. M. Sullivan, and R. L. Tanguay. *Oregon State University, Corvallis, OR.*

The aryl hydrocarbon receptor (AhR) is required for normal vertebrate development and is also activated by several chemicals including polycyclic aromatic hydrocarbons (PAHs) and 2,3,7,8-Tetrachlorodibenzodioxin (TCDD). AhR activation is well understood, but the roles of downstream molecular signaling events are largely unknown. Previously, we conducted transcriptomics in 48-hours post fertilization (hpf) zebrafish exposed to 16 PAHs. In addition to the expected cytochromes P450 like *cyp1a1* and *cyp1c1*, one of the most highly elevated transcripts by several PAHs was *wfikkn1* (WAP, kazal, immunoglobulin, kunitz and NTR domain-containing protein), a potential novel biomarker for AhR activation. The purpose of the present study is to investigate the functional role of *wfikkn1* in the AhR signaling pathway. Quantitative RT-PCR was used to demonstrate that *wfikkn1* is expressed in developing zebrafish from 2.5 to 120 hpf. Using *in situ* hybridization in 48-hpf zebrafish, *wfikkn1* mRNA expression was identified in several organs including the brain, otic vesicle, and the trunk. When AhR2 (ortholog of human AhR)-null and Wildtype zebrafish were exposed to DMSO or TCDD and the expression of *wfikkn1* was quantified at 48 and 120 hpf, the significant induction of *wfikkn1* was AhR2-dependent at both time points. To functionally characterize *wfikkn1*, a *wfikkn1* CRISPR-Cas9 mutant zebrafish line with a 16 bp exon deletion that produces a truncated protein was generated. The mutant zebrafish appear morphologically normal, but are hyperactive in a photomotor response assay at 120 hpf. To identify genes/pathways associated with *wfikkn1*, Wildtype and mutant

zebrafish were exposed to DMSO or TCDD, and mRNA from 48-hpf zebrafish was sequenced. Over 200 genes were differentially expressed ($p < 0.05$, $\log_2FC > 2$) between each pair of treatment combinations. The significant GO term processes associated with *wfikkn1* mutants included ATP-binding, immunoglobulin, and iron binding processes. ATP-binding, transmembrane, and protein kinase processes were uniquely altered in TCDD-exposed *wfikkn1* mutants compared to TCDD-exposed Wildtype zebrafish. We are currently conducting in-depth analyses of the RNA-sequencing data, and characterizing both *in vitro* Wfikkn1 protein activity and *in vivo* protein localization. Understanding downstream transcriptional events that occur upon AhR activation and play a role in toxicity pathways is necessary to accurately guide remediation strategies. *This study was supported by the SRP Grant P42 ES016465 and NIEHS Training Grant T32 ES007060.*

1356 A Multidonor Comparison of Human 3D Lung Epithelial Culture Models

D. Bovard, A. Giralt, K. Trivedi, L. Neau, P. Kanellos, A. Iskandar, K. Luettich, S. Frentzel, J. Hoeng, and M. Peitsch. *Philip Morris International, Neuchâtel, Switzerland.*

In vitro models of the human lung play an essential role in evaluating the toxicity of inhaled compounds and understanding the development of respiratory diseases. 3D organotypic models derived from lung epithelial basal cells and grown at the air-liquid interface (ALI) resemble the human airway epithelium in multiple aspects, including morphology, cell composition, transcriptional profile, and xenobiotic metabolism. Whether the different characteristics of basal cell donors, such as their ethnicity, age, sex, or smoking status, have an impact on the tissue characteristics and responses remains unknown. A major limitation of *in vitro* studies using cellular models from single donors is the potential bias towards a donor-specific response. In this study, we compared the characteristics of lung cultures grown at the ALI (bronchial and small airway) from different donors for morphology (histology and whole-insert immunostaining), functionality (transepithelial electrical resistance [TEER] and cilia beating frequency [CBF]), and metabolic capacity (cytochrome P450 [CYP] 1A1/1B1 activity). Bronchial and small airway cultures from 5 and 6 donors were evaluated from weeks 5 to 9 and weeks 8 to 11 after air-lift, respectively. The results showed differences in the thickness and cell-type composition of the epithelium across the donors and time after air-lift. TEER varied among the donors and, in general, progressively decreased over time. The frequency of ciliary beating increased in response to isoproterenol treatment irrespective of the donor or culture type. Untreated cultures presented low basal CYP1A1/1B1 activity, but treatment with 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) for 48 h induced CYP1A1/1B1 activity regardless of the donor. In conclusion, our results show that lung epithelial cultures prepared from different donors present diverse morphology but similar functionality and metabolic activity. However, we detected certain variability in the degree of responses following stimulation, for example, with isoproterenol (for CBF) or TCDD (for CYP1A1/1B1 activity). Overall, our study shows that the characteristics of lung epithelial cultures grown at the ALI change over time, and the sensitivity of cultures from different donors to some stimuli is variable. Therefore, for experiments with primary cultures, it is pertinent to have appropriate controls for each assay and time-point measurement.

1357 Identifying Molecular Pathways Highly Sensitive to Chemical Exposure Using Bioinformatic Methods

V. R. Salemme, J. McGaunn, S. Amir, A. A. Poluyanoff, M. Teffera, and A. Suvorov. *University of Massachusetts Amherst, Amherst, MA.*

A major trend in regulatory toxicology of the 21st century focuses on molecular pathways in toxicity testing. How do we know what pathways to asses for their sensitivity to chemical exposures? Previous toxicological research has identified a number of such molecular mechanisms. We hypothesize, however, that there are other molecular mechanisms highly sensitive to a broad range of chemical exposures, which were not yet identified. To test our hypothesis, we extracted a gene list from the Comparative Toxigenomic Database data on chemical-gene interactions from only high-throughput experiments with human, mouse or rat cells/tissues/organisms. The list of chemicals was than manually annotated. Endobiotics, pharmaceuticals, drugs of abuse, chemical warfare and research chemicals were excluded from further analysis as they interact with important molecular pathways by design and the search of molecular mechanisms sensitive to chemical exposures may be clouded by inclusion of these compounds. Further analysis was conducted for a subset of chemicals used in agricultural, cosmetics, environment, as food components, industrial chemicals and pollutants. This dataset included 330,605 chemical-gene interactions from 1,294 publications and covered 554 chemicals and 26,200 genes. A number of activating and suppressing gene-chemical interactions were identified for every gene in this dataset, and the resulting lists of genes were used for functional enrichment analysis using Metascape and GSEA. The top five genes undergoing downregulation in response to a broad range of chemical exposures included 3 members of the growth-hormone (GH) - IGF signaling pathway (IGF1, GHR and IGFBP3). Four out of the top five genes were upregulated by many chemicals, including Phase I xenobiotic metabolizing enzymes (HMOX1, NQO1, CYP1A1, CYP1B1). Enrichment analysis demonstrates that pathways of response to toxic substance, cytokine mediated signaling, apoptotic signaling, oxidative stress response and unfolded protein response are activated by broad range of chemicals, while pathways involved in lipid metabolism were suppressed by many chemicals. Our unbiased approach has confirmed the importance of major toxicological pathways, but also identified other pathways not represented widely in toxicological research, including GH-IGF signaling, lipid metabolism and cytokine mediated signaling.

1358 Use of Transcriptomics to Identify Cosmetic Ingredients' Biological Activity: A Read-Across Exercise

J. M. Naciff[1], Y. K. Shan[1], X. Wang[1], N. K. DeAbrew[1], M. Klaric[2], and G. P. Daston[1]. *[1]Procter & Gamble, Mason, OH; and [2]Cosmetics Europe, Brussels, Belgium.*

The objective of this work was to use transcriptional signatures to assess the biological activity of structurally related chemicals to define their biological similarity and with that, substantiate the validity of a read across approach usable in risk assessment. As a case study, we selected 4 short alkyl chain parabens: methyl-, ethyl-, butyl-, and propylparaben, as well as the main metabolite of these parabens, p-Hydroxybenzoic acid (pHBA). The comprehensive transcriptional response of MCF7 cells was evaluated (TempO-Seq, BioSpyder) after exposure to vehicle-control, each paraben or pHBA at 3 non-cytotoxic concentrations (1, 50 and 500 µM), for 6h. Differentially expressed genes (FDR ≥ 0.05, and fold change ±1.2≥) were identified for each of the parabens or pHBA at each dose of exposure and used to determine similarities between them. Each of the parabens is able to elicit changes in the expression of a large number of genes, as compared to controls, particularly at the highest dose tested. Importantly, the transcriptional profile elicited by each of the parabens shares a high degree of similarities across the category members. We identified 133 common genes whose expression is modified by each of the parabens in a significant manner in the same direction. pHBA elicited significant gene expression changes at the highest concentration evaluated (615 genes), however, these changes are mostly different than the ones elicited by any of the parabens. The highest number of genes commonly affected by the parabens was found between butylparaben and propylparaben, where 634 genes were in common. Pathway enrichment analysis (MSigDB v7.0) of the transcriptional profile for each paraben indicated a significant overlap in the up- and down-regulated pathways across the four parabens. This was indicative of their biological similarity, and thus the validity of the read across among the group. The highest similarity in biological activity was found between butylparaben and propylparaben. The top Hallmark pathways that are most up-regulated by these two parabens are: estrogen response early and late, and TNFA signaling via NFKB. While the top Hallmark pathways that are most down-regulated are: apical junction, NOTCH signaling, myogenesis, and hedgehog signaling. These pathways' similarities further support the conclusion that these two parabens are the most similar structural and biological analogs. *Supported by Cosmetics Europe.*

1359 From Input to Output: Understanding the Effects of *Epichloë coenophialum* Infection in Tall Fescue on the Fescue Plant and Grazing Beef Pathophysiology through Metabolomics and Microbiomics

R. S. Mote[1], J. H. Skarlupka[2], N. S. Hill[1], Z. P. Sanders[1], D. P. Jones[3], V. T. Tran[3], M. R. Smith[3], K. Liu[3], J. Lourenco[1], G. Suen[2], and N. M. Filipov[1]. *[1]University of Georgia, Athens, GA; [2]University of Wisconsin–Madison, Madison, WI; and [3]Emory University, Atlanta, GA.*

Epichloë coenophialum is a common endophyte in tall fescue and it increases plant vigor. However, *E. coenophialum*-infected tall fescue is referred to as toxic because the endophyte produces secondary metabolites (ergot alkaloids) that are detrimental to grazing livestock, resulting in fescue toxicosis (FT). We previously found toxic tall fescue (E+) grazing perturbs metabolic homeostasis and induces hindgut dysbiosis in beef cattle, but no study has assessed the impact of E+ on the tall fescue or rumen microbiota/metabolome, nor has this been integrated with fecal microbiota. We sampled novel, non-toxic (MaxQ) and E+ tall fescue plants, rumen contents, plasma, urine, and feces of Angus

steers grazing either MaxQ or E+ tall fescue for 28 days. 16S (bacteria) and ITS2 (fungi) rRNA sequencing and high-resolution metabolomics were used to assess changes in the microbiota and metabolomes resultant from *E. coenophialum* infection or exposure. E+ significantly affected the global microbiota profiles (bacteria/fungi) in all biological matrices. Plant fungi were the only core microbiota influenced by E+, with increased *Pucciniaceae*, *Pleosporaceae*, and *Dissoconiaceae*, and decreased *Mycosphaerellaceae*. Numerous plant bacterial OTUs were detected in the rumen and feces of both MaxQ and E+ steers, without much overlap for plant fungi. Most fungal taxa were significantly decreased by E+ across the GI tract. Bacterial *Lachnospiraceae*, *Coriobacteriaceae*, and *S24-7* families were increased in E+ rumen solids, liquids, and feces. The *Mogibacteriaceae* family was increased in both the rumen liquids and feces of E+ steers, while the *Veillonellaceae* was increased only in rumen liquids. Bacterial changes were more similar between the rumen liquids and feces than other biological matrices, indicating the overlap between the fore- and hindgut microbiota is driven by rumen liquids. Tropane, piperidine, and pyridine alkaloid biosynthesis was the top metabolic pathways significantly different between MaxQ and E+ tall fescue. Many metabolic pathways were affected by E+ in the rumen liquid (steroid and histidine metabolism), plasma (phenylalanine, tyrosine, and tryptophan metabolism), and urine (terpenoid backbone biosynthesis). Differential network analysis showed a highly correlated structure of OTUs and metabolites that are fescue cultivar specific, demonstrating global changes to the structure of the microbiota/metabolome in response to E+ grazing. Overall, this study provides a global view of plant and animal responses to *E. coenophialum* infection and E+ grazing, respectively, while deepening our understanding of FT etiology. *Support: USDA (NIFA 67030-25004).*

1360 Bioengineering of Artificial Thymoma Spheroids as a 3D Model for *In Vitro* Toxicity Testing Employing a Novel Microslot Nuclear Magnetic Resonance Technique

M. AlWahsh[1,2], R. Marchan[3], A. Telfah[1], E. Tolstik[1], R. Hergenröder[1], A. Marx[2], D. Belharazem[2], and J. Lambert[1]. *[1]Leibniz-Institut für Analytische Wissenschaften, Dortmund, Germany; [2]University Medical Center Mannheim, University of Heidelberg, Mannheim, Germany; and [3]Technical University of Dortmund, Dortmund, Germany.*

The metabolic pathogenesis of thymic carcinomas (TCs) is poorly understood and adjuvant therapy has limited success in metastatic disease and tumor recurrence. Most studies on TCs use two-dimensional (2D) cell culture models, which are not considered as physiologically relevant, and consequently translation to the *in vivo* situation remains challenging. Tissue-specific architecture, based in part on interactions with the microenvironment is an essential component of tumors and may be better recapitulated in three-dimensional (3D) cell culture models. We established 3D models of two thymic carcinoma cell lines, TY82 and 1889c, in normal and serum free media using simple rotation for the former cell line, and 3D molds for the latter, which was co-cultured with Extracellular Matrix Protein (ECM). Characterization of the 3D models were performed using live imaging with a variety of dyes, as well as structural analyses. Subsequently, the effect of bortezomib, the most commonly used drug for thymomas, was compared between 2D and 3D models using traditional toxicity assays, as well as *in vivo* imaging. A technique was established using Nuclear Magnetic Resonance (NMR) that is suitable for measuring ultra-small volume samples, like 3D tumor models in order to perform metabolic profiling in these 3D models as a function of spatial position. For the first time, 3D spheroids could be made of reproducible size and quality using two thymic cancer cell lines. We could also produce spheroids using serum free media to decrease differentiation of the cells normally seen in this cancer type. Live/dead dyes showed that the cells in the untreated spheroids were viable; with evidence of a hypoxic core the larger the spheroid. Metabolic profiling of the 2D and 3D models for both cell lines were identified, Treatment with increasing concentrations of bortezomib showed higher IC50 values for the 3D models than 2D models with 2 different viability assays - CellTiter-Glo® and Prestoblue. Finally, we could establish the very first assay for noninvasive toxicity testing employing NMR. The present findings using 3D models of thymic cancer confirm that they are more resistant to drug-induced toxicity compared to 2D models. In addition, our novel approach using NMR allows for the measurement of small tissue-like models, which are normally not feasible with standard analytical techniques. The currently-available methods only provide a "snap-shot" of the measured time point and tend to be destructive, e.g. dissecting or optical cleaning of the specimen to gain 3D Information - a limitation we overcome with our current method using NMR spectroscopy.

1361 Comprehensive Histone, DNA Methylation, and mRNA Expression Analysis of Murine Liver Repeated Exposure to Chemicals—Percellome Project Update

J. Kanno[1,2], K. Aisaki[2], R. Ono[2], and S. Kitajima[2]. *[1]Japan Bioassay Research Center, Hadano, Kanagawa, Japan; and [2]National Institute of Health Sciences, Kawasaki, Kanagawa, Japan.*

The Percellome Project aims at reinforcing and replacing the "safety factor" by comprehensively identifying the transcriptomic networks induced by xenobiotics. "Percellome" normalization method was developed to generate absolute copy numbers of mRNAs in a "per one cell" basis from the Affymetrix GeneChips. Data of mouse liver after a single oral gavage (4 time points (2, 4, 8, and 24 hours after dosing) x 4 dose levels (control, low, middle, and high), triplicate, 48 GeneChip data per chemical/organ from 48 mice) on 160 chemicals are compiled. In addition, data from newly designed repeated-dosing studies are added. This study uses 48 wild-type mice repeatedly given a same dose of a chemical for 4 or 14 days to create a "chemically induced transgenic state", and then, the next day, a single gavage of a chemical in four dose levels was given, and the liver was sampled at 2, 4, 8, and 24 hours thereafter. Up to now, GeneChip data on CCl_4, tributyltin, deet, clofibrate, valproic acid, acetaminophen, phenobarbital, thalidomide, 5-fluorouracil, acephate, imidacloprid, and diethylnitrosamine are obtained. Repeated dosing of CCl_4 suppressed the baseline expression of genes related to ER stress and also affected the rapid response to the final dosing. 14 day repeated dosing of valproic acid did not affected both the baseline expression and rapid response induced by the final dosing. As a result, we found that the effect of repeated dosing can be interpreted as a combination of two elements, i.e. baseline response (BR: gradual shift of the basal expression level) and transient response (TR: alteration of the magnitude and/or pattern of the quick response in 2 to 24 hours). To clarify the molecular basis of the BR and TR, whole genome bisulfite analysis (WGBA) and ChIP-seq against H3K4me3, H3K27me3, H3K27Ac, and H3K9me3 were performed on the liver samples of CCl_4 and Valproic acid repeated dosing studies. WGBA was validated by a F1 of C57BL/6 and Japanese domestic syngeneic JF1 mice that have 10 million SNPs so that maternal and paternal strands of imprinting genes can be clearly identified. In short, 14 days of CCl_4 treatment did not alter DNA methylation. On the other hand, ChIP-seq revealed that BR and TR of mRNA of some characteristic genes was in good correlation with histone modification. Detailed analysis of CCl_4 and Valproic acid studies will be presented.

1362 Early-Life TCDD Exposure Shapes Gene Expression and Chromatin Profiles across the Life Course of Mice

J. P. Parker[1], J. D. Fredenburg[1], T. I. Konneker[1], N. E. Allard[1], B. Horman[1], A. Safi[2], H. B. Patisaul[1], G. E. Crawford[2], and D. L. Aylor[1]. *[1]North Carolina State University, Raleigh, NC; and [2]Duke University, Durham, NC.*

2,3,7,8-Tetracholorodibenzodioxin (TCDD) is a potent environmental toxin that is generated as a byproduct of industrial operations involving high temperature processing of organic material. It enters into environmental systems as a constituent of solid waste and flue gas. In vertebrate systems, TCDD activates the AhR-mediated xenobiotic response which modulates transcription of numerous genes responsible for metabolizing toxic compounds. The World Health Organization recognizes links between early-life exposure to TCDD and late-onset pathologies including neurological disability, reproductive impairment, and increased cancer risk. Our goal is to understand the consequences of early-life TCDD exposure on the molecular state of multiple tissues. Mice were exposed to TCDD from preconception through gestation and lactation. Tissue samples were taken three weeks, five weeks, twenty weeks, and forty weeks after birth. From our measurements of transcriptional profiles, we show that gestational TCDD exposure shapes gene expression and open chromatin profiles both in the short-term and in the long-term. Substantial changes in molecular profiles accompanied early life exposure after accounting for signatures of tissue, age, and sex. Expression of 1497 genes and accessibility of 1571 loci were altered in liver combined over both sexes across all ages. The effects of TCDD differed dramatically between males and females. Though there were clear signatures of TCDD exposure at all age points, few changes observed at three weeks persisted into adulthood. Blood showed few differentially expressed genes at three weeks but substantially more in adult mice. However, there is no overlap between responses in liver and blood. We conclude that a complex cascade of gene regulatory events is set in motion by early-life TCDD exposure which results in long-term gene expression and chromatin accessibility differences in adult mice.

1363 Toxicokinetic Model Predicts Cellular Exposure in Organ-on-Chip Microdevices

K. M. Tasneem, A. W. Auner, D. A. Markov, L. J. McCawley, and M. S. Hutson. *Vanderbilt University, Nashville, TN.*

Organ-on-chip microdevices have proven useful to evaluate chemical toxicity in human cells cultured in 3D heterotypic microenvironments; however, such microdevices are often fabricated from polydimethylsiloxane (PDMS), which has high affinity for small hydrophobic molecules. When potential toxicants are tested in such devices, hydrophobic chemicals may partition into PDMS surfaces and reduce the dose that reaches the cultured cells, severely impacting dose-response curves. We investigated binding to PDMS surfaces for nineteen chemicals of interest in environmental toxicology – many of those have a range of uses from pesticides to pharmaceuticals and are linked to endocrine disruption or reproductive toxicity. For those chemicals that did bind PDMS, we fully characterized the chemicals' toxicokinetics to quantify chemical bioavailability in PDM-based microdevices to predict actual cellular exposures. Two representative test chemicals, propiconazole and molinate, which are known reproductive toxicants, were used to study the reproductive toxicity in fetal-membrane-on-chip microdevice. We experimentally observed that up to 90 ± 2% of propiconazole and 50 ± 10% of molinate bound to a PDMS test specimen with 1/e time-constants of 9.7 ± 1 and 13.6 ± 2 hr, respectively. The binding of molinate, but not propiconazole, was reversible, with 12 ± 2% able to leach back out in fresh aqueous solvent (time constant of 6.1 ± 1 hr). From these experiments, we extracted kinetic binding parameters to model the impact of PDMS-toxicant interaction on in-device cellular exposure under realistic flow conditions and device geometry. For an irreversible binder like propiconazole, a simulated acute dose of 10 μM for 4 hr yields an in-device cellular exposure of just ~1 μM, an order of magnitude less than the nominal dose. For a reversible binder like molinate, delivery of an acute dose of 2700 μM for 4 hr yields not only a reduced acute dose, but tails of extended low-dose exposure of up to 53 μM that lasted for tens of hours after the nominal dose. For such chemicals, where a significant proportion is lost into PDMS surfaces within a microdevice, this sequestering may yield false negatives in toxicant screens and could lead to incorrect conclusions from nominal-dose-response curves. Our toxicokinetic model demonstrates how to model such impact of PDMS-chemical interactions to predict chemical bioavailability and to estimate actual in-device cellular exposures in organ-on-chip microdevices.

1364 High-Content and -Throughput 3D Mouse Embryonic Stem Cell Spheroid Cultures for Characterizing the Developmental Toxicity Potency of Chemicals

Z. Chen[1], L. Kamelia[2], Y. Liu[1], O. Sirenko[3], and I. Rusyn[1]. *[1]Texas A&M University, College Station, TX; [2]Wageningen University, Wageningen, Netherlands; and [3]Molecular Devices LLC, San Jose, CA.*

Prenatal developmental toxicity (PDT) testing is both animal- and resources-intensive. The mouse embryonic stem cell test (mEST) is widely used as one *in vitro* alternative to test for the potential developmental effects of chemicals and drug candidates. The traditional mEST model uses a "hanging drop" culture of embryonic stem (ES) cells that differentiate into beating cardiomyocytes in 3D embryoid bodies (EBs). This test evaluates chemical's potential to inhibit cell differentiation by manual quantification and microscopic analysis, a tedious procedure that is limiting broader application of this test due to low throughput and limited number of endpoints. The goal of the present study was to develop a higher throughput method based on high-content confocal imaging to characterize phenotypic changes of EB in response to test compounds. To achieve this goal, we focused on improving the workflow and throughput, as well as expanding the range of the phenotypes. First, we improved the workflow by generating functional EB in a bioprinting system by using magnetic nanoparticles and 384-well magnetic plate. Second, we evaluated additional phenotypes with a one-step staining procedure followed by rapid high-content confocal imaging and streamlined image processing algorithm that enables efficient comparison of different EB phenotypes. Finally, effects on the beating of functional EB are also recorded. The new high-throughput mEST method was tested with a number of compounds that have known embryonic toxicity. In addition, we screened a library of diverse environmental chemicals. Results showed that the performance of the optimized high-throughput mEST is comparable to the standard mEST and to *in vivo* embryotoxicity potency. In addition, different responses to tested compounds from 2D and 3D culture, as well as 3D cultures from different testing models (bioprinting plate and u-bottom low adhesion plate) were compared. In conclusion, the method developed in this study enables rapid multi-parameter evaluation of cytotoxicity in both 2D and 3D mEST systems and may be used as a screen for potential developmental toxicity of a wide range of compounds and mixtures. *This research was funded by P42 ES027704.*

1365 An *In Vitro* Physiologically Based Kinetic (PBK) Modeling-Based Testing Strategy to Predict Human Cardiotoxicity of Methadone

M. Shi[1], M. Strikwold[2], I. M. Rietjens[1], and H. Bouwmeester[1]. *[1]Wageningen University and Research, Wageningen, Netherlands; and [2]Van Hall Larenstein University of Applied Sciences, Leeuwarden, Netherlands.*

Within the framework of developing novel alternative testing strategies to predict human toxicity, the aim of the present study was to investigate whether the cardiotoxicity in humans could be predicted by combining *in vitro* toxicity assays with PBK modelling-based reverse dosimetry. Methadone was used as a model compound because several human studies report cardiotoxic effects in clinical settings. The PBK model was developed based on metabolic parameters obtained from *in vitro* incubations with pooled human liver microsomes and parameters derived from *in silico* simulations and the literature. The *in vitro* methadone concentration-response curve based on prolongation of field potential duration was obtained by using a multi-electrode array (MEA) assay with human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CM). Using PBK modelling-based reverse dosimetry the *in vitro* concentration-response curve was converted to an *in vivo* dose-response curve representing effects of methadone on prolonged QT interval and related cardiotoxicity in humans, taking differences in protein binding in the *in vitro* and *in vivo* situation into account. Results show that cardiotoxicity predicted with the *in vitro* PBK approach was comparable to methadone toxicity data derived from published clinical studies with less than a 3-fold difference. Results also reveal that protein binding in plasma is an important factor in the sensitivity of different individuals for the adverse cardiac effects of methadone. Therefore the individual variation in plasma binding might provide an important factor in a personalized prediction of undesirable side effects of methadone treatment in the clinic. The results provide a proof of principle for an alternative testing strategy to predict *in vivo* electrophysiological cardiotoxicity for humans using the *in vitro* hiPSC-CM MEA assay integrated with PBK modelling-based reverse dosimetry. Given that cardiotoxicity is a leading cause of drug failure during drug development, the presented approach to predict *in vivo* cardiotoxicity in humans, might be a valuable addition to preclinical drug development testing strategies to detect cardiac safety liabilities.

1366 Assessment of Rat and Human Gut Microbial Metabolic Impact on the Isoflavone Daidzein and Its Metabolite *S*-equol Using Physiologically Based Kinetic Modeling

Q. Wang[1], B. Spenkelink[1], R. Boonpawa[2], I. M. Rietjens[1], and K. Beekmann[3]. *[1]Wageningen University and Research, Wageningen, Netherlands; [2]Kasetsart University Chalermphrakiat, Sakon Nakhon, Thailand; and [3]Wageningen Food Safety Research, Wageningen, Netherlands.*

The human body provides a habitat for vast microbial communities, the majority of which reside in the gastrointestinal tract, especially the distal gut. The gut microbiota plays a significant role in the health of the host due to a wide range of biochemical and metabolic activities that can affect the toxicity and bioavailability of xenobiotics. Current *in vitro-in silico* based testing strategies used for quantitative *in vitro* to *in vivo* extrapolation (QIVIVE), however, do not include the gut microbiome. To assess the impact of gut microbial metabolism of daidzein for rat and human, an *in vitro* method was developed to quantify the kinetics of gut microbial metabolism in order to define a physiologically based kinetic (PBK) model that included the gut microbiota. The isoflavone daidzein was used as model compound, which is known to be converted by gut microbiota to dihydrodaidzein (DHD) as an intermediate metabolite and further to *O*-desmethylangolensin (*O*-DMA) and *S*-equol. Anaerobic *in vitro* incubations of rat and human* fecal samples were optimized to allow definition of the maximum velocity (V_{max}) and Michaelis-Menten constant (K_m) of microbial metabolism of daidzein. To this end, fecal concentration and incubation time were selected from their respective linear ranges before testing a range of substrate concentrations. Apparent V_{max} and K_m for daidzein depletion and formation of the metabolites DHD, *O*-DMA and *S*-equol were quantified. Results showed that the gut metabolic catalytic efficiency for conversion of daidzein, expressed per kg bw, was more than 200-times higher in rat than human. Derived kinetics were used as input parameters for the PBK model, to predict both daidzein and *S*-equol plasma concentrations in rat and human. Predicted plasma concentrations of daidzein and *S*-equol were comparable to reported plasma concentrations in *in vivo* studies reported in literature. The described *in vitro-in silico* strategy allows prediction of *in vivo* consequences of intestinal microbial metabolism of xenobiotics, thereby contributing to 3Rs (Replacement, Reduction and Refinement) principles and 21st century toxicity testing strategies. **Approval has been obtained from The Medical Ethical Reviewing Committee of Wageningen University, the METC-WU.*

The METC-WU has reviewed the above-mentioned research file and believes this research does not fall within the remit of the Dutch 'Medical Research Involving Human Subjects Act'.

1367 Use of Human Polarized Intestinal Epithelial Monolayers for *In Vitro* Protein Hazard Characterization

J. M. Roper[1], A. D. Eaton[2], R. F. Snow[2], C. S. Zimmermann[3], B. F. Delaney[4], and B. P. Hurley[2]. *[1]Corteva Agriscience, Newark, DE; [2]Massachusetts General Hospital and Harvard Medical School, Boston, MA; [3]Corteva Agriscience, Johnston, IA; and [4]Firmenich SA, Plainsboro, NJ.*

Previous work has demonstrated the utility of using human-derived intestinal epithelial cell (IEC) lines cultured as polarized monolayers on permeable Transwell® filters to differentiate between hazardous and non-hazardous proteins. The purpose of the current study was to explore exposure to various amounts of test proteins to determine effective concentrations that best resolve hazardous from non-hazardous proteins. The effects on IECs of several known hazardous (*C. perfringens* epsilon toxin, Listeriolysin O, *Phaseolus vulgaris* erythroagglutinin, *E. coli* Shiga toxin 1, *C. difficile* Toxin B and wheat germ agglutinin) and non-hazardous proteins (Ara-h2, β-lactoglobulin, fibronectin and RuBisco) were evaluated at different concentration ranges. Monolayer integrity effects (measured by TEER and flux of FITC-inulin or HRP) and cell viability (measured by MTT reduction and LDH release) were evaluated after 48-hour exposure of IECs to each dose of protein. Known hazardous proteins were largely identified as hazardous and could be effectively distinguished from non-hazardous proteins. Concentration range selection emerged as an important factor to consider when optimizing the ability to distinguish hazardous from non-hazardous proteins. This experimental platform may be expanded to serve as a component in the assessment of the safety of proteins expressed in agricultural biotechnology crops that are genetically modified (GM) to impart traits such as insect resistance or herbicide tolerance. Such proteins that have a history of safe consumption based on multiple *in vivo* high-dose acute oral toxicity, 28-day repeated dose, whole food/feed and animal performance studies, would be useful to evaluate in further assessing the utility of the cultured human IEC line monolayers as a component of the safety assessment for future proteins to be expressed in GM crops.

1368 Evaluating Mechanism of Aflatoxin B_1 and Fumonisin B_1 Interaction in *Caenorhabditis elegans*

K. Xue, L. Tang, and J. Wang. *University of Georgia, Athens, GA.*

Contamination of mycotoxins is a world-wide food safety problem, and exposure or co-exposure to mycotoxins and their adverse effects has been a public health concern for decades. Two of the toxicologically significant mycotoxins, aflatoxin B_1 (AFB_1) and fumonisin B_1 (FB_1), were drawn specific attentions because their co-exposure induced considerably stronger toxic and carcinogenic effect than when exposed to either of the toxins alone in various animal models. However, the specific mechanisms pertaining to the co-exposure remain to be elucidated. Individually, AFB_1 is classified as Group 1 human carcinogen, and is found to be associated with increased risk to hepatocellular carcinoma and childhood stunting, while FB_1 is classified as Group 2B carcinogen, and is shown to be associated with esophageal cancer in various developing nations. In this study, the model organism, *Caenorhabditis elegans*, were treated with various concentrations of AFB_1, FB_1, and mixtures of both to evaluate various toxicological endpoints. Additionally, total RNA was extracted from worms treated with EC10 levels of the mycotoxins to assess alterations of lncRNA involved in toxic mechanisms. Using combination index method, we found that there is a greater-than-additive interaction between AFB_1 and FB_1 toxicity for all three tested toxicological endpoints, namely, growth, brood size, and lifespan. While FB_1 does not cause visible DNA damage, treatment with mixture of AFB_1 and FB_1 induces significantly greater amount of DNA lesion than treatment to the same concentration of AFB_1 alone. When comparing the lncRNA of AFB_1-FB_1 mixture to AFB_1-only exposures, the most differentially expressed lncRNAs are related to the genes *casy-1* (up-regulated) and *par-1* (down-regulated). The most differentially expressed antisense lncRNA are related to the mRNAs of *casy-1* (up-regulated) and *cpna-2* (up- and down-regulated). A few significant KEGG pathways affected by the additional FB_1 treatment include up regulation of cytochrome P450-related genes and down-regulation of alanine, aspartate, and glutamate metabolism. It may be plausible that FB_1 potentiates the toxicity of AFB_1 by potentiating the phase I metabolism involved in activating AFB_1 toxicity, while potentially down-regulating phase II and other detoxification pathways.

1369 Co-exposure of Bisphenol A and High Sucrose Diet Aggravates Diabetes-Mediated Renal Tubule Dysfunction Phenotypes in *Drosophila melanogaster*

L. Rani. *CSIR-Indian Institute of Toxicology Research, Lucknow, India.*
Sponsor: H. Gupta

The prevalence of diabetes has become a global epidemic that is magnifying the incidence of diabetic nephropathy cases. However, the traditional factors such as obesity, sedentary lifestyle, family history and excess carbohydrate are well recognized, but other risk factors such as environmental chemicals are poorly studied. Bisphenol A (BPA) is an environmental chemical that is used as a base compound to synthesize the epoxy resins and polycarbonate plastics. Humans are continuously exposed to BPA and in consequence, BPA has reported to be associated with the diabetes and reduced kidney function. However, limited experimental studies are reported on the role of BPA in diabetes mediated kidney dysfunction. Here, we have used Malpighian tubules (MTs) of *Drosophila* that share developmental and functional similarities with the mammalian renal tubule. The potential of BPA (0.1 and 1.0 mM) alone and co-exposure of BPA and high sucrose diet (HSD) (1.0 M sucrose) was investigated to induce diabetes and MTs dysfunction. Twenty days exposure of BPA (1.0 mM) alone to newly emerged flies resulted in imbalance of glucose homeostasis and perturbations in the insulin signaling, while co-exposure of BPA and HSD further elevated glucose level and perturbs insulin signaling in the exposed organism. Efflux activity and fluid secretion rate (functional assay) of MTs were found to be significantly declined in exposed organism at 1.0 mM BPA alone, while BPA + HSD treatment resulted in further decline in the above endpoints. Uric acid level was also found to be elevated in the BPA (1.0 mM) alone treatment of *Drosophila*. The effect was more drastic in BPA + HSD treatment condition. The study, therefore, suggests that co-exposure of BPA and high dietary intake of sucrose aggravates renal tubule dysfunction in exposed *Drosophila*.

1370 A Three-Dimensional Microfluidic Platform for Modeling Human Extravillous Trophoblast Invasion and Toxicological Testing

Y. Pu, and A. Veiga-Lopez. *Michigan State University, East Lansing, MI.*

Placental trophoblast cells invasion into the maternal uterus is an essential and complex event in the formation of the maternal-fetal interface. However, due to the complexity of the placental microenvironment, the development of the ideal *in vitro* trophoblast invasion model remains a challenge. We aimed to develop a microfluidic 3-dimensional (3D) model that recreates the invasion placental microenvironment. We used a 3D silicone polymer polydimethylsiloxane (PDMS) microfluidic chip, composed of a circular central compartment surrounded by two arched channels separated by a 50 µm barrier with 3 µm gap interspaced PDMS pillars. The 3D chip was coated with extracellular matrix (ECM), and seeded with human umbilical vein endothelial cells (HUVECs) and mCherry tagged first-trimester human placenta cells (HTR8/SVneo) in the central compartment and channels, respectively. We optimized the ECM pre-coating (gelatin *vs*. Matrigel *vs*. fibronectin), cell seeding density (10 - 30 million cells/ml) and culture medium flow speed (0.01, 0.05 and 0.1 µl/min). After optimization (fibronectin, 30 million cells/ml, 0.01 µl/min flow speed), we tested 1) the filtering ability of the endothelial-trophoblast barrier using a permeability assay and 2) HTR8/SVneo invasiveness using a chemoattractant (folic acid, FA) and invasion suppressor (tunicamycin, TUN). The permeability assay showed that the diffusion of FITC-Dextran is prevented between compartments when cells were at confluency. FA stimulated invasion of HTR8/SVneo cells into the fibronectin/endothelial layer, which was counteracted by TUN. Using the combination of this new 3D platform and fluorescent-tagged cells, we were able to harvest and sort by flow cytometry invading cells to further characterize specific gene expression patterns of invasion. This novel 3D microfluidic chip reproduces key elements of the human placenta barrier: a two-cell interface with a space barrier, a supporting ECM layer, and constant medium flow resembling *in vivo* shear stress. Using this platform, we were able to perform real-time monitoring, imaging, quantification, and harvest of invasive cells for detailed transcriptomic analyses. This new platform represents an advantage over 2D culture systems as it better resembles the placental microenvironment and may prove important for future toxicological screening testing in a complex organ such as the placenta. *Funded by SOT Alternative Research Grant and NIEHS R01ES027863 to A.V-L.*

1371 Cellular and Molecular Characterization of Brain Glucose Metabolic Changes in *Nauphoeta cinerea* Using Streptozotocin Treatment

O. C. Olagoke[1], B. A. Afolabi[1,2,3], and J. B. Rocha[1]. [1]*Universidade Federal de Santa Maria, Santa Maria, Brazil;* [2]*Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; and* [3]*Bowen University, Osun, Nigeria.*

The brain depends on a regulated supply of glucose, and conditions that impair glucose availability to it severely impacts on its function. Insects, like vertebrates, depend on glucose as the main source of energy for the brain. However, little is known about how disruptions of glucose utilization by the brain and fat body modifies general metabolic activities in these important organs of cockroaches. We developed a novel model of streptozotocin-induced hyperglycemia in *Nauphoeta cinerea* and found raised glucose concentration and relative mRNA expression of glucose transporter 1, as well as, markers of oxidative stress in head tissues. Fat body glycogen and insect survival, as well as, acetylcholinesterase activity, triglyceride content and viable cells in head homogenate were reduced. The decrease in glycogen, triglycerides and MTT reduction may indicate a disruption in glucose utilization by the head and fat body of insects after toxic treatment with streptozotocin. The insects were able to increase their glutathione s-transferase activity and total thiol levels, possibly via activation of nuclear factor erythroid 2 related factor, to attain a balance between the generation of reactive oxygen species and antioxidants. Other researchers have shown that the haploinsufficiency of glucose transporter 1 is linked with neurodegenerative conditions like Alzheimer's disease, our data present *Nauphoeta cinerea* as a viable model for studying the cellular responses to brain and fat body glucose alterations, and we phylogenetically demonstrated conservation between *N. cinerea* glucose transporter 1 and those of other Insects.

1372 Hepatocyte Spheroid Models and High-Throughput Transcriptomics as New Approach Methodologies in Predictive Toxicology Screening

S. C. Ramaiahgari, S. S. Auerbach, T. O. Saddler, K. S. Lavrich, M. J. DeVito, P. R. Bushel, B. A. Merrick, R. S. Paules, and S. S. Ferguson. *NIEHS/NTP, Durham, NC.*

Three-dimensional (3D) spheroid models with improved tissue-like functionality may offer better *in vitro* safety assessment of chemicals. Combining these models with emerging low-cost, high-throughput transcriptomics would enable systematic characterization of chemical induced effects on biological systems. We have developed spheroid liver models of human progenitor cell line, HepaRG, and primary rat hepatocytes in 384-well formats. HepaRG and rat spheroids exhibit several hallmarks of polarized hepatocytes and tissue-like functionality. Activities of xenobiotic metabolism enzymes, CYP1A2, CYP2B6 and CYP3A4 were 2 to 20-fold higher in HepaRG spheroids compared to the sandwich-cultured primary human hepatocytes. Similarly, specific activities of CYP1A2 and CYP3A enzymes in rat hepatocyte spheroids remained at the same levels as freshly isolated hepatocytes even after 14-days in culture, displaying longevity in drug metabolism activity. High-throughput gene expression analysis using the S1500+ gene set was performed on HepaRG spheroids treated with ten concentrations of a reference set chemicals for 96-hours in repeated exposure regimens. Baseline gene expression and biological pathway responses showed significantly higher enrichment scores in spheroids compared to monolayer cultures. Exposure to aflatoxin B1 and benzo(a)pyrene showed activation of genes and pathways related to their metabolism and anticipated downstream signaling events such as cell cycle, p53 signaling, DNA damage and cancer. BMDExpress was used to calculate point of departure for individual genes and pathways associated with concentration-related molecular perturbations. Activation of nuclear receptor pathways (CAR/RXR and PXR/RXR) was evident with lower concentration of phenobarbital and rifampicin preceding onset of stress-related pathways at higher concentrations. Similarly, biologically relevant pathways associated with exposure of chlorpromazine and valproic acid were activated at sub-lethal concentrations. Differences in gene and pathway-level expression between liver injury chemicals (trovafloxacin, troglitazone and tolcapone) and their structurally similar analogs was observed. The initiation of molecular events associated with chemical exposure and progression of events that lead to adverse outcome effects were clearly evident with high-throughput transcriptomics visualized on ten-point concentration-response analysis. *In vitro* models utilizing spheroids and data-rich approaches may offer better resolution in identifying molecular level perturbations of biological systems and prediction of hazardous substances

1373 Scaffold-Free 3D *In Vitro* Model of Ovarian Toxicity Exhibits Physiologically Relevant Hormone Response

B. C. Ip, and J. R. Morgan. *Brown University, Providence, RI.* Sponsor: K. Boekelheide

Ovarian granulosa cells are the functional unit of the ovary with steroidogenic activities and play a pivotal role in regulating reproductive health of females. Humans are consistently exposed to thousands of environmental chemicals that have been detected in female follicular fluid. Many of these chemicals have never been tested and can have direct disruption on granulosa cell function, thus result in toxic effects in reproductive health. Therefore, there is an urgent need to develop effective platforms that can efficiently screen a vast number of chemicals for their potential health impact. The present study aim to develop a high throughout platform to screen for chemicals that may impact the steroidogenic activities of human granulosa cells. Three-dimensional human granulosa spheroids were generated by seeding human ovarian granulosa-like tumor KGN cell line into the Microtissue Inc agarose platform. KGN cells self-assembled into scaffold-free spheroids inside the agarose molds within 24 hours of cell seeding, and expressed the steroidogenic CYP19 aromatase enzyme. We demonstrated that in the presence of testosterone, KGN spheroids have significantly greater estradiol and progesterone production than KGN cells cultured in two-dimension (2D), with an estradiol production rate that is comparable to primary human granulosa cells culture in 2D as previously reported. Hormone production by KGN spheroids also had a dose-response increase in the presence of follicle stimulating hormone (FSH) and dibutyryl-cAMP, both of which stimulates the steroidogenic function of CYP19. Overall, these functional KGN spheroids are highly promising for predictive *in vitro* toxicity testing, and we envision using them to screen chemicals in follicular fluid including polychlorinated biphenyls and per- and polyfluoroalkyl substances.

1374 A Systematic Variation of Experimental Conditions to Help Harmonize Zebrafish Early Life Stage Bioactivity Screening

L. B. Wilson, L. Truong, and R. L. Tanguay. *Oregon State University, Corvallis, OR.*

Zebrafish are used extensively to discover novel pharmaceuticals, investigate mechanisms of chemical action and for human disease model research. Although the zebrafish model is gaining acceptance for 21st century toxicology research, there is a lack of harmonized experimental approaches for its use in developmental toxicity screening, limiting full model adoption. A few identified sources of variability include: the presence/absence of the chorion (an acellular membrane that could pose a barrier to chemicals), the photoperiod, and the precise dosing regimen (daily renewal v. static exposure). To address these variables, a systematic approach was taken to alter each experimental condition for nine chemicals and a single nanomaterial. These materials were intentionally selected to represent a range of physiochemical properties including photo-lability and log K_{OW}. Utilizing the Tanguay lab early life stage exposure paradigm, the ten compounds were assessed for bioactivity across three exposure conditions: dechorionated v. chorion on, dark exposure v. light/dark cycle exposure, and static exposure v. daily solution renewals. Embryos were exposed at 6-8 hours post-fertilization (hpf) and screened for 22 morphological and two behavioral endpoints at 120 hpf. The bioactivity profiles for each chemical were compared across all conditions by calculating concentrations which produced a 50% response (EC_{50}). Results show chorion status affects the bioactivity of four of the compounds tested and exposure regimen affects bioactivity for six of the compounds tested. The results of this study will provide information necessary to help investigators tailor zebrafish assay conditions to better match the physiochemical properties of test agents. This should increase data reproducibility, confidence, and acceptance, moving the field one step closer to utilizing the powerful zebrafish screening platform to broadly predict chemical bioactivity.

1375 High-Throughput Assessment of Compound-Induced Proarrhythmic Effects in Human iPSC-Derived Cardiomyocytes

O. Sirenko[1], C. Crittenden[1], P. Lertkiatmongkol[2], A. Guan[2], N. Servant[2], S. Vargas-Hurlston[1], and H. Wei[2]. [1]*Molecular Devices, San Jose, CA; and* [2]*Eurofins, San Diego, CA.* Sponsor: Y. Zhao

Drug-induced QT interval prolongation and Torsades de Pointes (TdP) arrhythmias are the leading causes for drug withdrawals from market and compound attrition during drug development. To assess clinical potential

drug-induced TdP, the Comprehensive *in vitro* Proarrhythmia Assay (CiPA) is a new cardiac safety testing paradigm that includes *in vitro* assays using human induced pluripotent stem cell derived cardiomyocytes (hiPSC-CM). In order to adopt this paradigm, we developed a high-throughput hiPSC-CM assay using calcium-sensitive dyes that exhibit fast kinetic fluorescence detected by high-speed fluorescence imaging platform. We evaluated concentration-dependent responses of 28 pharmacological agents linked to low, intermediate, and high TdP risk categories. Compound-induced proarrhythmic effects such as changes in beating rate and durations of these 28 agents were quantified and reported by monitoring changes in intracellular Ca2+ oscillations. Characterization of calcium oscillations allows us to evaluate complex waveforms and events. In addition to beat rates and duration, we observed compound-induced proarrhythmic effects or peak prolongations at concentrations correlated to clinically-relevant concentrations of QT prolongation and TdP arrhythmias. We also characterized waveform irregularities and more than 20 other dose-dependent read-outs. Moreover, we assessed cellular and mitochondrial toxicity of these 28 compounds in the follow-up assay using high-content imaging to simultaneously monitor acute & chronic dosing effects of structural cardiotoxicity with multiple toxicity indicators. Taken together, we demonstrate that our high-throughput assay can provide an *in vitro* drug-induced proarrhythmia assessment as a part of the cardiac safety paradigm encouraged by CiPA initiative and strengthens pharmacological safety profiles of drug candidates.

PS 1376 The Cross-Laboratory Testing and Evaluation of a Cardiac Microphysiological System

C. Sakolish[1], B. Charrez[2], N. Huebsch[2], K. Healy[2], and I. Rusyn[1]. *[1]Texas A&M University, College Station, TX; and [2]University of California Berkeley, Berkeley, CA.*

Cardiotoxicity, and a poor understanding of human pharmacokinetics have long been cited as major reasons for safety-based pharmaceutical withdrawals. This is in part due to the limitations of existing animal and *in vitro* models to adequately represent human biology. To address these limitations, microphysiological system (MPS) models of cardiac tissue are being actively developed; however, the adoption of these and other MPS has been slow due to lack of wide-spread use of these devices outside of the developer laboratories. Here, we conducted a cross-laboratory evaluation of a 3D, human, ventricular MPS which had previously demonstrated cell alignment, realistic mass transport properties, and IC_{50} and EC_{50} values more consistent with human responses than traditional cellular-scale studies. First, the cardiac model was transferred from the University of California Berkeley to Texas A&M University and tested to ensure cell alignment, as well as determine baseline beating parameters (beat rate, time interval, and contraction and relaxation velocities). Next, a dose escalation treatment with cisapride, verapamil, and isoproterenol (1nM - 10uM, 15-minute exposures) was applied to monitor changes these cell responses. Finally, the cardiac model was challenged with sorafenib, carbamazepine, or atenolol over a period of 1 week at a constant exposure (0.01-100uM) to determine sub-acute effects on the tissues within the chips. These studies were carried out in parallel with standard 2D well-based cultures as a comparator to determine the differences in sensitivity for a variety of beating parameters. Additionally, multiple cardiomyocyte cell sources (in-house differentiation vs. commercial) were evaluated in the cardiac MPS, as lot-to-lot variability is often a major challenge for any *in vitro* model. Here, we highlight differences in culturing methods (2D vs. 3D), cell sourcing, and data collection methods (phase contrast image analysis vs calcium-flux) in deriving human relevant point of departures. We also show that effects on beating parameters can be observed and quantified, and IC50 values determined. Results indicate that cells cultured in 3D exhibit higher sensitivity to drug-induced effects, at times deviating from baseline values at concentrations 10-1000X lower than 2D counterparts. Additionally, parameters like beat velocity (contraction and relaxation) are more difficult to quantify in an adherent 2D monolayer due to cell adhesion on the surface of the plate, but could serve as a useful metric in 3D culture. This model could potentially be used as a tool to estimate efficacy and dosing of drug candidates prior to clinical studies. *This research was funded by grants from NIH (U24 TR001950 and U24 TR002633).*

PS 1377 Evaluation of AAV Transduction Efficiency among Novel Human and Monkey *In Vitro* Liver Models

J. Finley, J. Harney, A. Kopec, J. Qian, S. Kumpf, A. Vargas, L. Newman, E. Oziolor, L. Whiteley, and A. Burdick. *Pfizer Inc., Groton, CT.*

The emerging field of Gene Therapy (GTx) relies heavily on the use of adeno-associated viruses (AAV) as a delivery vehicle for transgenes. Recent non-clinical toxicology studies with high-doses of AAV have demonstrated acute, severe hepatoxicity and systemic inflammation in non-human primates (NHP). To better understand the mechanisms and potential risk for AAV-induced liver toxicity in human clinical trials, we evaluated novel *in vitro* culture systems which more closely resemble *in vivo* liver. Sandwich culture hepatocytes (SCH) are widely used in the pharmaceutical industry to study drug metabolism but suffer from poor AAV transduction efficiency, mostly attributed to lack of liver architecture and cell type heterogeneity. In this work, we compared AAV transduction of SCH with three dimensional (3D) spheroid liver microtissues (LiMT) and microfluidic-enabled liver-chips comprised of either human or cynomolgus monkey-derived cells. SCH were seeded on collagen-coated dishes and overlaid with Matrigel according to standard practices. The LiMT were prepared with primary human or monkey hepatocytes and human non-parenchymal cells (InSphero). Liver chips were seeded with primary human or monkey hepatocytes and liver sinusoidal endothelial cells (Emulate Bio). Cell viability was assessed across all models by LDH or ATP assays and demonstrated AAV to be essentially non-cytotoxic at viral concentrations up to $1x10^6$ MOI gc/cell and $3x10^{10}$ gc/mL under static and flow conditions, respectively. AAV transduction efficiency was assessed by quantifying eGFP transgene expression through high content imaging, ddPCR, immunohistochemistry and confocal microscopy. Infection of LiMT with AAV at time of aggregation, as opposed to post-aggregation, led to higher transduction and deeper penetration of virus into the spheroid. Preliminary analysis suggests that liver chips exhibited higher eGFP mRNA expression compared with SCH. Full transcriptome RNA-seq was conducted to compare each *in vitro* model to normal liver. These evaluations are expected to identify an AAV-transducible and physiologically relevant *in vitro* model that will enable further mechanistic research to understand the relevance of high-dose AAV toxicity in NHP as it pertains to human safety risk in GTx programs utilizing AAV.

PS 1378 Drug-Induced Seizure Liability Mechanism of Action Analysis by Sequential Principal Component Analysis and Clustering Using Multiple Metric Parameters from Microelectrode Arrays Data of Primary Rodent Neurons

N. Miyamoto[1], A. Ojima[1,2], S. Minagawa[1,2], I. Suzuki[3], and T. Yoshinaga[1]. *[1]Eisai Co. Ltd., Tsukuba, Japan; [2]TechnoPro Inc., Tsuchiura, Japan; and [3]Tohoku Institute of Technology, Miyagi, Japan.* Sponsor: A. Suganuma

Detection of drug-induced seizure liability is challenging. Dissociated cultured neurons and micro-electrode array (MEA) system is a potential non-clinical *in vitro* seizure liability screening model. The effects of known compounds with defined seizure liability profiles on neuronal activity on the MEA, with the goal to identify activity signatures that associate with specific liability profiles that could be used to screen unknown compounds for seizure liability. Primary cortical neurons were prepared from fetal Wistar rats, 18 days post-coitum, and then seeded on 48-well Classic MEA plates for extracellular recording using Maestro-1. Sixteen seizure positive compounds (4-aminopyrdine, amoxapine, amoxicillin, bupropion, chlorpromazine, diphenhydramine, enoxacin, linopyrdine, pentylenetetrazole, phenytoin, picrotoxin, pilocarpine, strychnine, theophylline, tiagabine and tramadol) and seizure negative acetaminophen were added to the cells (n = 6) at 5 concentrations for each compound to see phenotypic changes on spontaneous electrical activity in neural networks, after 19 days of culture. Mechanism of action (MOA) analysis was carried out by principal component analysis (PCA) and clustering sequence using 73 multiple metric parameters, which are calculated by AxIS Metric Plotting Tool. The clustering well classified inhibitory neuron suppression type compounds (penthylenetetrazole, picrotoxin and strychinine) and the other seizure positive- and negative compounds. However, enoxacin alone was classified in the seizure negative cluster, combination treatment of nonsteroidal anti-inflammatory drugs, and NSAIDs (felbinac, flubiprofen or ketprofen) induced seizurogenic phenotype of enoxacin. The clustering result showed combination of enoxacin and NSAIDs were located in the inhibitory neuron suppression compound's cluster as reported seizurogenic MOA of new quinolone antibiotics and NSAID combination previously. We have a plan to do structure-seizure liability relationship MEA analysis of new quinolones in the next step. MEA technology has the potential to predict the seizure liability of drugs and drug candidates with MOA by PCA and clustering using multiple metric parameters.

1379 A Novel Co-culture Model of Prostate Epithelial and Stromal Cells

H. Li[1], S. Madnick[1], A. Simmons[1], S. Hall[1], M. Dent[2], and K. Boekelheide[1].
[1]Brown University, Providence, RI; and [2]Unilever, Bedfordshire, United Kingdom.

The 3-dimensional (3D) *in vitro* models have the potential to improve the physiological relevance, and the development of a normal prostate model in 3D can greatly advance the risk assessment of endocrine disruptors. The goal of this project is to develop an *in vitro* prostate model for high-throughput exposure-led safety assessment to enable robust safety decision making for endocrine disruptors. The development and normal function of the prostate is highly dependent on the interaction between stromal and epithelial cells; therefore, in this study, we established a co-culture model composed of the red fluorescent protein (RFP)-labeled benign human prostate epithelial (BHPrE) cells and green fluorescent protein (GFP)-labeled benign human prostate stromal (BHPrS) cells grown in scaffold-free hydrogels. The optimal 3D co-culture condition was defined for cell seeding density, epithelial to stromal ratio and cell culture medium composition. In the current model, epithelial differentiation was observed in both fluorescent images and hematoxylin and eosin (H&E) stained microtissue sections. Cytokeratin 5/6 (CK5/6) and Cytokeratin 18 (CK18) immunohistochemical staining further revealed the heterogeneity of the epithelial population. Image analysis pipelines for morphological feature identification were developed in the software of Harmony and CellProfiler. 3D image analysis-based cell counting and cellular volume analysis suggested no significant epithelial or stromal cell proliferation or cell death within 7 days. Among the hundreds of morphological features output from the pipeline analyses, we have identified a cluster of morphological features of the epithelial compartment, including sphericity, ellipticity, maximum thickness, and maximum cross-section area to combine into a composite description of response to androgen and anti-androgen treatment for screening. In summary, this BHPrE and BHPrS co-culture prostate model shows reproducible morphological features of differentiated prostate epithelium, which is responsive to androgen and anti-androgen treatment, allowing this co-culture prostate model to serve as an endocrine disruption chemical screening platform.

1380 Developmental Toxicity Induced by Heavy Fuel Oil Extracts Is Mediated by Their 3- to 7-Ring PAHs with a Role for the Aryl Hydrocarbon Receptor (AhR) Activation

L. Kamelia[1], L. de Haan[1], H. Ketelslegers[2], I. Rietjens[1], and P. Boogaard[1,3].
[1]Wageningen University and Research, Wageningen, Netherlands; [2]European Petroleum Refiners Association, Brussels, Belgium; and [3]Shell International B.V., The Hague, Netherlands.

Heavy fuel oils (HFO) are heavy petroleum substances (PS) that may contain high amounts of 3- to 7-ring polycyclic aromatic hydrocarbons (PAHs) and are known to be able to induce developmental toxicity in animal experiments. In contrast, highly refined base oil (HRBO) consisting primarily of saturated hydrocarbons tested negative for developmental toxicity. In an attempt to develop and apply alternative testing strategies for assessing the developmental toxicity of highly complex PS, the present study uses the ES-D3 cell differentiation assay of the embryonic stem cell test (EST) to assess the embryotoxicity potency of DMSO-extracts of 8 HFO, possessing different CAS number and a systematic variation in their 3- to 7-ring PAH content, and 1 HRBO, containing no aromatics. In the EST, all DMSO-extracts of HFO induced concentration-dependent inhibition of ES-D3 cell differentiation and this potency was appeared to be proportional to the level of 3-7 ring PAHs they contain. Moreover, all HFO extracts also showed aryl hydrocarbon receptor (AhR)-mediated activities, as tested in the AhR CALUX assay. On the other hand, the HRBO extract tested negative in both assays. To investigate whether activation of the aryl hydrocarbon receptor (AhR) plays a role in the HFO-induced inhibition of ES-D3 cell differentiation, ES-D3 cells were co-incubated with HFO extracts and the AhR antagonist trimethoxyflavone (TMF). Results showed that the HFO-induced inhibition of ES-D3 cell differentiation was counteracted by the addition of TMF, confirming the role of the AhR in mediating the observed effects in the EST. Furthermore, a good correlation (R^2:0.99) between the *in vitro* and the *in vivo* developmental toxicity potencies of the HFO extracts understudy was obtained. In conclusion, our findings corroborate the hypothesis that developmental toxicity induced by some PS, e.g. HFO, is mediated by their 3-7 ring PAHs content and that the observed *in vitro* developmental toxicity is partially AhR mediated.

1381 Zebrafish Early Life Stages as a Preclinical Model to Predict Acute Oral Toxicity

L. B. Brito, G. G. Costa, M. C. Valadares, and G. A. Oliveira. *Universidade Federal de Goiás, Goiânia, Brazil.* Sponsor: D. Oliveira

Zebrafish (*Danio rerio*) early-life stages have emerged as a promising model in preclinical drug screening so as to bridge the current gap between *in vitro* and rodent studies. The purpose of this work was to evaluate the acute toxicity of substances with different GHS categories using zebrafish early-life stage to determine LC_{50} (lethal endpoints) and EC_{50} (sublethal endpoints) values and compared with *in vivo* acute oral toxicity data from literature. Thirteen substances (2-propanol, Acetaminophen, Acetylsalicylic acid, Atropine sulfate, Cadmium II chloride, Dichlorvos, Ethanol, Glycerol, Mercury II chloride, Propranolol, Sodium chloride, Sodium oxalate, Verapamil HCl) were evaluated by Fish Embryo Acute Toxicity (FET) test based on OECD guideline no 236. Groups of 20 embryos were exposed in triplicate to a negative control and five concentrations of different chemicals. The test was performed in climate chambers at 26 ± 1.0°C with a 12:12 h light:dark cycle. Lethal and sublethal effects were evaluated during 96 h of exposure to determine LC_{50} and EC_{50} values. A linear regression-model using the log-transformed of these values was generated for the prediction of LD_{50} from LC_{50} values. This model resulted in the following equation Log (LD_{50}) = 0.4659 x log (LC_{50}) + 1.736 with R^2 of 0.7597. The correlation between CL_{50} and DL_{50} values was confirmed testing LQFM021, a promising anti-inflammatory, analgesic and antinociceptive agent. Considering acute oral systemic toxicity assessment in Swiss female mice was found lethal dose between 300 < LD_{50} < 2000 mg/kg, which classified as Category 4. The DL_{50} predicted with FET test was of 647.58 mg/kg, which also classified as Category 4. LQFM021 showed significant sublethal effects such as delayed of yolk sac ($CE_{50\text{-}96h}$ 77.68 mg/L), equilibrium ($CE_{50\text{-}96h}$ 77.27 mg/L) and edema cardiac ($CE_{50\text{-}96h}$ 71.28 mg/L). These results can be compared to acetylsalicylic acid, atropine sulfate, propranolol and sodium oxalate (category 4), which present the same effects like delayed of yolk sac ($CE_{50\text{-}96h}$ 21.28 - 1445 mg/L) and equilibrium ($CE_{50\text{-}96h}$ 8.8138 - 885.5 mg/L). Our results suggested that zebrafish early-life stages can be used as a preclinical model to predict acute oral toxicity.

1382 Yeast *Saccharomyces cerevisiae* as a Model Organism to Study Environmental Chemical Exposure and AhR Signaling

E. Vazquez-Rivera[1], B. Rojas[1], J. L. Marrero-Valentin[2], A. E. Hoover[1], P. Carney[1], C. Stroetz[1], C. Mesa[1], B. Bocanegra[1], and C. A. Bradfield[1].
[1]University of Wisconsin–Madison, Madison, WI; and [2]Universidad Ana G. Méndez Carolina, Carolina, Puerto Rico.

The aryl hydrocarbon receptor (AhR) is a soluble ligand-activated transcription factor and a member of the Per-Arnt-Sim (PAS) superfamily. As cellular regulator, the AhR plays an important role in the metabolic and physiological adaptation to the external environment. To study the effects of environmental chemical exposure, we developed an AhR biosensor using the yeast, *Saccharomyces cerevisiae* as a model system. A series of optimization studies consisted of: yeast growth phase characterization, defining time of exposure, determining media composition and multi-well plate configurations. Conditions were established that allow reproducible analysis of AhR ligand activity in high throughput. While initially being less sensitive than CALUX. The sensitivity of the yeast system was enhanced by the introduction of the proteins ARA9 and ARA3 to the system. The yeast system is rapid, low cost, and displays pharmacological similarity to mammalian systems.

1383 A Human iPSC-Based *In Vitro* Neuronal Network Formation Assay for Regulatory Developmental Neurotoxicity Testing

K. Bartmann, F. Bendt, L. Stürzl, S. Masjosthusmann, and E. Fritsche.
IUF—Leibniz Research Institute for Environmental Medicine, Duesseldorf, Germany.

The spatiotemporal orchestration of key neurodevelopmental processes (KNDP) is essential for brain development. If at least one KNDP is impaired due to exposure towards a compound during a critical period of neurodevelopment, an adverse outcome is expected. To study developmental neurotoxicity (DNT) hazards, animal-free new approach methods (NAM) have been developed, which model certain KNDP *in vitro* and *in silico*. One of these KNDP is the formation and function of neuronal networks (NNF), the ultimate, functional readout for nervous system function. For studying NNF, the NNF assay based on hiPSC-derived human glutamatergic excitatory and GABAergic inhibitory neurons, as well as primary human astroglia (NeuCyte, USA) was developed.

These pre-differentiated cells were seeded in standardized ratio on 48-well microelectrode array (MEA) plates. We let the cells differentiate for one week until we received first recording as an internal control for a 'positive' (firing) well. After one week of differentiation in absence of test compounds, cell and network activity was measured via the assessment of spike-related (e.g. mean firing rate), burst-related (e.g bursting ratio) and network-related parameters (e.g. network synchronicity) using the Axion Maestro Pro System. These measures served as the baseline for subsequent neurodevelopmental testing. Treatments started on active wells by exposing from day 7 to day 35. With this protocol, the positive compounds BIS-I and Mevastatin were established as endpoint-specific controls for the assay. Both compounds reduced the values of the above described parameters in a time- and concentration-dependent manner. Data from control wells demonstrate low plate-to-plate and well-to-well variability of the assay. Currently, a set of 35 pesticides, that are known to either affect or not affect brain development based on the rodent DNT guideline study (OECD TG426), is tested in the NNF assay. These results are presented. The human NNF assay will be a valuable addition to the current DNT *in vitro* testing battery as neuronal network formation converges on multiple neurodevelopmental KE like neurite outgrowth, dendritic spine formation and synaptogenesis.

1384 Automated Image Analysis of Cell Morphology for High-Throughput Toxicology Assays Using Deep Learning Methods

A. Tandon[1], A. Maharana[1], B. Howard[1], S. Ramaiahgari[2], P. Dunlap[2], J. Rice[2], M. DeVito[2], B. A. Merrick[2], R. Shah[1], R. S. Paules[2], and S. S. Ferguson[2]. *[1]Sciome LLC, Research Triangle Park, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

High throughput toxicology screening assays often employ morphological analysis of pictomicrographs acquired from 96- and 384 multi-well cell culture plates. Thousands of images generated from these assays require time-consuming and tedious manual analysis. Moreover, human interpretation of cell culture morphologies remains semi-subjective with reader-to-reader variation that can be a barrier for regulatory adoption of morphological observations. To automate this process, we have developed deep learning methods to automatically classify cell morphology images acquired with phase-contrast microscopy. We have trained a convolutional neural network (CNN) to perform binary and multi-binning classification. The binary classifier assigned assay images into healthy (comparable to vehicle controls) and altered (not comparable to vehicle-controls) classes with >98% accuracy; the multi-binning classifier assigned assay images into healthy, stressed and altered classes with >93% accuracy that accounts for cell loss. Our dataset comprised 2,156 and 2,254 high-resolution (1392x1036 pixels) images from proliferating and differentiated cultures of HepaRG cells. The dataset was manually annotated into four classes, i.e. Cell Loss, Stress, Abnormal and Normal by expert annotators. In our previous work, CNN showed better accuracy than traditional machine learning methods. In this study, we have focused on testing and fine-tuning various CNN architectures, including ResNet 34, 50 and 101. In addition, we used the watershed algorithm and a combination of image processing approaches to count the number of healthy and dead cells, which indeed correlated with the 4 image classes. To visualize regions in the images classified by CNN model, we employed Class Activation Maps (CAM). This allowed us to better understand the inner workings of the neural network and led to further optimizations of the algorithm. Finally, we are exploring various methods to perform dose-response analysis of the classification scores that may eventually be used to compute benchmark dose concentration upon chemical exposure. Together, these results demonstrate that automated deep-learning based image classification of cell morphology pictomicrographs can yield reproducible and highly accurate classification of changes associated with cellular stress upon chemical exposure.

1385 Systematic Application of New Approach Methods to Uncover the Mode-of-Action of Herbicides and Fungicides with Unanticipated Toxicological Properties: A Joint EU-ToxRisk and Syngenta Case Study

R. Graepel[1], K. Wolton[2], B. ter Braak[1], S. Escher[3], D. Kroese[4], L. Wolters[1], A. Wilmes[5], P. Jennings[5], I. Suciu[6], X. Dolde[6], M. Leist[6], B. van Vugt[7], B. van der Burg[7], L. Farcal[8], T. Mohoric[9], T. Exner[8], B. Hardy[8], O. Hatley[10], I. Gardner[10], R. Currie[2], and B. van de Water[1]. *[1]Universiteit Leiden, Leiden, Netherlands; [2]Syngenta, Bracknell, United Kingdom; [3]Fraunhofer Institute for Toxicology and Experimental Medicine, Hanover, Germany; [4]Netherlands Organisation for Applied Scientific Research, Zeist, Netherlands; [5]Vrije Universiteit, Amsterdam, Netherlands; [6]Universität Konstanz, Konstanz, Germany; [7]BDS, Amsterdam, Netherlands; [8]Edelweiss Connect GmbH, Basel, Switzerland; [9]Edelweiss Connect, Basel, Switzerland; and [10]SimCyp, Sheffield, United Kingdom.*

Fast and reliable identification of toxic effects is crucial in the development of new active substances. New approach methods (NAMs) enable high throughput screening without the costs and ethical concerns of animal tests. Also, NAMs provide insights into underlying mechanisms of toxicity, which can be useful in screening new active substances. Syngenta provided 10 compounds that are either commercially available or research compounds that were discontinued due to developmental and reproductive toxicity (DART) effects. A selection of the EU-ToxRisk *in vitro* test battery was applied to determine if they can be used in hazard assessment or screening of new active substances for weed and disease control in cereals. 20 CALUX assays and 14 HepG2 BAC-GFP reporter gene assays were chosen to study activation of (nuclear) receptors and cellular signaling pathways. Cell type specific assays included high content imaging in primary human hepatocytes (PHH) and cell migration (UKN2) or neurite outgrowth assays (UKN4) in human dopaminergic neuronal cell lines. Hierarchical clustering was applied to the points of departure (PoDs) that were determined in each test system. This analysis revealed three distinct clusters of activity patterns that correspond to the known modes of action of the 10 case study compounds (1) Brequinar; (2) ACCase inhibitors; (3) fungicides of unknown mode of action. The results also gave insights into potential mechanisms underlying the toxicities observed *in vivo*. Group 1 showed a high activity pattern across the *in vitro* tests with activation of endocrine receptors, steroidogenesis and oxidative stress pathways and inhibition of neuronal function. Group 2 displayed a low activity pattern with activation of cellular stress response pathways and some effects on neuronal cells. Group 3 showed a moderate activity pattern across test systems with activation of several cellular stress response pathways and effects on neuronal function and viability. Combined but not individual analysis of the results gave the best match of clusters to known activity mode. Mechanisms of toxicity will also be analysed through transcriptomic changes in liver (PHH) and kidney (RPTEC/TERT1) cells. Computer models will be applied to determine the oral equivalent doses of the PODs for extrapolation to the human situation in hazard assessment.

1386 High Content Imaging Analysis for the Testicular Toxicity Prediction Using an 87-Compound Library in a Three-Dimensional Testicular Cell Co-culture Model

L. Yin[1], H. Hsiao[1], J. Siracusa[2], and X. Yu[2]. *[1]Reprotox Biotech LLC, Athens, GA; and [2]University of Georgia, Athens, GA.*

Novel *in vitro* alternative testing approaches for reproductive is essential, supporting the principle of reducing, replacing and refining, as well as reducing the time and costs associated with costly reproductive toxicity testing. In our previous study, we developed an *in vitro* three-dimensional (3D) testicular cell co-culture model. We observed a strong correlation between the *in vitro* IC50 and *in vivo* rLOAEL with 32 tested compounds and confirmed that this model was able to discriminate reproductive toxicants. In this study, we integrated this testicular cell co-culture model with single-cell phenotypic analysis using high-content imaging to further validate this *in vitro* model using an 87-compound library. This 87-compound library provided by the National Toxicology Program (NTP) included known and suspected toxicants such as flame retardants, drugs, industrial chemicals, polycyclic aromatic hydrocarbons (PAHs), pesticides as well as negative controls. The co-culture cells were treated with 87 compounds in a wide range of doses (1-100 µM), and the multi-parametric high-content analysis (HCA) was conducted. High-content assays included multiple endpoints of adverse outcome pathways including nuclear morphology, DNA synthesis, DNA damage, and cytoskeleton structure. The data from the single-cell-based image analysis were geometrically averaged for each well for statistical analysis. Compounds were ranked by potency on individual endpoints, such as half-maximal effective concentration

(EC50) and selectivity of adverse outcome signaling pathways for hazard prioritization. Dose-dependent changes of these known reproductive toxicants were observed. Furthermore, the compounds displayed differential toxicity profile and demonstrated their unique mechanisms of toxicity. None of the presumptive negative controls and vehicle controls were shown toxicity in this culture model. This study not only validates the efficiency of this *in vitro* model but also tests the robustness and relevance of the model system with multiple endpoints that associated with adverse outcome pathways of the male reproductive system. *Supported by R44 ES027374 funding.*

1387 Methylmercury Myotoxicity during Development

A. E. Peppriell, and M. D. Rand. *University of Rochester School of Medicine and Dentistry, Rochester, NY.*

Methylmercury (MeHg) is a ubiquitous environmental contaminant and potent developmental toxicant. Prior studies showing outcomes of cognitive and motor deficits stemming from prenatal and early life MeHg exposures has solidified the notion that MeHg has a preference for neural targets. Nonetheless, recent work from our lab now establishes that processes of muscle development are sensitive to MeHg. Using the *Drosophila* model, we have shown that developmental exposure to MeHg compromises subsequent formation of adult indirect flight muscles (IFM) during pupal metamorphosis, inducing a "balling" or myosphere phenotype consistent with a failure in muscle-tendon attachment in late-stage pupae. This finding is consistent with a prior genome wide association study (GWAs) in *Drosophila* for susceptibility to MeHg that resolved candidate genes that are involved in muscle structure and development. Two such factors were *kon-tiki (kon)* and *inflated(if)*. *Kon* encodes a Chondroitin-sulfate-proteoglycan-4 (CSPG4) homolog, while *if* encodes an alpha-integrin, both being conserved cell adhesion proteins essential in a number of morphogenic processes in vertebrates. Both *kon* and *if* are expressed in IFM muscle and are required to form attachments across the myotendinous junction (MTJ). We hypothesize that MeHg targets these factors, resulting in aberrant MTJ formation and compromised muscle function. Exposure to 10 µM MeHg is seen to elevate *kon* transcript expression during a specific window of pupal development that precedes timepoints when the overt myosphere phenotype occurs. In contrast, no change in *if* transcript level is seen across pupal stages with MeHg. Transgenic overexpression of *kon* phenocopies the myosphere phenotype induced by MeHg. Knocking-down *kon* expression with RNAi restricted to an early pupal developmental window is able to partially rescue myosphere formation induced by 10 µM MeHg, consistent with the notion that failure in the MTJ is mediated through MeHg influence on *kon*. Additional studies in progress aim to discern the particular sequence of event(s) of MTJ formation that fail as a consequence of MeHg. Resolving these underlying mechanisms of failure in muscle attachment are likely to shed light on conserved mechanisms of muscle morphogenesis that are targeted by MeHg in vertebrates.

1388 Defining the Reproducibility and Applicability Domain of devTOX *quick*Predict, a Human Pluripotent Stem Cell-Based Developmental Toxicity Assay

J. A. Palmer, E. L. Donley, A. M. Smith, M. R. Colwell, and R. E. Burrier. *Stemina Biomarker Discovery, Madison, WI.*

To establish confidence in new approach methods (NAMs) and enable their use in a regulatory setting, it is necessary to assess a NAMs accuracy and reproducibility, as well as define its applicability domain, in terms of both chemical and biological space. Over 100 chemicals have been evaluated with the devTOX *quickPredict* (devTOX^{qP}) assay, which predicts the developmental toxicity potential of a chemical based on changes in human iPS cell metabolism. The assay predicted the developmental toxicity potential across this diverse set of chemicals with 87% accuracy (88% sensitivity, 86% specificity). Within individual chemical classes (i.e., pharmaceuticals or pesticides), assay accuracy ranged from 81% to 94%, demonstrating the broad applicability of the assay. The reproducibility of the predictive model was evaluated using independent replicates of three chemical treatments (carbamazepine, n=34; methotrexate, n=34; thalidomide, n=9) conducted by multiple technicians with multiple iPS cell lines, freeze lots and reagents over the course of 5 years. The interpolated developmental toxicity potential (dTP) values (determined using the devTOX^{qP} predictive model) were within two standard deviations of the mean for each of the chemicals, demonstrating that the assay endpoints are reproducible over time. To understand the applicability domain of the assay, the results were separated into different pharmacological categories and performance was assessed. The assay's sensitivity in the different pharmacological categories ranged from 50% to 100% and provides insight into the assay's biological applicability domain. For example, developmental toxicants classified as channel, kinase, and transcription modulators and DNA modifiers were predicted as developmentally toxic with 100% sensitivity. In contrast, receptor modulators were predicted with 50% sensitivity, and were highly dependent upon whether the iPS cells expressed the specific receptor being modulated. These data demonstrate the importance of understanding a NAM's biological system, its strengths and its limitations. Taken together, these data demonstrate the accuracy, reproducibility and broad applicability domain of the devTOX^{qP} assay and support its use as an alternative to animal models for developmental toxicity testing.

1389 Implementation of a Human-Based Medium-Throughput Screening Assay in a Developmental Neurotoxicity (DNT) Testing Battery

S. Masjosthusmann[1], F. Bendt[1], U. Hübenthal[1], N. Förster[2], E. Keßel[1], J. Klose[1], M. Pahl[1], L. Stürzl[1], A. Mosig[2], and E. Fritsche[1,3]. *[1]IUF—Leibniz Research Institute for Environmental Medicine, Düsseldorf, Germany; [2]Ruhr-Universität, Bochum, Germany; and [3]Heinrich-Heine-Universität, Düsseldorf, Germany.*

It is widely accepted that *in vitro* methods allow faster and cheaper toxicity testing for hazard identification than traditional animal experiments. However, except for some areas (e.g. skin sensitization, genotoxicity) those methods are not accepted by regulatory agencies. In the field of developmental neurotoxicity (DNT) there is consensus that a large number of chemicals needs to be tested to fill the current knowledge gap. Such a plethora of compounds cannot be tested according to current animal guideline studies. It was therefore recognized by stakeholders from academia, industry and regulators, that there is an urgent need for a regulatory accepted testing strategy that allows DNT evaluation of large numbers of chemicals in a reasonable time. Therefore, under the guidance of the European Food Safety Authority, we set up DNT test methods (NPC1-5) as part of a larger, international testing battery, that cover a variety of neurodevelopmental key events (KE) over developmental time. NPC test methods are based on aggregated primary human neural progenitor cells (hNPC) called neurospheres, which allow chemical screening on hNPC proliferation (NPC1), migration (NPC2), neuronal (NPC3), and glial (NPC5) differentiation. These assays are set up in a medium-throughput format in an automated experimental workflow with fully automated image analyses and evaluation. We are currently evaluating the effects of >100 compounds in a concentration-dependent manner on hNPC development using this workflow. Here we present the screening results of NPC1-5 and demonstrate how this model, that already produced reliable toxicity data with much smaller number of compounds and manual handling in the past, performs with a much larger set of substances in an automated experimental workflow. We show test methods performances, concentration-response curves for selected compounds, prediction models and benchmark concentrations of the chemical test set. The outcome of this screening project will further contribute to an OECD guidance on the use and interpretation of this DNT test battery. Here, an emphasis will be put on the relation between *in vitro* effective concentrations and human *in vivo* exposure levels for risk assessment and thus will accelerate the development and use of DNT *in vitro* test methods for regulatory purposes.

1390 Human Liver-on-a-Chip as a Model for Biotransformation Studies

M. van der Zande, L. Duivenvoorde, N. Pinckaers, T. Nguyen, A. A. Peijnenburg, and J. Louisse. *Wageningen University and Research, Wageningen, Netherlands.*

Organ-on-chip concepts are promising to improve current *in vitro* models that often fail to mimic organ complexity, and as such may facilitate the replacement of animal models. The aim of this study was to develop a liver-on-a-chip model based on human liver HepaRG cells with a high relevance for biotransformation studies. To test the performance of the system, we extensively characterised the chip model versus the conventional "static" HepaRG model and against primary hepatocytes grown under static conditions. After seeding, the HepaRG cells were allowed to proliferate for two weeks, followed by two weeks of differentiation. During differentiation and another six weeks thereafter, the cells were characterised. Cellular morphology was analysed weekly using confocal microscopy, showing the presence of hepatocytes, biliary cells, and bile canaliculi during the entire period similar to the static HepaRG model. Metabolic activity of CYP1A1/2 and CYP3A4, with and without stimulation with TCDD (induction of CYP1A1) and rifampicin (induction of CYP3A4), was evaluated weekly using an EROD and Luciferin-IPA assay, respectively. Gene expression of various metabolic enzymes and transporters was assessed at the start and end of the full differentiation period in the HepaRG cells and in

the primary hepatocytes. The chip and static system showed clear differences in basal metabolic activity with a higher CYP1A1/2 activity and lower CYP3A4 activity in the chip system. After stimulation, the activity of both CYP1A1/2 and CYP3A4 was lower in the chip system, but CYP1A1/2 activity in the chip resembled that of primary hepatocytes. For both HepaRG systems, CYP3A4 activity was lower than in primary hepatocytes. In summary, the HepaRG cells can be successfully grown under dynamic conditions in a chip maintaining their morphology. Metabolic activity was shown to be influenced by the dynamic conditions in the chip compared to the static system, but the observed differences were not unidirectional. Compared with primary hepatocytes, the dynamic system showed a similar CYP1A1/2 activity, but lower CYP3A4 activity after enzyme activity induction. Results show that the HepaRG dynamic chip system maintains metabolic activity up to six weeks after full differentiation and is thus a suitable system for biotransformation studies.

1391 Transcriptomic Data of Liver and Kidney Cells Treated with Valproic Acid and Analogues to Support Read-Across Assessment

M. Wehr[1], A. Bitsch[1], N. G. Vrijenhoek[2], B. van de Water[2], L. Capinha[3], A. Limonciel[3], P. Jennings[3], and S. E. Escher[1]. *[1]Fraunhofer Institute for Toxicology and Experimental Medicine, Hanover, Germany; [2]Universiteit Leiden, Leiden, Netherlands; and [3]Vrije Universiteit Amsterdam, Amsterdam, Netherlands.* Sponsor: C. Dasenbrock

A read-across assessment usually starts with a list of initial source compounds sharing structural and physico-chemical properties. The finally selected source compounds also should exhibit similar toxicodynamic and kinetic properties. The conclusion on similar dynamic properties is often challenging, in particular because mechanistic data are usually not available. Legacy animal repeat dose oral exposure data show longer-chain analogues, like Valproic acid induce microvesicular liver steatosis as primary toxic effect with renal weight loss at higher dosing. Short-chain analogues, like 2-Ethylbutyric acid and Pivalic did not show adverse liver or kidney effects. We treated the human liver cancer cell line HepG2 and the human renal proximal tubule cell with 18 carboxylic acids (six concentrations) and conducted transcriptomic analysis using TempO-Seq. Unsupervised clustering of differentially expressed genes (DEGs) revealed clustering of steatotic versus non-steatotic carboxylic acids using the HepG2 model. Activity increased with increasing side chain length. A similar response was found with RPTEC/TERT1 cells. Further comparative analyses like pathway analyses among all analogues in both HepG2 and RPTEC/TERT1 cells are discussed. In summary, by studying the mode of action on a transcriptional level, we anticipate to support risk assessment by providing qualitative similarity data on a mechanistic level. By testing different cellular models, we will also learn more about the minimal scope needed to conclude on shared modes of action. *This work received funding of the EU-ToxRisk project (Grant agreement No 681002).*

1392 A Weight-of-Evidence Approach for Androgen Receptor Conservation across Vertebrate Species

S. M. Vliet[1], S. G. Lynn[2], K. Markey[2], and C. A. LaLone[1]. *[1]US EPA, Duluth, MN; and [2]US EPA, Washington, DC.*

The US EPA's endocrine disruptor screening program (EDSP) is tasked with assessing thousands of chemicals for their potential to adversely impact human health and the environment through perturbation of endocrine pathways. Traditionally, chemical screening is performed using a tiered toxicity testing strategy that includes whole-animal studies. This approach, however, has proven challenging due to the extensive time, resources, and animals needed to evaluate a single chemical for endocrine activity. Therefore, the EDSP has been transitioning towards the use of *in vitro* high-throughput screening (HTS) techniques to rapidly and efficiently prioritize chemicals for further testing. Despite their utility, the ability of these mammalian-based HTS assays to accurately reflect chemical interactions with non-mammalian targets remains uncertain. One goal of the EDSP is to evaluate biological pathway conservation across taxa to understand how broadly these HTS results can be extrapolated to non-mammalian species. Identification of chemicals that modulate the androgen receptor (AR) is of interest to the EDSP because many chemicals have androgenic activity that can disrupt the endocrine system by mimicking or antagonizing natural hormones. Therefore, the objective of this study is to gather weight of evidence for AR pathway conservation across species using a combination of *in silico* structural comparisons and systematic review of available toxicity literature, both *in vitro* and *in vivo*, to determine whether current AR HTS assays are predictive of activity in other vertebrates. Results of this work provide lines of evidence toward structural conservation of AR across vertebrate species and suggest that chemicals shown to interact with AR ligand binding domain in mammalian HTS assays should behave similarly in non-mammalian vertebrates.

1393 Historical Comparison of Vehicles for 3T3 Neutral Red Uptake Phototoxicity Test (3T3NRUPT)

L. F. Pratt, and G. DeGeorge. *MB Research Laboratories, Spinnerstown, PA.*

The *in vitro* 3T3 NRU PT is used to identify potentially phototoxic test substances that are induced after exposure to light. The test evaluates phototoxicity by the relative reduction in viability of cells exposed to the chemical in the presence versus the absence of light. Substances identified by this test are likely to be phototoxic *in vivo* after systemic application and distribution to the skin, or after topical application. Depending on chemical solubility, different solvents may be used as vehicles to dilute the substance for the test. Test substances are diluted from a top concentration of 1 mg/ml or the limit of solubility in a decimal geometric series for a total of eight concentrations in an aqueous vehicle, and applied to a 3T3 mouse fibroblast cell line monolayer plated in two 96-well tissue culture plates. One plate is exposed to 5J/cm^2 of solar simulated light (+SSL), while the other plate is placed in the dark (No SSL) (50 min.). The effective concentrations at which the viability of the cells is reduced to 50% of untreated cells (EC_{50}) is calculated for each condition, and the photo-irritation factor (PIF) is defined as a ratio of the EC_{50} of the +SSL cells to the No SSL cells. These values are used to determine potential phototoxicity, where a PIF of less than 2 is considered to be non-phototoxic, a PIF greater than 2 and less than 5 indicates a probable phototoxin, and a PIF greater than 5 is phototoxic. A positive control, usually chlorpromazine (CPZ), must have a PIF value of greater than 6. We present 14 years of historical data +SSL and No SSL, and PIF values of the positive control, chlorpromazine (CPZ), in the recommended vehicles of Hanks' Balanced Salt Solution (HBSS), 1% dimethyl sulfoxide (DMSO) in HBSS and 1% ethanol (EtOH) in HBSS to compare the effects of vehicle choice on CPZ on the 3T3 NRU PT. The average PIF values of chlorpromazine in the three vehicles are similar: 44.5 (HBSS), 34.6 (1%DMSO), and 37.3 (1%EtOH). Although the dilution vehicle in which the substances are tested has some potential to affect these values, it is concluded that all three vehicles are acceptable without compromising study results.

1394 Development of an *In Vitro* Assay for Inhalation Toxicity

S. D. Slattery, A. Mistry, L. Bowen, and J. K. Hartman. *ScitoVation, Research Triangle Park, NC.*

A shift in toxicity testing from *in vivo* animal models to *in vitro* human cell-based models is a major focus of current research, due to the high cost, low throughput, ethical concerns, and questionable human relevance of *in vivo* testing. *In vitro* testing for point-of-contact inhalation toxicity is a particular challenge, and in doing so two factors should be considered. The first is the physiological relevance of the cell culture model used in the test. A more complex organotypic culture, such as the EpiAirway (MatTek) primary-derived, differentiated bronchial epithelium, may better replicate adverse outcome pathways, whereas a simpler model system, such as the BEAS-2B immortalized bronchial epithelial cell line, may be more applicable to high-throughput testing. The second consideration is the route of exposure. Whereas exposure of submerged cultures to compounds in solution is a commonplace approach, compatible with many *in vitro* assays and amenable to scaling for high-throughput testing, exposure of cultures grown at the air liquid interface to compounds in gas or vapor form may better simulate *in vivo* inhalation exposures. To better understand how these parameters affect testing results, we have developed a four-quadrant matrix of testing approaches that combines simple (BEAS-2B) or complex (EpiAirway) cell culture models with in-solution or vapor-phase exposures. As an initial test compound, we have chosen methyl iodide for its well-understood and direct mechanism of action in airway epithelia (depletion of glutathione and subsequent cytotoxicity). We found little difference between the cell culture models in sensitivity to methyl iodide-induced cytotoxicity. This was true when treated in solution (IC50s: 2.6 mM for BEAS-2B and 3.1 mM for EpiAirway) or as vapors (IC50s: 972 ppm for BEAS-2B and 1191 ppm for EpiAirway). However, we found that the in-solution sensitivities could not predict the vapor-phase sensitivities when converted to equilibrium vapor concentrations. The vapor IC50s calculated from solution IC50s were approximately three times higher than the measured vapor IC50s. This may be explained by the fast evaporation of methyl iodide from exposure medium, with a half-time of ten minutes. Therefore, in-solution exposure was of limited duration, whereas vapor-phase exposure could be maintained for longer durations. We conclude that vapor-phase exposure better mimics in-life exposure scenarios for volatile compounds.

1395 An *In Vitro* Alveolar Epithelial Cell Model Recapitulates *In Vivo* LRRK2 Inhibitor-Induced Increases in Lamellar Body Size

J. Harney, J. Finley, P. Koza-Taylor, T. A. Lanz, C. Doshna, C. Somps, C. Houle, P. Bajaj, and K. Adkins. *Pfizer Inc., Groton, CT.*

Alveolar type II cells (ATII) contain lamellar bodies (LB) which synthesize and store lung surfactants. In animals, pharmacological inhibition or knockout of leucine-rich repeat kinase 2 (LRRK2) leads to increases in both the size and number of LBs in ATII cells. The consequences of these changes to the health or function of the lung are unknown. To understand the impact of pharmacological LRRK2 inhibition in lung, we developed an *in vitro* assay to examine changes in LBs in ATII cells. In this model, primary human alveolar epithelial cells (AEC) were cultured on Matrigel and collagen-I coated transwell inserts resulting in the display of similar phenotypes to ATII cells *in vivo*. By day 3 in culture, microvilli and LBs were apparent, and by day 7, after transition to air-liquid interface (ALI), LBs fused with the cell membrane and surfactant was released into the apical chamber. After 7 days under ALI conditions, typical ATII mRNA markers including ABCA1 and the surfactant proteins B, C and D were strongly upregulated, compared with cells cultured on standard plastic culture conditions (2D). The alveolar type I (ATI) cell marker AQP5 was also upregulated, suggesting a heterogeneous population of alveolar epithelial cell types. We also noted increases in both mRNA and protein levels of LRRK2 from cells cultured in this model, relative to 2D; a finding which agrees with reports of LRRK2 expression in lung being the highest within the human body. Additionally, we demonstrate that treatment of AECs with a potent LRRK2 inhibitor reduces endogenous phospho-LRRK2 and significantly increases LB size; an effect which is also seen in non-human primate lungs treated with the same compound. In summary, this model could expand understanding of LRRK2 and surfactant biology with the potential to provide clinical translation of the biological effects observed with LRRK2 perturbation in animals.

1396 Approaches in the Evaluation of Equipment Used for *In Vitro* Phototoxicity Testing to Ensure Proper Assay Performance and Regulatory Compliance

K. Cantrell, K. Bouchard, G. Price, J. Filbert-Findley, M. Conahan, and A. Hilberer. *Institute for In Vitro Sciences Inc., Gaithersburg, MD.*

Generation of accurate and compliant data hinges on monitoring assay performance. Specific assay equipment are required for photosafety assessments as outlined in OECD TG 432: *in vitro* 3T3 NRU Phototoxicity test and in the ICH S10 Document. We demonstrate the importance of evaluating the solar simulator and UVA meter achieve proper assay performance. A comparison of the UV emission spectra of two solar simulator bulbs showed variation in the UVA/UVB range with a noted abnormal shift in the 300-360 nm range for one bulb. To evaluate if the differences could affect assay performance, three reference compounds were tested. The absorbance peaks for hexachlorophene (non-phototoxic), chlorpromazine (phototoxic), and amiodarone (phototoxic) are predominately >200 nm to < 350 nm. In the bulb with an abnormal spectrum, amiodarone did not produce a significant shift in toxicity to fall into a probable phototoxic or phototoxic prediction as outlined in OECD TG 432. Our initial findings justify the importance of a spectral analysis measurement prior to use in an assay. UVA broadband meters are used to measure light output to ensure proper irradiance of cells equivalent to approximately 5 J/cm^2. Five different radiometers were sent for calibration - the historical meter and four others for comparison. During assay use, the historical meter read 1.7 ± mW/cm^2, but none of the new meters had a similar reading. One new meter was selected due to its stability and reproducibility; and after multiple comparative readings were taken, a conversion factor range of 1.25-1.27 was assigned. To confirm appropriate light exposure and assess tolerance of the cell line to light exposure, a cell sensitivity check was performed. The Balb/c 3T3 cells were exposed up to 9 J/cm^2 without adverse effect and the viability was >80% relative to control group. In addition, a positive control, chlorpromazine, was conducted to assure appropriate irradiance to elicit a phototoxic response. The results were compared to a historical database with a current Mean Photo Effect (MPE) range of 0.394 – 0.749. In summary, these approaches are important in providing confidence in the test system to produce reliable, accurate, predictive, and quality data.

1397 Generation of Machine-Learning Models to Anticipate Endocrine Disruption

K. M. Zorn[1], D. H. Foil[1], D. P. Russo[2], A. M. Clark[3], W. Hillwalker[4], D. Feifarek[4], F. Jones[4], W. Klaren[4], A. Brinkman[4], and S. Ekins[1]. *[1]Collaborations Pharmaceuticals Inc., Raleigh, NC; [2]Center for Computational and Integrative Biology, Rutgers, The State University of New Jersey, Camden, NJ; [3]Collaborations Pharmaceuticals Inc., Quebec, QC, Canada; and [4]S. C. Johnson & Son Inc., Racine, WI.*

Endocrine disruption is a major focus of toxicology research, and thus human estrogen and androgen receptors are key targets of interest. Downstream effects of receptor activation are difficult to anticipate without expensive, time-consuming *in vitro* and *in vivo* testing, so the Environmental Protection Agency (EPA) has prioritized alternative methods. Recently, the EPA has used high-throughput ToxCast/Tox21 screening data across relevant targets and processes to construct mathematical models capable of predicting the likelihood of estrogen or androgen pathway agonism/antagonism of a chemical. One limitation of these studies is the requirement of *in vitro* data for prediction; in contrast, machine learning methods are capable of prospective prediction from molecular structure alone. Particularly, Bayesian machine learning models (BMLMs) have shown broad applicability to drug discovery and toxicology applications. The current study describes the generation and evaluation of several groups of BMLMs using androgen and estrogen receptor data, including *in vitro* ToxCast/Tox21 data, EPA mathematical model output scores, and binary data considering bioactivity and cytotoxicity. Group performance was evaluated by cross-referencing external predictions of *in vitro* and *in vivo* reference chemicals. These predictions were evaluated to produce an overall active/inactive classification for each chemical, and classifications were then compared to the results reported by mathematical model studies published by the EPA. BMLM prediction accuracies ranged from 86-93% for reference chemicals of androgen and estrogen receptors, for both agonist and antagonist action. Exploration of other machine learning algorithms, including deep learning, was conducted on training datasets for further comparison. This study demonstrates that prospective prediction using ToxCast/Tox21 assays is achievable at the same level of accuracy seen in recent EPA publications, on the basis of molecular structure alone.

1398 Quantification of the Total, Free, and Intracellular Concentration of Selected Compounds *In Vitro*

D. Dimitrijevic[1], E. Fabian[1], B. Nicol[2], I. Sorrell[2], C. Gomes[1], B. van Ravenzwaay[1], and R. Landsiedel[1]. *[1]BASF SE, Ludwigshafen am Rhein, Germany; and [2]Unilever, Bedford, United Kingdom.*

Research in *in vitro* dosimetry is needed to improve *in vitro - in vivo* extrapolation in order to translate *in vitro* derived effect-concentrations to *in vivo* doses. Commonly used nominal concentration (C_{Nom}) may not represent the effect concentration initiating toxic events. Here, Balb/c 3T3 cells were incubated with test compounds to determine the medium (C_{Med}) and cellular concentrations (C_{Cell}) over time. A steady-state mass balance model (Armitage et al., 2014, Fischer et al., 2017, Kramer et al., 2012) was implemented to estimate predicted concentrations (C_{Pred}) which were compared to experimental results. Balb/c 3T3 cells were treated for up to48 h with Acetaminophen (APAP), Ketoconazole (KET), Methyltestosterone (MT) at subtoxic nominal concentrations of 60, 15 and 14 µM. Corresponding analytical concentrations were at 64.6, 12.6 and 12.7 µM, respectively. Total C_{Med} was corrected by the protein binding, determined by rapid equilibrium dialysis (RED). HPLC-MS/MS analysis was used for quantification of the compounds in medium, cells and RED samples. After 48 h, C_{Cell} for APAP, KET and MT were at 34.7, 21,0 and 260.5 µM and C_{Med} were 62.6, 8.8 and 6.3 µM. Comparison of C_{Med} and C_{Cell} to C_{Pred} for APAP, a fold difference of 0.1 and 4 is observed. For MT, fold differences of 0.1 and 47 for C_{Med} and C_{Cell} were observed. C_{Med} and C_{Cell} detected for KET show fold differences of 0.4 and 0.5 and are therewith close to C_{Pred}. Free C_{Pred} were found in close agreement to the experimental data. In conclusion, the work provides an insight into the quantification of *in vitro* dosimetry concepts in a diffusion-based *in vitro* assay versus a model-based approach.

1399 Integration of Transcriptome Data into the Hazard Assessment of Volatile Compounds: A Read-Across Approach

M. Wehr[1], J. Koschmann[2], C. Meckbach[3], S. Schramm[1], K. Sewald[1], A. Bitsch[1], M. Niehof[1], J. Knebel[1], D. Ritter[1], T. Hansen[1], and S. E. Escher[1]. *[1]Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; [2]GeneXplain GMBH, Wolfsburg, Germany; and [3]Georg-August-Universität Göttingen, Göttingen, Germany.* Sponsor: C. Dasenbrock

Read-across is one of the most often used alternative methods in chemical risk assessment. It is often a challenge to conclude on shared toxicodynamic properties within the grouped substances based on observed adverse effects from *in vivo* studies. New models providing mechanistic information might be useful to support this assessment. ExITox II (Explain Inhalation Toxicity) addresses this question with compounds to which humans are exposed via the inhalation route. Human lung alveolar epithelial (A549) cells were exposed to five different read-across groups of airborne compounds, including gases, liquid aerosols and nanoparticles. The read-across groups comprise structurally related compounds. After repeated inhalation exposure aliphatic diamines, aldehydes and alkyl acrylates induced mainly pulmonary inflammation in rodents, whereas vinylester showed in addition hyperplasia and the nanoparticles led to fibrosis. Cytotoxicity was measured using mainly air-liquid exposure with the P.R.I.T.® ExpoCube® setup and repeated exposure. Whole transcriptome analysis (TempO-Seq) revealed DEGs (differentially expressed genes) per read-across groups in a dose dependent manner, with some nanoparticles having only very few DEGs. With the geneXplain platform, enriched TFBS (transcription factor binding sites) and the corresponding transcription factors (TFs) were identify. These TFs were the input for a master regulator (MR) analysis, the postulated MRs may function as marker/key molecules for the investigated substance groups. Finally group specific functionalities of DEGS, TFs and signaling pathways were described. The experimental validation of the proposed MRs is ongoing by quantitative RT-PCR. Unsupervised clustering was used to group the compounds according to their DEG/MR pattern. Further comparative analysis among the read-across groups providing more evidence on the association of DEGs/MR and signaling pathways with the observed adverse *in vivo* outcome will be discussed. We intend to support hazard assessment within a read-across approach by providing more evidence on shared toxicodynamic properties using transcriptome data. *This work has been funded under grant agreement FKZ 031 L0120A (BMBF program).*

1400 Development of Heterogeneous 3D Tumor Spheroids Models for *In Vitro* Drug Testing

T. A. Nguyen, E. Hawkins, L. Herman, and J. Osborn. *Kansas State University, Manhattan, KS.*

The *in vitro* 3D model system provides an alternative to the inaccurate 2D system and animal models that are expensive and time-consuming. The 3D model system encompasses the complexity of ECM and the physiological relevance of an *in vivo* system. We designed and discovered a 19-residue self-assembling hydrogel-forming peptide in which this peptide directly assembled into a hydrogel by mixing the peptides with Minimum Essential Medium used in cell culture, and this hydrogel has desirable properties for 3D cell growth with a final peptide concentration as low as 1 mM (0.17%). This 3D model provides easy and safe cell isolation for further cell physiological and pathophysiological studies. The goal of this project is to synthesize the hydrogel peptide derivatives and support the 3D multicellular growth for the human tumor cell lines. Epithelial, endothelial, and fibroblast cells were co-cultured along with the hydrogel peptide derivatives in a suitable culture media. The results showed that the heterogeneous 3D tumor spheroids were generated successfully for three cancer types - breast, colorectal, and prostate. Analysis of heterogeneous 3D spheroids of colorectal cancer have a 12-fold increase of beta-catenin, compared to controls without hydrogel peptide derivatives in which these derivatives are linkers of epithelial and endothelial cells. Heterogeneous spheroids of prostate epithelial and endothelial cells have a 53% increase in spheroid size compared to the control without hydrogel peptide derivatives. Heterogeneous 3D spheroids for breast epithelial and endothelial cells have a significant increase in growth compared to controls. Overall, heterogeneous 3D spheroids with hydrogel peptide derivatives - linking epithelial, endothelial, and fibroblast cells - modulate the growth rate of the spheroids, creating a more accurate model for drug testing.

1401 Engineered *In Vitro* Technologies to Identify Risk Factors in Breast Cancer

S. Chittiboyina. *Purdue University, West Lafayette, IN.*

Microenvironmental stress created by reactive oxygen species (ROS), a consequence of exposure to environmental factors and individual genetic make-up have been known to play a role in breast cancer risk and when not cleared by antioxidant mechanisms lead to oxidative stress (OS). Besides playing a role in cell differentiation, ROS could also influence mammographic density, another risk factor for breast cancer by activation of fibroblasts and thus secretion of collagen I. Our preliminary studies show that under acute ROS exposure, epithelial cells show loss of polarity and altered nuclear morphology that controls chromatin arrangement and differentiation. Our central hypothesis is that microenvironmental stress in synergy with altered matrix stiffness leads to increased breast cancer risk. To test our hypothesis we use a 3D cell culture model that comprises of non-neoplastic human mammary epithelial HMT-3522 S1 and human mammary fibroblasts HMS32-hTERT cells. Acute OS was induced by exposure to 250 μM H_2O_2 for four hours and chronic OS by treating the cells with 25 μM H_2O_2 for 10 days. Phenotypic changes in fibroblasts were assessed using immunostaining the nuclei for DAPI, and phalloidin staining for cytoskeleton. To test the effect of matrix stiffness on nuclear morphology S1 cells were cultured on collagen I coated with laminin 111 to induce differentiation, and fibroblasts were embedded in collagen I matrix of normal and at-risk stiffnesses *in vivo*. Fibroblasts show a loss of spindle phenotype under chronic ROS. Both chronic ROS and increased stiffness lead to less circular and bigger nuclei in S1 cells suggesting that both ROS and matrix stiffness impact epithelial cells and fibroblasts independently. Effect of increased stiffness and ROS are being investigated by coculture of S1 cells on top of fibroblasts embedded in collagen1 matrix.

1402 Interaction and Adaptative Response of HepG2 Cells Exposed to Low Concentration of Mixtures of T-2 and Its Modified Forms

M. Taroncher, V. Zingales, J. Tolosa, Y. Rodríguez-Carrasco, and M. Ruiz. *Universitat de València, Valencia, Spain.* Sponsor: A. Juan-Garcia

The T-2 toxin (T-2) is a mycotoxin belonging to type A trichothecene produced by *Fusarium* species. The T-2 is a contaminant of considerable concern due to its wide distribution and its highly toxic effects. The common metabolites of T-2 in human are HT-2 toxin (HT-2), neosolaniol (NEO), T2-triol and T2-tetraol. The aims of this study were to determine the cytotoxic effect of individual mycotoxins T-2 and its modified forms in human hepatocarcinoma (HepG2) cells; to evaluate the adaptative response of cells to adverse effects of T-2 and its modified forms, and to establish the interaction of combining multiple mycotoxins. Cytotoxic effects were determined in HepG2 cells by the MTT and total protein content (PT) assays after 24 and 48 hours of exposure. Concentrations used were: T-2 (5-100 nM), HT-2 and NEO (5-150 nM), T2-triol (160-2620 nM) and T2-tetraol (210-3350 nM). Results show that cytotoxicity increase depending on the concentration and exposure time. The IC_{50} for T-2 and its modified forms values were similar by both assays used. The IC_{50} range from 62 to 71 nM for T-2, from 60 to 68 nM for HT-2, from 56 to 121 nM for NEO, from 870 to 1240 nM for T2-triol and from 1380 to 2770 nM for T2-tetraol. To determine the hormesis effect, cells were pretreated with 2.5-10 nM of mycotoxin during 2 and 24 hours. Then, the medium was removed and increasing concentrations of each mycotoxin were added. The results obtained demonstrated that hormesis is an adaptative process in HepG2 cells as consequence of a favorable biological response only when low pretreatment of mycotoxins were used or at short time of exposure. To evaluate the interactions of mycotoxins mixtures, the isobologram analysis was applied for the five mycotoxins assayed in binary and tertiary combinations. The higher cytotoxic effect in mixture combinations compared to individual toxicity was observed. In the combinations, a synergistic effect was detected (CI < 0.75 ± 0.09) at low fraction affected (*fa*), whereas, at medium-high *fa* additive effects (CI from 1.05 ± 0.14 to 1.51 ± 0.31) were observed for the mixtures. In some combinations antagonistic effect (CI > 2.05 ± 0.37) was observed, and it could be associated to the competition of the mycotoxins to similar receptors. *Acknowledgements: Spanish Ministry of Economy and Competitiveness (AGL2016-77610-R).*

1403 Effect of Variable Electronic Cigarette Voltage on Respiratory Cell Barrier Model

J. Adragna. *New York University Langone Health, New York, NY.*

The popularity of electronic cigarette has grown over time, whereas their health effects remain poorly explored. Traditional animal models are costly, ethically problematic, and do not suffice for the exploration of human toxic

exposures. The Calu-3 human derived adenocarcinoma cell line is a good compromise *in vitro* model. Calu-3 cell models are inexpensive, easily grown, and express important drug transporter proteins. When cultured at an air liquid interface (ALI), the monolayer polarizes and forms tight junctions and a functional respiratory epithelial barrier. Using a Calu-3 ALI model, we investigated the effects of varying e-cigarette aerosol generation voltage on the respiratory barrier as measured by Trans-Epithelial Electrical Resistance (TER). Calu-3 grown at ALI in trans-well units were exposed to an e-cigarette aerosol generated at 3.5V, 3.8V and 4.3V at a concentration of 10g/m^3 for 30 minutes after which their TER was recorded at 4, 24, and 48 hours post-exposure. We found an initial decrease in TER for all groups 4 hours post-exposure with increases over baseline values at 24 and 48 hours, particularly at the highest voltage. These findings may indicate instability in the cell model, barrier immaturity, or barrier stimulation following exposure to e-cigarette aerosols.

1404 Novel Approaches to Predicting Bioeffects of Exposure to Unknown Compounds

P. M. McLendon[1,2], C. N. Davidson[2], R. H. Migliozzi[1,2], H. J. Fullenkamp[2], D. W. Cowan[1,2], H. A. Pangburn[2], D. K. Ott[2], J. M. Gearhart[3,2], and D. P. Yamamoto[2]. *[1]UES Inc., Dayton, OH; [2]Air Force Research Laboratory, Wright-Patterson AFB, OH; and [3]Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD.*

Rapid characterization and prediction of exposure bioeffects of unknown compounds is needed to improve military medicine, as the unique occupational environment contains myriad potential toxicants. Improved prediction methods are necessary to better inform decision makers and personnel of current or future exposure risks so that contact with potentially hazardous agents are minimized and mitigate overall health risks to our warfighters. This study assesses exposure risks of compounds that already exists in military environment - organophosphates and compounds in a USAF paint shop. A combinatorial approach - predictive computational modeling and *in vitro* studies - assessed toxicant effects in the lung. Thousands of compounds from the paint shop inventory was reduced to 53 representative compounds (volatile and non-volatile.) High-throughput toxicokinetics was used to estimate compound LC50s in cells, which provided midpoints in dose-titration treatment curves. A549 lung cells were treated with a dose-response curve of compounds for 24 or 48 hours followed by imaging. We assessed toxicity by cell viability and mitochondrial function. Images were ingested into our proprietary image analytics platform for unbiased image analysis, viability analysis and phenotyping. We quantified relative cell death from treatment of these compounds and, using unbiased phenotyping, uncovered morphological feature signatures that describe specific chemical exposures. We measured over 11,000 morphological features on every cell in each experiment - downselection of redundant features provide unbiased information about chemical exposure, as well as concentration/duration of exposure, allowing toxicological risk assessment. Comparative analyses allow determination of compounds that behave similarly and may share mechanisms of action, especially when compared with mechanistic toxicity assays. These feature fingerprints provide phenotype data to computational models, improving prediction of exposure. The results of this work improve predictive analytics efforts and enable creation of searchable databases containing *in vitro* toxicity and *in silico* pharmacokinetics, such that risk information can be extracted using *in vitro* image data or chemical structure.

1405 Validation of Multiple *In Vitro* Skin Sensitization Tests

M. Troese, D. Sergeyev, C. Kalimtzis, and G. DeGeorge. *MB Research Laboratories, Spinnerstown, PA.*

Skin sensitization is the initial process that leads to an allergic response following contact with a chemical. The process by which skin sensitization occurs is outlined in an Adverse Outcome Pathway (AOP). The first Key Event (KE1) is the covalent binding of electrophilic substances to skin proteins. KE2 takes place in keratinocytes and the antioxidant/electrophile response element (ARE-Nrf2). KE3 is the activation of dendritic cells (DC). The OECD has published guidelines to test these AOP events using non-animal methods. We validated the following *in vitro* sensitization assays to provide alternatives to animal testing: Direct Peptide Reactivity Assay (DPRA; OECD 442C), KeratinoSens (OECD 442D), LuSens (OECD 442D); Human Cell Line Activation Test (h-CLAT; OECD 442E) and the Genomic Allergen Rapid Detection (GARD) skin assay. DPRA is used to measure KE1, KeratinoSens and LuSens for KE2, and h-CLAT and GARD skin for KE3, where h-CLAT measures increase in the expression of CD54 and CD86 surface markers, while GARDskin measures changes in RNA transcription. These assays can be used in a weight of evidence based approach (i.e. 2 out of 3 AOP events) to correctly identify skin sensitizing materials. We tested 10, 10, 10, 15 and 9 chemicals, in DPRA, KeratinoSens, LuSens, h-CLAT and GARD, respectively. In our laboratory, for these limited numbers of test chemicals, the DPRA achieved 100% accuracy, sensitivity and specificity. LuSens achieved 90% accuracy, 83% sensitivity and 100% specificity. KeratinoSens achieved 100% accuracy, sensitivity and specificity. h-CLAT achieved 100% accuracy, sensitivity and specificity. GARD achieved 100% accuracy, sensitivity and specificity. These results are evidence for the consistency and reliability of *in vitro* sensitization assays. By incorporating *in vitro* assays in the OECD framework for the testing of chemicals, dermal sensitization testing has the potential to move further away from the use of animal models and fulfill the longstanding aim of reducing, refining and replacing animal testing altogether.

1406 Further Validation of a Nonanimal Integrated Testing Strategy (ITS) for Identification of Eye Irritants (GHS Category 2) Using the BCOP-EIT

B. Varsho, M. Troese, E. Delacruz, and G. DeGeorge. *MB Research Laboratories, Spinnerstown, PA.*

OECD non-animal test guidelines for identification of ocular hazards state no single *in vitro* test method will be able to fully replace the *in vivo* Draize eye test to predict across the full range of serious eye damage/eye irritation responses for different chemical classes. GHS guidance further states that assignment of GHS Category 2 (eye irritant) classification is impossible using any single test. Based on these recognized limitations, we have previously evaluated an integrated testing strategy (ITS) combining the EpiOcular™ Eye Irritation Test; EIT (OECD 492) and the Bovine Corneal Opacity and Permeability (BCOP) Test (OECD 437) to identify eye irritants (GHS Category 2). By using the combination of the EIT and BCOP test, we have accurately identified GHS Acute Eye Hazard Category 2 chemicals that cause reversible eye irritation. When a BCOP test rules out GHS Category 1 and the EIT rules out GHS No Category, analysis of these results indicates the only other possible designation - Category 2. Per GHS, Category 2 classification defaults to Category 2A, because differentiation between Category 2A and 2B cannot be made. After additional blinded testing, expanding our dataset from 42 to 51 chemicals, we correctly identified 92% of the Category 2A/B chemicals as Category 2. This additional testing raised our overall accuracy for predicting Category 1, Category 2, or No Category to 90%. This novel BCOP-EIT integrated testing strategy has been adopted by several chemical manufacturers to identify ocular hazards while simultaneously reducing animal usage.

1407 A Mathematical Model for Estimating the Dissolution Rate of Synthetic Vitreous Fibers from *In Vivo* Studies

J. Hoffman, W. Eastes, R. Potter, and J. G. Hadley. *Owens Corning, Granville, OH.*

Currently, measurement of biopersistence of synthetic vitreous fibers (SVF's) uses rat models to demonstrate regulatory compliance, typically via the half time ($T_{1/2}$) for clearance of long, respirable fibers. Historically the clearance rate of long fibers in such tests was associated with the rate of dissolution (K_{dis}) of fibers in near-neutral pH simulated lung fluids. *In vitro* testing mimicked the interaction between an inhaled fiber and extracellular fluid in the pleural space, which resulted in predictive models based on fiber dissolution rates at near-neutral pH. Developments in SVF chemistry resulted in fibers which demonstrated low biopersistence despite very low solubility at neutral pH, challenging the 'single dissolution rate' models. Clearance of these fibers is often mimicked using a dissolution rate at acidic pH (K_{acid}). Here we address this complexity with a single model which can estimate the clearance rates of commercial SVF's. We based the model on *in vivo* fiber clearance data with the outcome a prediction of long, short, and WHO fiber clearance over time. The model uses an initial distribution of fibers (length and diameter) and follows the time evolution of the fiber length-diameter distribution. Iterative simulations incrementally varying K_{dis} and K_{acid} as the fitting parameters for each fiber while minimizing the chi-squared statistic let us determine the 'dissolution rates' showing the best agreement with experimental data .A series of simulations using publicly available *in vivo* clearance was used to refine the initial concept into a working simulation methodology. The methodology that best described known *in vivo* results involves following the time evolution of an initial distribution of fibers subject to three potential clearance mechanisms (1) long fiber cleavage by acidic dissolution (macrophage attack) (k_{acid}) (2) macrophage mediated clearance of short (< 15 micron length) fibers and (3) congruent dissolution of the fibers at a neutral pH (k_{dis}). Studying the relationship between the tested fiber chemistry and these 'best estimates' of dissolution rate permitted the development of correlations between fiber chemistry and K_{dis} and K_{acid} which provide useful design guidance. Going forward, beyond the value for fiber developers, the authors believe this ap-

proach and/or improvements on this approach could become a viable tool for avoiding animal studies when assessing the biopersistence of glass, stone, and slag wool fibers as required by Note Q of Regulation (EC) No 1272/2008.

1408 Inflammatory Profile of Respiratory System Cells as an *In Vitro* Tool for Evaluation of Respiratory Sensitizers

A. G. Silva, S. M. Carvalho Filho, and M. C. Valadares. *Universidade Federal de Goiás, Goiânia, Brazil.* Sponsor: D. Oliveira

Inhalation toxicity is traditionally evaluated using rodents, which can be submitted to different exposure schemes for assessment of acute, sub-acute and sub-chronic toxicity of a test material. However, although such *in vivo* models are the only that have regulatory acceptance, these models only employ the lethality as an endpoint for classification, while effects upon the respiratory system are not evaluated separately. Moreover, there are no available methods for evaluation of pulmonary allergenicity and this is partially due to the fact that the Adverse Outcome Pathway (AOP) for lung sensitization remains incompletely understood. The objective of this work was to evaluate the inflammatory alterations triggered by different respiratory sensitizers upon different cell types of the respiratory tract. We selected six respiratory allergens (Chloramine-T, Piperazine, Maleic Anhydride, Glutaraldehyde, Cyanuric Chloride and Trimetilic Anhydride Chloride) and evaluated the cytotoxicity upon four different cell types, including bronchial epithelial cells (BEAS-2B), lung fibroblasts (MRC-5), endothelial cells (EA.hy926) and monocytic cells (THP-1), using the MTT reduction assay. Further, we exposed these cells to the cell viability 80% concentration of each test material for 24 hours, prior to determination of pro-inflammatory (IL-1β, IL-6, IL-8, IL-12p70 and TNF-α) and anti-inflammatory (IL-10) cytokines levels, using the Cytometric Bead Array (CBA) method in both cell lysates and supernatants. The results demonstrated that respiratory sensitizers promoted inflammatory alterations in all the investigated cell types, increasing the production of pro-inflammatory cytokines, highlighting the involvement of epithelial and monocytic cells. Besides that, all the cells increased the production of IL-8 in response to exposure. The obtained results demonstrate that the production of pro-inflammatory cytokines by respiratory system cells can be a valuable endpoint for *in vitro* assessment of lung sensitization potential. Furthermore, the production of IL-8 by such cells seems to be a determinant feature for the chemically induced respiratory disorders.

1409 Utility of the VITROCELL Cloud System for Investigating the Effect of Oseltamivir on Human Airway Epithelium *In Vitro* after H1N1 Infection

S. Frentzel[1], S. Constant[2], S. Huang[2], and J. Hoeng[1]. *[1]Philip Morris Products S.A., Neuchatel, Switzerland; and [2]Epithelix, Geneva, Switzerland.*

Respiratory viral infections, such as flu, are a worldwide concern and a source of huge economic burden for the society. Most antiviral drugs to date are delivered systemically by an oral or intravenous route of administration. Inhalation of aerosolized antiviral drugs would not only allow direct and quick access to the site of infection but also help avoid first-pass effects. As such, aerosolized drug delivery could increase the antiviral efficiency of drugs while reducing their side effects. To explore the *in vitro* efficiency/toxicity of an antiviral drug (prescribed for oral treatment in humans), we describe here a novel method for delivering oseltamivir to the infection site to counter a virus infection (H1N1 virus) through aerosolization. To this end, we took advantage of the VITROCELL™ Cloud system to nebulize oseltamivir and expose 3D organotypic air-liquid interface (ALI) tissue cultures to the drug. In contrast to more complex exposure systems that are based on continuous flow, the VITROCELL™ Cloud system operates through an injection mode of aerosol delivery by using a clinically relevant nebulizer, which also limits the need for larger quantities of the drug for testing. MucilAir™Pool, an *in vitro* human reconstituted standardized nasal epithelia pooled from 14 different donors, is a physiologically relevant test system for studying antiviral compounds. By using this system in combination with the "Cloud chamber", we were able to successfully demonstrate the efficiency of nebulized oseltamivir against H1N1 infection as well as preservation of respiratory epithelial function, with low cytotoxicity (less than 20%). The efficiency of oseltamivir has been demonstrated by a decrease in viral copy number as well as through endpoints responsive to viral infection, such as ciliary motility and secretion of soluble factors (RANTES, CAMP, and β-defensin 2). Overall, the results of this conceptual study highlight the combination of VITROCELL™ Cloud system and MucilAir™ as a suitable *in vitro* exposure and test system for inhalable drugs as well as inhalation as an alternative to oral delivery of antivirals.

1410 Alternative Testing Strategies for Assessing Eye Irritation/Corrosion of Agrochemicals under the New Brazilian Human Health Authority (ANVISA) Regulation

S. Catalano[1], M. Corvaro[2], R. Settivari[3], J. Henriquez[4], S. Kellum[3], and S. Gehen[4]. *[1]Corteva Agriscience, Barueri, Brazil; [2]Corteva Agriscience, Abingdon, United Kingdom; [3]Corteva Agriscience, Newark, DE; and [4]Corteva Agriscience, Indianapolis, IN.*

Global harmonization in toxicological testing requirements is a need to implementation of alternative testing strategies for agrochemical formulations. The recent Brazilian regulation for human health toxicological assessment of pesticides (ANVISA Res. 294, 2019) established scientific weight of evidence (WoE) and harmonized approaches to international best practices including application of GHS for classification and labeling for end-use products, risk-based assessment of new active ingredients and promotion of new assessment methodologies. Historically, accepted regulatory tests for formulated products have generally been *in vivo*. Alternative methods has been legally introduced in the new resolution. However, there is a challenge to better define their applicability domain and the uncertainties related to their prediction of human outcomes. Eye irritation has generally been performed in Albino rabbits according to the Draize method (OECD 405). This poster presents a tiered approach for assessment of eye irritation/corrosion endpoints for regulatory evaluation of agrochemical formulations in Brazil using example case-studies. First, evaluation of the necessity of testing and a decision between top-down vs bottom-up approach is based on existing information including pH (≤2or ≥11.5; avoid test and self-classify as corrosive) and outcome of the GHS calculation. If the test item is evaluated as corrosive, the top-down approach is selected, and if irritating or non-irritating (NC), a bottom-up approach is recommended. For example, if the bottom-up approach is selected, EpiOcular test (OECD 492) is conducted and if negative results are obtained, no further testing is necessary; otherwise a corrosion test as Bovine Corneal Opacity and Permeability (OECD 437) should be performed. Based on calculation methods, *in vitro* results and prevalence of irritancy properties for the product class of agrochemical formulations, the test item may be classified as GHS categories 1 or 2 or NC. An *in vivo* test should be used as a last resort and may clarify the severity and persistency of ocular damage, where required. Regardless of the testing strategy selected, relevant information should always be presented as a WoE taking into consideration the respective strengths and limitations of each method used.

1411 New Approach to Evaluation and Classification of Irritation Intensity of Oral Care Ingredients Using a Three-Dimensional Human Buccal Mucosal Model

S. Aizawa[1], H. Yoshida[2], K. Umeshita[3], S. Watanabe[1], Y. Takahashi[2], S. Sakane[3], H. Sakaguchi[2], K. Yoshida[1], and S. Kataoka[1]. *[1]Lion Corporation, Odawara-shi, Japan; [2]Kao Corporation, Ichikai-machi, Japan; and [3]Sunstar Inc., Takatsuki-shi, Japan.* Sponsor: S. Aizawa, Japanese Society of Toxicology

Oral mucosal irritation is an important issue in the safety assessment of oral care products and ingredients. A three-dimensional human buccal mucosal model has been established as an alternative to the oral mucosal irritation test *in vitro, and the new EpiOral (manufactured by MatTek Corp., Ashland, MA, USA)* is one such model. Here, investigators at Kao Corporation, Sunstar Inc. and LION Corporation aimed to determine whether the EpiOral could serve as an *in vitro* test that reflects oral mucosal irritation scores *in vivo* by evaluating the concentration dependence, inter-facility reproducibility, and correlations between *in vivo* and *in vitro* findings based on cell viability. Five materials for oral care products that have been evaluated in terms of irritation *in vivo* according to Cosmetic, Toiletry, and Fragrance Association (CTFA) guidelines served as test materials. Cells that had been incubated with cultured EpiOral for 30 min were exposed to 100 µL of each test material (0.25%, 1%, 2%, 4%) for 30 or 120 minutes. Thereafter, the test material was rinsed out with PBS, and cell viability was calculated using MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazolium bromide) assays. Cell viability significantly correlated with oral mucosal irritation scores *in vivo* and the duration of exposure to each test material (ANOVA, $P < 0.0001$). Inter- and intra-facility reproducibility and concentration dependence were confirmed. These data indicated that materials with irritation scores *in vivo* of ≥ 1 could be distinguished from non-irritating materials based on 60% cell viability at 120 minutes of exposure. We also found that materials with irritation scores *in vivo* of > 3, could be distinguished from those with irritation scores *in vivo* of 1 to ≤ 3 based on 60% cell viability at 30 minutes of exposure. These results support a new approach to establishing an oral mucosal irritation test *in vitro* using different exposure durations.

1412 Evaluation of Historic *In Vivo* Data to Characterize the Emetic Properties of Liquid Cleaning Products and Provide a Framework for the Development of an *In Silico* Predictive Algorithm

P. L. Andrews[1], S. Li[2], F. Meli[2], P. K. Vinson[2], H. W. Broening[2], and J. F. Nash[2]. *[1]St George's, University of London, London, United Kingdom; and [2]Procter & Gamble, Mason, OH.*

Accidental ingestion of household cleaning products frequently results in emesis (vomiting) in both children and adults but it is not known which physicochemical properties of the formulation are primarily responsible. Preclinical studies using dogs to assess the emetic potential of product formulations administered by gavage were undertaken routinely by industry over 30 years ago but this is no longer the case. To investigate whether the data on emesis collected in these extensive historic company-sponsored studies could provide novel insights into the constituents responsible for emesis, we re-analysed the historic data for a total of 74 liquid cleaning formulations of which 6.7% did not evoke emesis within 60 min. The incidence (Respond/Tested) of emesis was dose-related with calculated ED_{50} values between 0.012-8.4 ml/kg with 57% of formulations having an $ED_{50} \leq 1$ ml/kg. The median value for the latency of onset of emesis was 10.0 min (95% CI, 8-12 min) with the number of vomits over one hour ranging from 1-10 (median 2). Detailed analysis of all components (e.g., incidence, latency and intensity) of the emetic response for a subset of formulations and their physicochemical properties revealed that formulations with a high percentage of non-ionic surfactants (alcohol ethoxylates) or high ionic strength were associated with a higher emetic potential. This was independently verified by statistical modeling, i.e., multivariable linear regression and recursive partitioning analysis, using calculated ED_{50} values from these historical beagle dog studies and formula ingredients/physiochemical measures as variables. By comparing the present data with published studies of a range of emetic agents administered by gavage in the dog and mechanistic studies in other species, we hypothesise a critical role for the enteroendocrine cells in the mucosa of the upper digestive tract. Although using historic data collected over an extended period has limitations (e.g. methodological changes), analysis of such data has provided novel insights into the emetic characteristics of this class of product and has informed the development of a *in silico* model to predict the emetic liability of novel formulations without the need for additional *in vivo* studies, hence contributing to 3Rs principles.

1413 Development of an *In Vitro* Exposure-Circulation-Metabolism Model to Mimic the State of Nicotine Exposure to the Lung and Metabolism by the Liver

C. Hua, H. Wang, X. Li, P. Shang, J. Zhao, and F. Xie. *Zhengzhou Tobacco Research Institute of CNTC, Zhengzhou, China.* Sponsor: R. Meng

Single-cell cultures have a strong advantage in studying specific endpoints, but they show insufficient ability to predict and assess the toxic effects of exogenous substances after metabolic activation *in vivo*. When microfluidic and co-culture techniques are widely used for *in vitro* toxicity assessment, this study aims to establish an *in vitro* nicotine exposure-circulation-metabolism model (ECMM), namely: a model that simulates the circulation of nicotine through the lungs into the blood vessels of the body to the liver, and the metabolites are exposed to the lungs. In this study, an exposure-circulation-metabolism platform (ECMP) was constructed by selecting suitable materials, namely, tube (D: macrophages), circulating pump, and three independent chambers (A: Beas-2b; B: Huvec; C: 25 donor liver microsomes) were connected in series to form a loop. In the platform, the morphology of Beas-2b and macrophages were observed under the microscope to determine whether the platform was suitable for cell growth; CCK-8 and ELISA were used to detect the cell viability and IL-8 expression levels of macrophages at different flow rates and times to obtain a flow rate that did not cause cell damage and inflammation; the distribution of the loading buffer was used to determine whether the platform allowed material transfer. Microscope and CCK-8 were used to detect the cell morphology and cell proliferation curve of Beas-2b, Huvec and macrophages in different medium ratios and cell concentrations to obtain optimal culture conditions. The cells and liver microsomes were cultured in the platform under optimized conditions to establish an ECMM. In this model, nicotine was added to the chamber A, and nicotine and cotinine in chamber A were detected by HPLC-MS/MS 3h later. Beas-2b and macrophages could be well grown in ECMP constructed by transwell chambers, glass, rubber tubes, dialysis bags and 0-5 ml/min circulating pumps, etc.; the flow rate of 1 mL/min had no significant effect on macrophages damage and inflammatory reaction; and the loading buffer could be fully delivered in the platform within 2h at 1 mL/min; under the culture conditions (Medium:BEBM: ECM: DMEM (1:1:1; 500 mL) + respective factors + serum 25ml + $5*10^4$cells/ml+1ml/min), the three cells could proliferate well, substance could be passed and liver microsomes could exercise metabolic function; within this model, chamber A nicotine was significantly reduced and cotinine production was found. These results indicate that this study established a nicotine ECMM *in vitro* by using Beas-2b, Huvec, 25 donor liver microsomes and macrophages, which is expected to be used for *in vitro* exposure metabolic toxicology test.

1414 Characterization and Use of Organotypic Lung Model to Assess the Pulmonary Fibrosis of Nanomaterials

M. Sharma[1], B. Rothen-Rutishauser[2], H. Barosova[2], V. Stone[3], P. Hayden[4], A. Maione[4], and A. J. Clippinger[1]. *[1]PETA International Science Consortium Ltd., London, United Kingdom; [2]Adolphe Merkle Institute, Fribourg, Switzerland; [3]Heriot-Watt University, Edinburgh, United Kingdom; and [4]MatTek Corporation, Ashland, MA.*

Inhalation is one of the major routes by which exposure to nanomaterials (such as multi-walled carbon nanotubes (MWCNTs)) may occur and lead to adverse effects in humans, such as pulmonary fibrosis. Presented here is a reconstructed primary human alveolar cell-based model (EpiAlveolar™, MatTek Corp.) that can be used to assess the potential of test materials to cause pulmonary fibrosis. EpiAlveolar™ —comprised of alveolar epithelial cells, pulmonary endothelial cells, and fibroblasts—was developed to mimic the *in vivo* human alveolar microenvironment. Characterization of the model shows presence of alveolar epithelial Type I (ATI) and Type II (ATII) cells, expression of pro-surfactant C, and formation of a tight epithelial barrier. When challenged with transforming growth factor β (TGF-β)—a known positive control for pulmonary fibrosis—the EpiAlveolar™ model demonstrated gradual signs of fibrosis over a period of 21 days such as a significant decrease in barrier integrity (transepithelial electrical resistance (TEER)), increase in extra-cellular matrix proteins (fibronectin and collagen 1A1), and thickening of tissues (hematoxylin and eosin staining). The aforementioned fibrotic biomarkers were also expressed after repeated sub-chronic exposures (1 - 30 μg/cm² for up to 21 days) to two types of MWCNTs (Mitsui-7 and Nanocyl) using an air-liquid interface exposure device (VITROCELL® Cloud). The EpiAlveolar™ model has shown value in measuring several key events along the proposed adverse outcome pathway for pulmonary fibrosis (https://aopwiki.org/aops/173). This system can be used in a mechanism-based *in vitro* testing strategy using human-relevant methods to predict pulmonary toxicity and to enable effective risk assessment of substances including MWCNTs.

1415 Variability in the Rabbit Skin Irritation Assay

J. P. Rooney[1], N. Choksi[1], R. Rai[1], D. G. Allen[1], N. C. Kleinstreuer[2], and W. Casey[1]. *[1]Integrated Laboratory Systems Inc., Research Triangle Park, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

For decades, the gold standard for skin irritation testing has been the *in vivo* rabbit skin test. As a result, it has been the benchmark against which new approach methodologies have been compared. *In vitro* methods following the Organisation for Economic Co-operation and Development's Test Guideline 439 are accepted as partial replacements for the *in vivo* test because they are capable of separating irritant from non-irritant chemicals. However, because none are capable of classifying moderate and mild irritants, there are currently no *in vitro* methods that are considered full replacements for the *in vivo* assay. A limiting factor in identifying a full replacement for the *in vivo* method could be the variability inherent to the subjective scoring of erythema and edema responses in the rabbit test. This is particularly relevant for mild and moderate irritants, which alternative methods have had difficulty differentiating with high concordance. To better characterize the reproducibility of the *in vivo* assay, in this study we assessed variability in results from chemicals tested multiple times. We compiled and curated a dataset of 3056 test records, representing 727 unique chemicals for which GHS classifications were available. Each chemical was tested at least twice in the *in vivo* assay. Where possible, primary dermal irritation indexes (PDII) were estimated from the available data and used to classify chemicals according to the US Environmental Protection Agency skin irritation classification criteria. Conditional probabilities were used to evaluate the reproducibility of the *in vivo* method in identification of severe, moderate, and mild irritants, and non-irritants, according to both GHS and EPA categorization methods. Chemicals classified as moderate irritants at least once were classified as mild irritants or non-irritants over 40% of the time when tested repeatedly. The level of variability found was greatest between mild and moderate irritants. This analysis indicates that the level of variability present in the rabbit skin irritation test should be taken into consideration when evaluating the performance of nonanimal alternative methods. *This project was funded in whole or in part with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C.*

1416 Examining the Effects of Volatile Agents Using Cell-Based Gaseous Metabolite Production

M. Madden[1], M. Angrish[2], M. Wallace[2], A. Ghio[1], L. Dailey[1], J. Pleil[2], and B. Winters[3]. *[1]US EPA, Chapel Hill, NC; [2]US EPA, Research Triangle Park, NC; and [3]GSI Environmental, Oakland, CA.*

Many agents (e.g., pollutants, pharmaceuticals, additives) requiring toxicity testing are gaseous and cannot be screened adequately in standard cell exposure systems. Submerged cell culture systems impede delivery of gases to cells due to media interference. Gas-media component reactions could form toxic products. We are using an exposure system and cell line (BEAS-2B human airway epithelial cell line) that can tolerate a lack of medium on the apical cell side for potential screening of gaseous agents minimizing the confounding effects of media. The system also can examine the conversion of an exogenously added volatile substrate to a gaseous metabolite. Monitoring production of a gas phase metabolite can be utilized to screen metabolism perturbations induced by an agent of interest (i.e., "probe molecule approach" to toxicity testing). Cells were incubated with 1 or 2% ethanol (EtOH) for up to 6 hr without the loss of cell viability (using released LDH activity and trypan blue dye exclusion). In a 37ºC flow through system (with air plus 5% CO_2 inflow), EtOH was added apart from the cell culture dishes. Acetaldehyde (C2) was collected onto dinitrophenylhydrazine packed cartridges on the outflow line. C2 was eluted from the cartridges and analyzed by LC\UV\MS. With EtOH exposures alone, increased cell C2 production was observed compared to vehicle controls (0% EtOH). The effects of pharmaceutical and flavoring agents on EtOH-induced C2 production were then examined. Cells pretreated with disulfiram (to inhibit C2 catabolism) and exposed to EtOH had increased C2 compared to untreated cells. Co-incubation of cells with EtOH and an e-cigarette flavoring component, cinnamaldehyde, decreased C2 production suggesting effects on alcohol dehydrogenase and/or other enzymes. These findings show the utility of this exposure system for measuring effects of different classes of agents on the metabolism by an important enzyme pathway. The use of this flow through gas system shows promise for 1) the ability to expose cells to volatile substances and preserve cell viability for several hours, and 2) capture a gas phase metabolite for use in probe molecule approaches for screening the induction of toxicity by gaseous agents. The use of *in vitro* substrate metabolism for chemical toxicity screening may reflect *in vivo* metabolism responses induced by exogenous chemicals. *This abstract may not reflect official US EPA policy.*

1417 Using a Measurement Science Approach to Increase Confidence in the EASA Skin Sensitization Assay

J. D. Gordon[1], R. Uhl[1], B. Toman[2], J. Elliot[2], and E. Petersen[2]. *[1]Consumer Product Safety Commission, Rockville, MD; and [2]National Institute of Standards and Technology, Gaithersburg, MD.*

NICEATM is coordinating a multi-laboratory validation study to characterize the Electrophilic Allergen Screening Assay (EASA) for risk and hazard assessment for skin sensitization classification. The EASA assay functions by assessing potential skin sensitizers by measuring depletion of one of two probe molecules. The use of this assay in a single cuvette format resulted in multiple measurement challenges, such as low throughput and inability to include sufficient control measurements. We redesigned this assay protocol to work with a 96-well plate format. Process control measurements were incorporated into a 96-well plate design to quantify key sources of variability each time the assay is run. Examples of process controls added are: positive control standard curve, bubble/precipitate interference, and QC charting. We also conducted considerable robustness testing (i.e. stability, pipetting, disposables, etc.) Additional control experiments were performed to evaluate photodegradation of probe molecules, bias from bubbles caused by pipetting, and statistical power of the assay system. Sixty compounds from NTP were tested in the 96-well plate design. One key insight revealed by this process was the interference from test compounds, namely producing an absorbance or fluorescence signal similar to that of the probe molecules, which would not have been previously detected using the single cuvette assay. Not taking the interference into account has been shown to lead to potential false negative identification. We also replaced the traditional static call line (i.e. 3 x SD) with a modified t-test to perform custom tailored "call lines" for each compound tested taking into account the uncertainty around its measurements. The data from the 60 compounds were analyzed using a Bayesian analysis as well as the student t-test statistic and has approximately 70 - 75% concordance with LLNA data. Overall, the measurement science approach described here provides steps that can be taken to increase confidence for *in vitro* assays by fully characterizing sources of variability and potential biases in the assay that will facilitate interlaboratory testing and standardization.

1418 A Novel Strategy Combining Kao ITS and Read-Across to Determine the Skin Sensitization Potency of Cosmetic Ingredients

K. Nakayama[1], A. Granitzny[2], S. Fritz[2], A. Fuchs[2], M. Miyazawa[1], and H. Sakaguchi[1]. *[1]Kao Corporation, Tochigi, Japan; and [2]Kao Germany GmbH, Darmstadt, Germany.*

The integrated testing strategy (ITS) developed by Kao covers three alternative models, namely h-CLAT, DPRA and DEREK, as a defined approach for the potency classification (EC3 < 2% = Strong; EC3 ≥ 2% = Weak; Non-sensitizer) of skin sensitization. To enable a quantitative risk assessment, especially for weak sensitizers, it is important to refine the potency estimation and to determine a specific point of departure (PoD). To address this issue, we developed a strategy combining the ITS and read-across using relevant analogues with LLNA data. Firstly, the ITS for a target chemical was performed to classify the sensitizing potency. The confidence in the ITS was evaluated based on predictive limitations. In a second step, read-across was performed to identify suitable analogues of the target, using four *in silico* tools (ToxGPS, ToxRead, OECD TB, TIMES-SS). By comparing the analogue LLNA data with the ITS result, the level of confidence in the ITS outcome was increased and a specific PoD was derived. To determine the applicability of the novel strategy, we performed two case studies, using weakly sensitizing cosmetic ingredients with known EC3 values, namely HC Blue No. 12 (EC3 = 5.0%) and 2,4-Diaminophenoxyethanol HCl (EC3 = 3.2%). The ITS correctly predicted both case study chemicals as EC3 ≥ 2%, indicating a high level of confidence in the classification. The identified analogue for HC Blue No. 12, namely HC Blue No. 2, showed a PoD (EC3 = 4.1%) that was close to the true EC3 of the target. Based on a comprehensive weight of evidence, the identified analogue EC3 value could serve as a relevant PoD for the target. The EC3 of 14.7% of 1,3-Bis-(2,4-Diaminophenoxy) Propane HCl, the identified analogue of Diaminophenoxyethanol HCl, was overpredicted by the ITS with an EC3 < 2%. Moreover, the results obtained from the *in vitro* tests and *in silico* predictions were inconsistent for the case study chemical and its analogue. These uncertainties led us to the conclusion that a lower limit of EC3 = 2% could serve as relevant target PoD. This value is more conservative than the true EC3 of the target. In summary, our case studies indicate that our novel strategy could be useful to estimate the skin sensitization potency of cosmetic ingredients sufficiently conservative.

1419 Development of QSAR Modeling for hERG Blockers and Protectors Using Large Datasets

M. Girireddy, and R. D. Saiakhov. *MultiCASE Inc., Beachwood, OH.*

hERG (human ether-a-go-go related gene) potassium channel is blocked by numerous structurally and functionally unrelated drugs, leading to life-threatening arrhythmias and cardiac death. It also leads to prolonged QT intervals. This made drugs of diverse chemical structures to be withdrawn from the market. Having a good prediction model with high coverage and accuracy would help in accurate identification of hERG blockers. Currently there are multiple QSAR models on hERG inhibition, each with a different approach. Our set of hERG models include hERG Blockers which helps in prediction of chemicals that block the potassium channel thereby causing long QT intervals and hERG Protectors which predicts if the chemical diminishes the potassium channel block and protects against long QT syndrome. The datasets are collected from various research papers and pubchem assays. The dataset for hERG Blocker started with 306895 (8723 positives, 298172 negatives) records and ended with a 12537 (5769 positives, 6768 negatives) training set and 3495 external set records. Similarly, hERG protectors started 305679 (1552 positives, 304127 negatives) records and ended with 2381 (1206 positives, 1175 negatives) training set and 622 external set records. Even though the dataset is reduced in its size because of smaller number of actives and curation of salts and mixtures, functionality of all the excluded chemicals are covered during the model building process by the addition of extra chemicals causing "out of domain" calls. These models can identify most of the common drugs withdrawn from the market accurately i.e. Cisapride, Sertindole, Terfenadine, Astemizole etc. The results for external validations of hERG Blockers model are 93% sensitivity, 93% specificity, 92% positive accuracy, 94% negative accuracy, 94% coverage, 0.954 ROC. With bootstrap cross validations, model exhibited 92% sensitivity, 90% specificity, 89% positive accuracy, 93% negative accuracy, 93% coverage, 0.942 AUC. The results for external validations of hERG Protectors model are 71% sensitivity, 71% specificity, 72% positive accuracy, 69% negative accuracy, 78% coverage, 0.726 ROC. With bootstrap cross validations, model exhibited 65% sensitivity, 68% specificity, 70% positive accuracy, 63% negative accuracy, 70% coverage, 0.669 AUC. This predictivity is higher than many of the currently available hERG models. Thus, we successfully built highly interpretable and accurate QSAR model for hERG.

1420 *In Vitro* Buccal Membrane Absorption Model for Tobacco Constituent Testing: Membrane Integrity Assay Assessment

M. E. Kraeling[1], K. Hieber[1], R. L. Jones[1], R. Justiniano[1], C. Vaught[1], D. Lauterstein[2], J. Crespo-Barreto[2], R. L. Sprando[1], R. Weil[2], R. P. Yeager[2], and J. J. Yourick[1]. *[1]US FDA/CFSAN, Laurel, MD; and [2]US FDA, White Oak, MD.*

Assays to provide information on chemical hazards and the influence of harmful and potentially harmful constituents (HPHCs) of tobacco on buccal permeability and absorption via the buccal pathway are sparse in the literature. Therefore, an *in vitro* buccal membrane absorption model (IVBMAM) was developed using porcine buccal mucosa as a tissue surrogate for human buccal mucosa given similarities in morphology and permeability. The model was developed by adapting *in vitro* dermal absorption methodologies. Membrane integrity assays were compared for use in validating test tissues. Porcine buccal mucosa was isolated from connective tissue and cut with a dermatome to a thickness of 400-500 µm. Buccal mucosa was mounted in flow-through diffusion cells and saliva permeability coefficients (Kp) were measured using tritiated artificial saliva, pH 7.7. The average baseline Kp value for porcine buccal mucosa using tritiated saliva was 2.5×10^{-2} cm/h (n = 6). The average baseline Kp value for porcine and human skin using tritiated saliva was 3.7×10^{-3} cm/h (n = 3) and 2.7×10^{-3} cm/h (n=3), respectively. Saliva Kp values were compared to transepidermal water loss (TEWL) and transepithelial electrical resistance (TEER) measurements to determine baseline criteria for the IVBMAM and dermal tissues. Buccal mucosa mounted on transwell plates exhibited average normalized TEER levels of 114.7 Ωcm^2, compared to 78.4 Ωcm^2 for porcine skin and 78.6 Ωcm^2 for human skin. TEWL values for the buccal mucosa averaged 67.3 $g/m^2/h$, compared to 40.9 and 6.1 $g/m^2/h$ for porcine and human skin, respectively. Saliva Kp values were over 10-times higher in buccal mucosa compared to skin (porcine and human). TEWL values were over 1.5-times higher in buccal mucosa compared to porcine skin and 10-times higher than human skin. TEER values for the buccal mucosa were about 1.5-times higher than the skin values. TEER values did not correlate with membrane integrity as measured by Kp and TEWL. Therefore, TEWL may be a better non-radiolabled measure of membrane integrity than TEER for this IVBMAM. *Supported in part by Oak Ridge Institute for Science and Education. Disclaimer: This presentation is not a formal dissemination of information by US FDA and does not represent Agency position or policy.*

1421 The Utility of a Human *In Vitro* Population-Based Model for Studies of Epigenetic and Genotoxic Mechanisms

L. Lewis[1], Z. Chen[1], S. Goodman[1], J. Matyjasiak[1], L. Erber[2], N. Tretyakova[2], and I. Rusyn[1]. *[1]Texas A&M University, College Station, TX; and [2]University of Minnesota, Minneapolis, MN.*

Genetic variability has a major impact on susceptibility to chemical exposures, yet there are few experimental models that address inter-individual variability, a critical need in hazard and risk assessment. We have previously demonstrated inter-individual variability in epigenetic effects and genotoxicity using a mouse population approach and a model known human carcinogen, 1,3-butadiene. Although data from an *in vivo* mouse model are important, they require animal experiments and species extrapolation. In this study, we tested a human *in vitro* population-based model as an experimental approach to assess and quantify variability in epigenetic alterations and genotoxicity in response to 1,3-butadiene metabolites. Specifically, we tested the hypothesis that a population-based model of human lymphoblasts and human pluripotent stem cells from a diverse set of individuals can be used to evaluate inter-individual variability in epigenetic and genotoxic effects of chemicals. We conducted a concentration-response screening of three butadiene metabolites (1,2-epoxybutene, 1,2,3,4-diepoxybutane and 3,4-epoxy-1,2-butanediol) in panels of human lymphoblasts and pluripotent stem cells from 100 and 30 individuals, respectively, that also included both sexes. Lymphoblast lines were from the 1000 Genomes Project and represented 9 populations of European, African, Asian, and admixed ancestry. The pluripotent stem cells were from the California Institute for Regenerative Medicine Induced Pluripotent Stem Cell Repository and represented 4 populations of African, Asian, Hispanic, and Caucasian. We evaluated 1,3-butadiene-induced cytotoxicity by measuring cell viability. Population variability in response to 1,2,3,4-diepoxybutane was most pronounced. However, there was minimal variability in the effects of 1,2-epoxybutene and 3,4-epoxy-1,2-butanediol. Next, we selected 10 pluripotent stem cells and 10 lymphoblast cell lines based on the variability in responses to cytotoxicity. Genotoxicity was evaluated by measuring N-7-(2,3,4-trihydroxybut-1-yl)-guanine adducts. For assessment of the changes in chromatin states, we used the assay for transposase accessible chromatin (ATAC) followed by sequencing. In addition, transcriptomic changes were assessed by using Tempo-seq. Overall this work evaluates the use of a novel human *in vitro* population-based model, which could serve as a valuable tool for high-throughput chemical screening to assess human risks of chemical exposure.

1422 Inter- and Intra-Laboratory Reproducibility of a Three-Dimensional Model of Human Buccal Tissue

M. Klausner[1], Y. Kaluzhny[1], Y. Handa[2], and S. Aizawa[3]. *[1]MatTek Corp, Ashland, MA; [2]Kurabo Industries Ltd., Neyagawa, Japan; and [3]Lion Corporation, Idawara, Japan.*

Human 3D tissue models of the human oral epithelia have been developed as alternatives to animal testing. These models are powerful tools for investigating basic biological function in response to various challenges including oral care products and environmental insults. To evaluate inter-laboratory reproducibility of the commercially available 3D buccal epithelial model, EpiOral, MTT tissue viability was monitored. Tissues were shipped to Lion Corp (Idawara, Japan) and Kurabo Industries (Osaka, Japan) and the MTT values for negative control (NC) tissues (exposed to ultrapure water, 60 min) and the time to reduce tissue viability to 50% (ET-50), following exposure to 1% Triton X-100, were determined. NC tissues gave an average MTT value of 1.633 (n=15 lots) and 1.829 (n=11) at Lion and Kurabo, respectively, in independent tissue lots; tissues packaged and stored overnight at MatTek gave NC values of 1.545 (n=22 lots). ET-50 of tissues tested at Lion and Kurabo averaged 64.3 ± 12.9 (n=15) and 54.7 ± 10.3 (n=11) min, respectively; tissues tested at MatTek gave 79.6 ± 13.7 min (n=22). All lots tested in Japan and the US fell within the acceptance QC range for the NC (MTT > 1.0) and ET-50 (34.8-105.8 min). In addition, histology of non-cornified buccal tissue produced in 2019 was highly reproducible (n=22 lots). For intra-laboratory reproducibility, functional analysis was performed by exposing the tissues to two inducers in independently produced tissue lots (n=3). Tissues were exposed to TNF-α/IL-1β to induce an inflammatory response or to 2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD) to evaluate xenobiotic metabolism. Adenylate kinase release, MTT activity, pro-inflammatory cytokine release and xenobiotic phase I enzyme expression were analyzed. Exposure of the oral tissues to the inflammatory inducers, TNF-α/IL-1β, showed statistically significant increases in secreted IL-8, IP-10, and MMP-1. TCDD induction also showed increased gene expression of the Phase I metabolism enzymes, CYP1A1 and CYP1B1. Overall, excellent reproducibility was observed for MTT and adenylate kinase endpoints over n=3 independent lots. In addition, reproducible trends in cytokine release and gene expression versus the NC tissues were observed in the n=3 tissue lots. In summary, the EpiOral model exhibited good inter-lab and intra-lab reproducibility and can serve as a tool to reduce animal experimentation for oral toxicity studies.

1423 Acute Oral Toxicity *In Silico* Models: Performance on Pharmaceutical Compounds

M. Rodas[1], and J. C. Graham[2]. *[1]St. John's University, Jamaica, NY; and [2]Bristol-Myers Squibb Company, New Brunswick, NJ.*

Acute oral toxicity (AOT) is generally defined by an LD50 which represents median lethal dose expected to cause death in 50% of animals (mg/kg) after an acute exposure. AOT hazards are generally conveyed on safety data sheets via GHS categories (United Nations Globally Harmonized System of Classification and Labeling of Chemicals), which are assigned based on the LD50 value as follows: Category 1: LD50 ≤5mg/kg; Category 2: 5<- ≤50mg/kg; Category 3: 50<-≤300mg/kg; Category 4: 300<-≤2000mg/kg; Category 5: 2000<-≤5000mg/kg. *In vivo* AOT studies are required by regulatory authorities with limited alternatives being accepted. AOT *in silico* models have been trained and validated utilizing publicly available data on common chemicals, which tend to be less complex PCs (pharmaceutical intermediates and APIs). Two AOT *in silico* models were evaluated within the PC space utilizing historical *in vivo* AOT data for >350 PCs. The *in silico* programs evaluated included the Leadscope AOT Suite (Leadscope) and the Collaborative Acute Toxicity Modeling Suite (CATMoS). Leadscope employs both an expert-alerts model and a statistical-based model to predict GHS AOT categories. Statistical-based models are generally referred to as Quantitative Structure-Activity Relationship (QSAR) models which predict toxicity endpoints using the chemical structure. Expert-rule-based platforms utilize expert knowledge of the structure to create rules around the likelihood of the compound to evoke toxicity. CATMoS has a QSAR prediction tool for five endpoints: Very-Toxic (LD50<50 mg/kg), Non-Toxic (LD50>2000 mg/kg), EPA Categories, GHS Categories, and LD50 point estimates. Structural files for >350 PCs were obtained and input into each *in silico* model and the AOT predictions were compared to historical data for each PC. It was found that 95% (365/384) of PCs fell within the CATMoS applicability domain and 88% (338/384) of the PCs fell within the Leadscope applicability domain (99% were covered by both mod-

els). The best overall accuracy was similar in the Leadscope statistical model (45%) and the CATMoS GHS Model (46%). Both programs exhibited low accuracy for the most hazardous compounds with the CATMoS VT model also showing 0% accuracy. The preferred model for worker safety purposes was Leadscope which accurately or over-predicted the GHS category for >90% (303/338) of compounds in domain. CATMoS, had a higher under-prediction rate of 28% (GHS model) and 18% (LD50 model).

1424 Generation of Novel *In Chemico/In Vitro* Skin Sensitization Data to Evaluate the Human Relevance of Defined Approaches

D. S. Macmillan[1], M. L. Chilton[1], G. Pastore[2], E. Montague[2], D. Bramham[2], and D. Kidd[2]. *[1]Lhasa Limited, Leeds, United Kingdom; and [2]Covance Laboratories Limited, Harrogate, United Kingdom.*

Skin sensitisation, leading to allergic contact dermatitis, is a common occupational health problem. Consequently, chemicals in products intended for human use must be assessed for their skin sensitisation potential. Traditionally this assessment has been carried out using *in vivo* assays like the murine local lymph node assay (LLNA), however, political and ethical pressure has led to increased use of non-animal alternatives such as *in chemico* and *in vitro* assays. Results from multiple information sources (non-animal assays, *in silico* models, physicochemical parameters) are often combined in what is known as a defined approach (DA). It can be difficult to assess how well DAs predict human skin sensitisation potential as the amount of publicly available *in chemico/in vitro* data with corresponding human data is sparse. As such, a collaborative project was devised whereby chemicals lacking *in chemico/in vitro* data but with human potency data would be identified and new *in chemico/in vitro* data generated - ideally to test the relationship between *in chemico/in vitro* data and human potency. Human data were taken from two publications which assigned a human potency category between 1 (extreme sensitiser) and 6 (non-sensitiser) to mainly fragrance-like chemicals based on human repeat insult patch test data, clinical data, and exposure. 80 chemicals were found with no or limited *in chemico/in vitro* data and of these, 34 were commercially available at a reasonable cost. These 34 were then prioritised into three groups based on the availability of LLNA data and (lack of) *in chemico/in vitro* data. The first group consisted of 8 chemicals and so far during this collaboration, DPRA, KeratinoSens™, and h-CLAT data have been generated using blind testing for this group. The predictivity of the individual assays when compared against LLNA data was between 50% - 88% and between 38% - 75% when compared against human data. When these novel data are used within 3 published DAs, the BASF 2/3, Kao ITS, and Lhasa DA, the predictivity against *in vivo* data ranges from 38% - 88%.

1425 Evaluation of the Impact of Cigarette Smoke and THS 2.2 Aerosol Exposure on Tooth Coloration and Chemical Identification of Discoloration Markers

F. Zanetti[1], A. Haiduc[1], P. A. Guy[1], W. K. Schlage[2], X. Zhao[3,4], S. Majeed[1], N. V. Ivanov[1], M. C. Peitsch[1], R. Yanfang[3], and J. Hoeng[1]. *[1]Philip Morris International, Neuchatel, Switzerland; [2]Biology Consultant, Bergisch Gladbach, Germany; [3]University of Rochester Eastman Institute for Oral Health, Rochester, NY; and [4]Peking University School of Stomatology, Beijing, China.*

Tobacco smoking is a risk factor for tooth discoloration. Pigmented compounds present in the particulate phase generated by combustion of tobacco may cause discoloration of dental hard tissues and restorative materials; the effect of exposure to aerosol from heated tobacco on tooth discoloration have not yet been explored. This study aimed to test if aerosol from a candidate modified risk tobacco product (MRTP), the Tobacco Heating System (THS) 2.2 (Philip Morris Products S.A.), had less impact on the color of dental hard tissues and composite resin restorations than cigarette smoke (CS) and, for the first time, to characterize potential markers of tobacco smoke-induced discoloration deposited on the enamel surface. First, 22 extracted human premolars restored with composite resins (Filtek™ Supreme Ultra) were exposed to cigarette smoke (3R4F reference cigarettes; University of Kentucky) and THS 2.2 aerosol for 3 weeks (56 min/day). The teeth were brushed with regular toothpaste every week, after which the enamel, dentin, and composite resins were measured for color. Second, for evaluation of discoloration markers, 60 bovine enamel blocks were exposed to the total particulate matter (TPM) of CS or THS 2.2 aerosol or to artificial saliva (control) for 2 weeks. Brushing (without toothpaste) and color measurements were performed every week. Noticeable discoloration of enamel, dentin, and composite resins was observed following exposure to CS (whole smoke or TPM). The discoloration was not distinguishable by eye ($\Delta E<3.3$) following exposure to THS 2.2 (whole aerosol or TPM), and no color mismatch between teeth and restorative materials was observed. To identify potential discoloration markers, surface-deposited chemicals were extracted using carbon disulfide solvent. Untargeted analyses using gas chromatography coupled to time-of-flight mass spectrometry were followed by PLS correlation against discoloration results obtained from CS TPM exposure (Pearson correlation of R^2=0.96). Eleven compounds were highlighted with a variable in projection (VIP) score above 2. Their identity searched through NIST17 library, after discriminant autocorrelation matrix of their mass spectral information, revealed a strong pattern association of the terpenoids family and no relationship to nicotine. In THS 2.2 TPM exposed samples, several of these compounds were also detected but at lower level, in line with the lower discoloration observed. Compared with CS TPM exposure, THS 2.2 TPM exposure resulted in lower deposition of color-related compounds on enamel surface, consistent with minimal discoloration of dental hard tissues and restorative materials.

1426 Computational Mining of Public Toxicogenomic Data Provides Insights into Liver Steatosis Adverse Outcome Pathway

M. AbdulHameed[1,2], V. Pannala[1,2], and A. Wallqvist[1]. *[1]US Army Medical Research and Development Command, Fort Detrick, MD; and [2]Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD.*

Exposure to certain chemicals can induce steatosis or fatty liver in humans. The adverse outcome pathway (AOP) framework aims to assist in the development of alternatives to animal testing, which will enable rapid screening and identification of such chemicals. In the current steatosis AOP, the activation of nuclear receptors, is considered the molecular initiating event (MIE) due to their ability to modulate lipid synthesis and transport. To be useful, however, this AOP needs to be evaluated using diverse steatogenic chemicals. Here we mined large, publicly available, toxicogenomic datasets obtained from rat *in vivo*, rat *in vitro*, and human *in vitro* studies involving exposure to 18 known steatogenic chemicals, including amiodarone and valproic acid, at different doses and time points of exposures. We identified differentially expressed genes (DEGs) associated with each chemical exposure, and then used them to perform pathway enrichment analysis and analyze the activation of steatosis MIEs. The most frequently identified DEGs in rat *in vivo* studies were those indicative of oxidative stress, such as *Aldh1a7*, *Aldh1a1*, *Akr7a3*, *Akr1b7*, and *Gsta3*, which are commonly associated with mitochondrial toxicity. Our MIE analysis revealed that exposure to these steatogenic chemicals led to the absence of activation of genes involved in lipid synthesis and transport, indicating that the causal links between the current MIEs and steatosis are insufficient. We identified eight DEGs (*Cyp1a1*, *Egr1*, *Ccnb1*, *Gdf15*, *Cdk1*, *Pdk4*, *Ccna2*, and *Ns5atp9*) and one pathway (retinol metabolism), which were conserved across the three test systems (rat *in vivo*, rat *in vitro*, and human *in vitro*). Such steatosis-relevant molecular mediators are likely to be relevant to human exposures. Collectively, our analyses suggest that mitochondrial toxicity is an important and overlooked MIE in chemical-induced steatosis. Our computational mining approach provides an important means to assess AOP development, identify knowledge gaps, suggest ways to improve AOPs, and aid the development of new screening tools.

1427 Linking Co-regulated Gene Modules with Polycyclic Aromatic Hydrocarbon-Related Cancer Risk (RPF) in the 3D Human Bronchial Epithelium

Y. Chang[1], K. M. Bastin[1], C. T. Huynh[1], J. E. Rager[2], and S. C. Tilton[1]. *[1]Oregon State University, Corvallis, OR; and [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Polycyclic aromatic hydrocarbon (PAH) exposures are linked to numerous adverse outcomes in humans, with cancer as the greatest concern. The cancer risk associated with PAH exposures is commonly evaluated using the relative potency factor (RPF) approach, which estimates PAH mixture carcinogenic potential based on the sum of relative potency estimates of individual PAHs, compared to benzo[a]pyrene (BAP), a reference carcinogen. This study set out to combine a novel 3D human *in vitro* bronchial epithelial cell (HBEC) model with transcriptomic and bioinformatic approaches to evaluate molecular mechanisms of direct relevance to PAH cancer risk. Significantly regulated genes from HBEC treated with PAHs and PAH mixtures were analyzed using a two-tiered WGCNA approach, first to identify co-modulated gene sets significantly correlated to RPF, and then to link genes to a more comprehensive list of regulatory values, including inhalation-specific risk values. Conditional Toxicity Value (CTV) Predictor was used to predict risk and toxicity values for chemicals present in mixtures with unavailable data. Over 3,000 genes from

cell cycle regulation, inflammation, DNA damage, and cell adhesion processes were found to be significantly correlated and co-modulated with increasing RPF (BAPeq). Benchmark dose modelling in BMDExpress 2 with a dose response of benzo[a]pyrene further identified DNA damage, cell adhesion, and cell cycle regulation (S phase) among the most sensitive pathways for gene regulation. Next, co-modulated genes were linked to additional cancer-relevant risk values, including inhalation unit risks and oral cancer slope factors. Gene modules significantly correlated in common between RPF, oral cancer slope factors, and IARC cancer categorizations were identified. These gene sets represent potential biomarkers that can be used to evaluate cancer risk associated with PAH mixtures. Here, we demonstrated a novel manner of integrating gene sets with chemical toxicity equivalence estimates through WGCNA to understand potential mechanisms. Similar studies could further inform cancer risk evaluations and assessments by incorporating organotypic human *in vitro* models with additional endpoints and risk values associated with chemical exposures.

1428 Utilizing Adverse Outcome Pathways as a Framework to Organize Evidence and Support Carcinogenicity Risk Assessment

S. A. Stalford, A. N. Cayley, R. Foster, S. Kane, and R. V. Williams. *Lhasa Limited, Leeds, United Kingdom.*

The ICH S1 guidelines relate to the assessment of human carcinogenicity risk for new pharmaceuticals. To satisfy this guidance, rodent carcinogenicity studies are routinely carried out. However, these tests are time consuming, expensive and use a lot of animals. Moreover, they do not always produce results of human relevance. In order to alleviate these shortcomings, recent proposals for changes to the guidance suggest using a weight of evidence (WOE) approach. This method involves collating evidence from other relevant sources, such as genotoxicity assays, chronic repeat dose studies and knowledge of pharmacology, in order to categorise human carcinogenic risk. The results may then negate the need for a rodent carcinogenicity study. One challenge in using WOE is the organisation and interpretation of this disparate information in a consistent way to reach a meaningful conclusion. A potential solution is to use an adverse outcome pathway (AOP) framework. This enables the organisation of knowledge and data in a transparent and logical manner to support decision making. In this work we utilised a previously developed network containing 38 AOPs for carcinogenicity and integrated assays, data, models and knowledge of human relevance in order to investigate the use of AOPs to support assessment. Overall, 70 assays were linked to appropriate key events. Several case studies were then examined, using assay data, *in silico* models and knowledge contained within the network to reach a conclusion and, where needed, reason between results when multiple pathways are implicated. The categorisation of these outcomes according to ICH S1 were then compared to results based on a conservative approach which uses unstructured data alone. Our work shows that evidence relating to carcinogenic risk can be organised into an AOP framework, making it easier to interpret and reason between data, models and knowledge. Preliminary validation shows that network analysis can allow for more accurate interpretation of carcinogenic risk than using unstructured data alone and thus reasonably negates the requirement for a rodent carcinogenicity study where appropriate. The approach also allows for additional knowledge beyond assay results to be captured, which may put conclusions into context and save time, money and animals.

1429 PhIP Exposure: Alzheimer's Disease Relevant Neurotoxicity

T. Syeda, R. M. Foguth, and J. R. Cannon. *Purdue University, West Lafayette, IN.*

Alzheimer's disease (AD) is a neurodegenerative disease characterized by two hallmark pathologies: accumulation of extracellular senile plaques composed of amyloid-beta peptide (Aβ) and intracellular neurofibrillary tangles. AD is a major public health crisis given the prevalence and lack of curative treatment and thus, it is critical to identify modifiable risk factors that could decrease risk of disease or disease course. The role of the diet in AD has received recent attention, with several studies suggesting that high levels of meat consumption may increase AD risk. Much of our prior work has shown that exposure to heterocyclic aromatic amines (HAAs) produced Parkinson's disease (PD)-relevant neurotoxicity. Given mechanistic and pathological overlap between AD and PD, we investigated whether exposure to 2-amino-1-methyl-6-phenylimidazo [4,5-b]pyridine (PhIP), a prevalent dietary HAA formed during high temperature meat cooking, may produce AD-relevant neurotoxicity. In the present study C57BL/6 mice were treated with 100mg/kg or 200mg/kg PhIP for 8h (single oral gavage) or 75mg/kg for 4 weeks and 16 weeks (oral gavage, 3 times/week). PhIP exposure for 8h resulted in increased acetylcholine, oxidative stress, synaptic proteins and β-Site amyloid precursor protein cleaving enzyme 1 (BACE 1), in the hippocampus. PhIP exposure for 4 weeks resulted in increased BACE 1 and oxidative stress in hippocampus. PhIP exposure for 16 weeks resulted in increased BACE 1, Aβ aggregation, tau phosphorylation and oxidative stress in hippocampus, all hallmark features of AD. Quantification of intracellular nitrotyrosine revealed oxidative damage in cholinergic neurons after 8h and 16 weeks PhIP exposure. PhIP exposure did not induce inflammation in the hippocampus. Furthermore, SH-SY5Y cells and primary cortical neurons exposed to PhIP also exhibited increased BACE 1 and oxidative stress. Our study demonstrates that PhIP exposure induces neurotoxicity similar to that seen in AD. *In vitro* studies also imply that increase in oxidative stress and BACE 1 might be a possible mechanism by which PhIP promotes Aβ aggregation. Collectively, our study suggests a potential link between diets high in HAAs and AD.

1430 Exposure to an Environmentally Relevant Level of Copper in Drinking Water Alters the Microbiome in a Humanized APP Knock-In Mouse Model of Alzheimer's Disease

J. Vidal[1], C. J. Rodriguez-Ortiz[1], S. Shiferaw[1], H. Katagiri[1], T. Saito[2], T. C. Saido[2], and M. Kitazawa[1]. *[1]University of California Irvine, Irvine, CA; and [2]RIKEN Center for Brain Science, Wako, Japan.*

While aging and genetics are the primary risk factors of Alzheimer's disease (AD), exposure to environmental factors are also known to modulate the disease pathology. Chronic exposure to copper is a putative environmental risk factor for AD. Recent epidemiological studies highlight that high serum levels of labile copper correlate with cortical thinning, accelerated cognitive decline, and earlier onset of AD. Although copper is an essential metal, environmental exposure to its inorganic cupric form (Cu^{2+}) may exert toxicity. However, exact toxic mechanisms of action of copper leading to AD remain largely undetermined. Here, we investigate its impact on the gut microbiome, as copper is a natural antimicrobial, and is normally ingested. Recent studies implicate gut dysbiosis in the onset and progression of AD in both humans and animal models. We hypothesized that chronic exposure to environmentally relevant copper through drinking water will alter a healthy composition of the gut microbiota in APP^{NL-G-F} knock-in (APP-KI) mice. Dysbiosis may perturb host metabolism and inflammatory homeostasis to contribute to AD neuropathology. Three-month-old male and female APP-KI and wildtype C57BL/6J mice were exposed to 1.3 ppm $CuCl_2$ in drinking water ad-libitum for 3 months. Fecal matter was sampled monthly and DNA was isolated for amplicon sequencing of the 16s rRNA V4 region. At sacrifice, blood and brain tissue were harvested. The brain was subject to standard techniques for immunohistochemistry and biochemistry. Plasma was analyzed for cytokines. Copper had no significant effect on the microbiota of WT mice. APP-KI mice had a higher Bacteroidetes to Firmicutes ratio due to an increase in the genus *S24-7* and decrease in the genus *Allobaculum* respectively. No significant differences were seen in plasma cytokines. Similarly, no significant change in amyloid plaque burden was detected in the brain of APP-KI mice. The microbiome of APP-KI mice is less resilient to effects of copper compared to WT mice. These results suggest that certain bacterial populations in the gut are sensitive to environmental agents and longer exposures with older animals may elucidate associations to AD.

1431 Chronic Exposure to Real-Time Traffic-Related Air Pollution Exacerbates and Accelerates Alzheimer's Disease Phenotypes in Wild-Type and TgF344-AD Rats

K. T. Patten[1], A. E. Valenzuela[1], C. Wallis[2], K. J. Bein[1], A. S. Wexler[1], and P. J. Lein[1]. *[1]University of California Davis, Davis, CA; and [2]Air Quality Research Center, Davis, CA.*

Traffic-related air pollution (TRAP) has been linked to increased risk of Alzheimer's disease (AD) or dementia in multiple epidemiological studies. However, this association has yet to be confirmed preclinically, in part because reproducing chronic real-world TRAP exposures is challenging in animal models. To overcome this challenge, we exposed male and female TgF344-AD and wildtype F344 (WT) rats to real-time TRAP or filtered air (FA) from postnatal day 28 to 15 months of age in an exposure facility that drew air from an adjacent highway tunnel in northern California. This preserved the particulate, gaseous, and semivolatile components of TRAP, and exposed animals to human-relevant TRAP concentrations. We hypothesized that TRAP triggers neuroinflammation to accelerate or exacerbate AD-relevant outcomes. At 3, 6, 10, and 15 months of age, brain samples were collected and analyzed for amyloid plaque burden, neuronal cell loss, glial cell activation, and cytokine protein levels. Amyloid plaques were detected in the brain of TRAP-exposed

TgF344-AD female rats at 3 months of age, prior to plaque development in any group, and both male and female TRAP-exposed TgF344-AD rats showed increased plaque burden at 6 and 15 months of age compared to FA controls. Amyloid plaques were not detected in WT rats. ELISA revealed that TRAP also significantly increased levels of triton-soluble Aβ42:Aβ40 in TgF344-AD rats, a parameter that is highly correlated with cognitive decline in humans. Both WT and TgF344-AD rats also exhibited increased neuronal cell loss at 15 months compared to age- and sex-matched FA-exposed controls. Interestingly, male WT, but not TgF344-AD rats exposed to TRAP showed cognitive deficits at 15 months of age. TRAP increased IBA1, but not GFAP, immunoreactivity in rats of both sexes in both genotypes, suggesting selective effects on microglia vs. astrocytes. Levels of pro- and anti-inflammatory cytokines, as quantified by Luminex, were also altered in TRAP-exposed rats at 3 and 6 months of age in a sex-dependent manner. Collectively, these findings demonstrate that chronic TRAP exposure exacerbates and accelerates several AD-relevant endpoints, and suggest that these pathologic responses may be mediated by microglial activation. *Supported by the NIEHS (grants R21 ES025570, P30 ES023513 and T32 ES007059) and NIA (grant P30AG010129).*

1432 Distinct N6-Methyladenosine Profiles in mRNA Caused by $CoCl_2$ *In Vivo* and *In Vitro*

J. Tang, C. Zheng, Q. Su, F. Zheng, Z. Guo, Y. Wang, P. Cai, W. Shao, H. Li, and S. Wu. *Fujian Medical University, Fuzhou, China.*

N6-methyladenosine (m^6A), which mainly occurs in brain tissues and concentrates on mRNA of genes related to cortical neurogenesis, cell cycle and neuron differentiation, thus playing an important regulatory role in the development and function of the central nervous system. Our previous study found that expose to cobalt *in vitro* and *in vivo* would cause neurodegenerative damage. In this study, we used human brain neuroblastoma cells (H4 cell) ($CoCl_2$; 400μM) and animal models ($CoCl_2$; 16 mg/kg) to test the neurodegenerative changes induced by cobalt. We have carried out an unbiased global analysis of m^6A in mRNA of mouse temporal cortex and human brain neuroblastoma cells. We show that there are intriguing differences in these samples with respect to the degree of methylation, functional classification of methylated transcripts. Specifically, we observe a pronounced ccumulation of m^6A sites in the vicinity of the translational stop codon. We also analyze potential correlations between m^6A and RNA target sites, binding sites of RNA binding proteins. In summary, our data confirm that by altering the original m^6A level, $CoCl_2$ disrupts the expression of some key genes and affects some important signaling pathways, thereby participating in the neurotoxicity caused by cobalt chloride. Our study provides a new basis for the future research on the neurotoxicity caused by m^6A modification involved in cobalt chloride. *This work was supported by National Natural Science Foundation of China (No. 81573195; 81973083); Fujian Province Science and Technology Innovation Joint Fund Project (No. 2017Y9105).*

1433 Chronic Copper Exposure Perturbs Microglial Transcriptomics Signatures in Wild-Type and Mouse Model of Alzheimer's Disease

S. Lim[1], H. Hsu[1], J. Zumkehr[1], J. Kilian[1], J. Vidal[1], P. Ayata[2], A. Schaefer[2], C. Rodriguez-Ortiz[1], and M. Kitazawa[1]. *[1]University of California Irvine, Irvine, CA; and [2]Icahn School of Medicine at Mount Sinai, New York, NY.*

Copper (Cu) is an essential metal that mediates a variety of biological reactions with its redox property. Cellular homeostasis of Cu is critical for human health as dyshomeostasis may lead to neuronal damage caused by subsequent impairment in biosynthesis of neurotransmitters, antioxidant defense, immune function, and synaptic transmission. Intriguingly, recent emerging evidence indicate that chronic exposure to Cu and its dyshomeostasis are linked to accelerated cognitive decline and increased risk for Alzheimer's disease (AD) and other dementias. We and others previously demonstrated that exposure to Cu through drinking water significantly increased parenchymal amyloid-beta (Aβ) plaques, aberrant microglial activation, and decreased endothelial low-density lipoprotein receptor-related protein 1 in mouse models of AD. In the present study, we continued to execute in-depth analysis of microglial transcriptomic changes and neuroinflammation in the brains of J20 transgenic mouse model of AD and wildtype (WT) littermate controls after exposing to 1.3 ppm Cu-containing drinking water for 3 to 5 months starting at 1 month of age. While the overall Aβ plaque burden at the early plaque stage of J20 mice remained unaffected by Cu exposure, microglial transcriptomes were markedly altered in Cu exposed mice even in pre-pathological stage at 4 months of age. The homeostatic signature genes were generally reduced while the cluster of degenerative genes was elevated in microglia-specific transcripts collected from intact brain tissues using translating ribosome affinity purification (TRAP) technique. Global RNA-seq analysis also revealed that inflammation- and cytokine-related genes were differentially expressed in microglia from Cu exposed mice. Notably, the Cu exposed mice also exhibited impaired cognitive function, which could potentially be mediated by exacerbated microglial dysfunction and neuroinflammation in the brain. These results collectively implicate that chronic Cu exposure triggered persistent transcriptomic and functional changes in microglia and induced neuroinflammation in either plaque-free WT mice or pre/early-plaque stage J20 mice.

1434 Discovery, Structure-Activity Relationship Study, and *In Vivo* Evaluation of Novel Series of Mono-amine Transporter Inhibitors

M. Ashraf-Uz-Zaman[1], G. Ji[2], K. Alvina[3], M. Sajib[1], C. M. Mikelis[1], M. Avila[2], V. Neugebauer[2], and N. German[1,2]. *[1]Texas Tech University Health Sciences Center, Amarillo, TX; [2]Texas Tech University Health Sciences Center, Lubbock, TX; and [3]Texas Tech University, Lubbock, TX.*

Monoamines, such as dopamine (DA), serotonin (5-HT) and norepinephrine (NE), have an important modulatory role in neurotransmission in the central nervous system (CNS). They are involved in numerous physiological functions and pathological conditions. Therapeutic application of selective or mixed monoamine transporter (DAT, SERT or NET) inhibitors include a variety of neurologic disorders, such as Parkinson's disease, Alzheimer's disease, multiple sclerosis, epilepsy, and others. The optimal selectivity profile varies between pathological conditions; however, the exact trend is not well understood yet. Thus, for direct comparison of produced effects, it can be beneficial to identify a class of compounds that includes structurally similar ligands with different selectivity profiles. Recently, we have serendipitously discovered a novel selective DAT inhibitor. Our compound UR118 showed strong DAT inhibition (Ki= 15 nM) with a moderate affinity to SERT (Ki= 1620nM). We design and synthesized a series of analogs of UR118 to initiate a structure-activity relationship (SAR) study. From the first series of analogs, we obtained selective DAT inhibitors (Ki= 40), as well as DAT-NET inhibitors (Ki= 6.5 and 167 nM, respectively). In addition to inhibition of transporters, UR118 blocked signaling of H1 (Ki= 32nM) and 5HT-2C (Ki= 335 nM) receptors. Further, this compound did not affect the remaining 45 GPCRs in the tested panel of CNS-related receptors. All tested analogs of UR118 have shown similar binding patterns with different selectivity profiles (data obtained from PDSP). Further, UR118 was found to moderately permeate the BBB (C_{max} = 1000nM, 10 mg/kg, i.p in mice) with the accumulation in adipose tissue, lung, and liver. UR118 was stable in rat liver microsome (63% remaining at 1 hr.). In pertussis-induced multiple sclerosis model (mice), we observed a significant improvement of symptoms in the UR118-treated group when compared to the vehicle-treated group of animals. In conclusion, we have discovered a novel series of monoamine transporter inhibitors with varying selectivity profile and favorable CNS-drug-like characteristics. Compound UR118 with DAT selectivity has shown definite therapeutic potential in *in vivo* model of multiple sclerosis.

1435 Interaction of Endoplasmic Reticulum Stress and Inflammation in Amyloid-Beta-Induced Neurotoxicity

P. Goswami, S. Ahmad, and S. Raisuddin. *Jamia Hamdard, New Delhi, India.*

Amyloid-beta (Aβ) peptide accumulation in the brain is a pathological hallmark of Alzheimer's disease (AD). Amyloid-β protein has toxic effects on neurons and induces the activation of microglia as well as astrocytes. As evidences support the involvement of endoplasmic reticulum (ER) stress in AD and other neurological disorders; here we investigated the involvement of ER stress and its interaction with inflammation and glial cell activation in Aβ-induced neurotoxicity. $Aβ_{(1-42)}$ was administered bilaterally through intra-cerebro ventricular (icv) injection in the brain of Wistar rats. After completion of treatment, acetylcholinesterase (AChE) activity and amyloid aggregation was measured in hippocampus (HP) and cerebral cortex (CC) regions of rat brain. ER signaling proteins- glucose regulated protein 78 (GRP78), growth arrest and DNA damage-inducible gene 153 (GADD153) and eukaryotic translation initiation factor-2α (eIF2α), neuronal marker protein- microtubule associated protein-2 (MAP-2) and microglial marker protein- ionizing calcium-binding adaptor molecule-1 (Iba-1) were assessed by western blot. Pro-inflammatory cytokines viz. Interleukin-1β (IL-1β), Tumor Necrosis Factor-α (TNF-α) and Interferon-γ (IFN-γ) were measured using ELISA kits. Apoptotic death of neurons was determined by mRNA levels of caspase-12 and caspase-3. Histological changes were also observed. ER stress inhibitor salubrinal was used to assess the specific role of ER stress and its interaction with inflammation. $Aβ_{(1-42)}$ treatment caused a significant increase in AChE activity, amyloid aggregation, expression of ER stress marker proteins, microglial activation, cytokines levels, caspase-12 and caspase-3 mRNA levels which were attenuated with salubrinal treatment. $Aβ_{(1-42)}$-induced histological alterations and decrease in MAP-2 levels were also inhibited by salubrinal which indicates that ER stress interacts with other

pathological events leading to neurodegeneration. Results of present study implicate ER stress as potential molecular mechanism in Aβ-induced neuropathology which could further emerge as a possible therapeutic target in AD.

PS 1436 Paraoxonase-2 Deficiency in the Aging Brain: Immunological and Neurodegenerative Consequences

J. M. Garrick[1], K. Dao[1], T. B. Cole[1], and L. G. Costa[1,2]. *[1]University of Washington, Seattle, WA; and [2]Università degli Studi di Parma, Parma, Italy.*

Paraoxonase-2 (PON2) is a member of the paraoxonase family consisting of PONs 1, 2 and 3. Unlike PON1 and 3 which circulate in the body associated with HDL, PON2 is a ubiquitously expressed intracellular antioxidant enzyme located at the inner mitochondrial membrane, where it maintains redox balance and manages oxidative stress generated during cellular respiration. PON2 deficiency has been shown to have adverse consequences in the CNS *in vitro*, with deficient astrocytes and neurons having higher levels of reactive oxygen species (ROS) and subsequent cell death. As oxidative stress is increasingly implicated in the etiology of neurodegenerative diseases, and PON2 deficiency is expected to cause higher oxidative burden based on *in vitro* studies, we sought to characterize PON2 deficiency *in vivo* in the aging brain and determine if lower PON2 levels predispose toward neurodegenerative disease. For this study, female and male wildtype (WT) and PON2 deficient (PON2 DEF) mice (N = 10 - 15 per group) were aged 18 - 24 months following a protocol approved by the University of Washington IACUC. After reaching aged status, brain regions (cerebellum, cortex, striatum, hippocampus) and other organs were collected for biochemical analysis. Multiple immunological and neurodegenerative targets at the transcript and protein level were compared between WT and PON2 DEF tissue, with significant sex-specific differences found in the cortex. PON2 DEF female mice had significantly lower mRNA levels of interferon gamma (IF-γ), tumor necrosis factor alpha (TNF-α), interleukin 1 beta (IL-1β) and interleukin 4 (IL-4) compared to WT, while PON2 DEF males only had significantly lower IF-γ and IL-1β. These results suggest a compensatory effect with PON2 deficiency, which may be reducing cytokine expression and subsequent inflammation in cortical tissue. Glucose transporter 4 (GLUT4) mRNA was also significantly higher in both female and male PON2 DEF mice, suggesting potential dysregulation of glucose transport pathways. Overall, the current findings suggest PON2 deficiency leads to significant changes in immunological and neurodegenerative related targets and supports further study of PON2 in the aging nervous system. *Supported by P42ES06496 and T32ES07032.*

PS 1437 Exposure to Ultrafine Particulate Matter *In Utero* Impairs Memory Function in Adult Wild-Type and APP Knock-In Mice

J. Kilian[1], D. Herman[1], R. Johnson[1], T. Saito[2], T. C. Saido[2], M. T. Kleinman[1], and M. Kitazawa[1]. *[1]University of California Irvine, Irvine, CA; and [2]RIKEN Brain Science Institute, Wako, Japan.*

Reports indicate that exposure to the airborne particulate matter (PM) during development impairs cognitive function later in childhood. In mice, *in utero* PM exposure leads to notable neurodevelopmental changes in the embryo. However, limited work has been done to elucidate underlying mechanisms by which and to what extent *in utero* exposure to PM alters brain structure and function and accelerates cognitive decline. To determine to what extent and the critical mechanisms by which PM exposure during development mediates neurotoxicity and cognitive impairment in adulthood, here we exposed a humanized Amyloid Precursor Protein (APP) knock-in mouse model of AD and wildtype mice to concentrated ultra-fine PM *in utero*, allowing them to age, and examined the cognitive impact in adult mice. Cognitive outcomes are measured using the object location memory (OLM) and object recognition memory (ORM) tasks. Wildtype (wt) C57BL/6J female mice were crossed with wt or APP^{NL-G-F} knock-in males, resulting in either wt or APP^{NL-G-F} heterozygous pups. Following congenital plug observation, females were exposed to either concentrated quasi-ultra-fine particulates ($PM_{0.18}$) collected from the ambient air at UCI or filtered air by the versatile aerosol concentration enrichment system (VACES) at the UCI Air Pollution Health Effects Lab during gestation. Total exposure time was approximately 3 weeks, for 5 hours/day, 4 days/week. Pups were then allowed to age to 11 months. Mice were then tested in the ORM and OLM tasks. Mice were sacrificed for tissue harvesting the following behavior tasks, at 12 months of age. Brain tissues are processed using standard techniques for immunofluorescent section staining, protein probing, and RNA analysis. Wt mice whose mothers were exposed to $PM_{0.18}$ during gestation exhibited decreased performance in the OLM task compared to mice in the filtered air group. No differences were seen within the APP^{NL-G-F} group in OLM, or between genotypes. In the ORM task the $PM_{0.18}$ exposed APP^{NL-G-F} heterozygous mice performed worse than those exposed to filtered air group, but no differences were seen in the wildtype group. Behavior task results indicate that PM exposure *in utero* contributes to memory impairment in adult wildtype and AD model mice. Biochemical tests are ongoing to determine whether AD pathology or other molecular pathways leading to neurodegeneration are impacted.

PS 1438 Lead and DDT Additively Increase the Levels of Amyloid Precursor Protein in Hippocampal HT22 Cells

F. M. Sammoura, A. Eid, and J. R. Richardson. *Florida International University, Miami, FL.*

Alzheimer's disease (AD) is the most common neurodegenerative disease, affecting over 5 million people in the United States. With the vast majority of AD cases being sporadic late onset of disease, there is rationale in investigating the potential role of the environment in the etiology of disease. We previously reported that serum levels of dichlorodipheyldichloroethylene (DDE), the metabolite of pesticide dichlorodiphenyltrichloroethane (DDT), were significantly higher in AD patients compared to age-matched controls. Likewise, it has been suggested that lead (Pb) exposure is a risk factor for AD based on multiple experimental studies in non-human primates and rodents. Both Pb and DDT have been reported separately to increase levels of amyloid precursor protein (APP) and increase amyloid-β (Aβ) in cells. Because these two contaminants were highly prevalent in the environment at the same time, we sought to determine whether they may interact to produce greater effects on the amyloid pathway. Here, we used the HT22 mouse hippocampal neuronal cell line, which has been shown to differentiate into cholinergic hippocampal neurons with N2 supplement. Exposure of HT22 cells to Pb, DDT or combinations of the two did not result in significant increases in APP levels, as determined by immunofluorescent staining. Upon differentiation of HT22 cells, we observed significant APP increases following 24 hr treatment with DDT and Pb separately and in combination; 1 μM DDT (63%), 10 μM Pb (98%), and 1 μM DDT and 10 μM Pb in combination (161%). Additionally, we found that after 48 hr of treatment, APP levels were further increased by 1 μM DDT (159%), 10 μM Pb (160%) and the combination (257%). These data demonstrate that Pb and DDT both increase APP levels and, that the combination of the two results in approximately an additive response. Taken together, these data suggest that Pb and DDT may act on similar mechanistic pathways affecting the amyloidogenic pathway. These data provide for a new understanding by which Pb and DDT may contribute mechanistically to AD risk. *Supported in part by NIH R01ES026057.*

PS 1439 Modeling Gene-Environment Interactions in Amyotrophic Lateral Sclerosis (ALS): A Relevant Genetic Model and Low Manganese Exposure Levels Do Not Trigger Paralysis *In Vivo*

Y. Nunez, A. Wu, S. J. Merwin, B. Saglimbeni, M. Gade, and D. B. Re. *Columbia University, New York, NY.*

Amyotrophic lateral sclerosis (ALS) is a fatal adult-onset paralytic disorder with mostly unknown etiology but believed to result from gene x environment (GXE) interactions. Most previous ALS GXE studies used animal models with a full-blown ALS phenotype combined with environmental exposures that are already highly toxic alone. However, this scenario may not realistically model GXE interactions in ALS as patients do not report any signs of neurotoxicity before clinical onset of the disease. Here, to test the hypothesis that ALS results from the interaction between silent exposures and silent genetic susceptibilities, we used a knock-in mouse model of an incompletely penetrant ALS variant of TDP-43 "G298S". The heterozygous (het-G298S) knock-in mice are "ALS-silent" over their lifespan but the homozygous knock-ins show mild neuromuscular junction denervation at an advanced age (2.5 yrs.), confirming the validity of these models. Primary spinal cord cultures from wild-type (WT) and het-G298S mice were generated to screen for possible GXE interaction with various neurotoxic metals previously proposed to have a role in ALS. This pilot *in vitro* study suggested that G298S increased the vulnerability of motor neurons to manganese (Mn) exposure. Thus, WT and het-G298S mice were chronically exposed via drinking water to 200ppm Mn -a low level of Mn below those reported to be neurotoxic in past studies. Mice were exposed for six months starting in young adulthood (P145). To control for sex, this study included 50% females and 50% males and it was powered based on our past ALS mouse studies. Mice were tested weekly by treatment/genotype-blinded investigators for grip strength (loaded grid) and general locomotor activity (rotarod) over the six months of the study. At the end of the study, mice were tested with the CatWalk™ for gait and quantitative assessment of footfalls. Mild motor differences (CatWalk paw contact intensity, print length and area, swing speed [$p<0.025$, ANOVA] and lower loaded grid score [$p<0.05$, linear

mixed model]) were detected in het-G298S mice relative to WT but independent of Mn treatment. These results indicate that 200ppm Mn exposure is likely too low to initiate clinical ALS in our genetically vulnerable knock-in model -even though this level of exposure is at the high end for humans. While tissue pathology analysis is ongoing, a subsequent cohort is underway in which mice are exposed to 400ppm Mn to evaluate the effects of a higher exposure level to Mn.

1440 Role of Microglia in Diesel Exhaust Particulate Extract-Induced Neurotoxicity and Clearance of α-Synuclein Aggregates in the Larval Zebrafish Brain

H. Murata, L. Barnhill, A. Kareddy, D. Juarez, S. Li, and J. Bronstein. *University of California Los Angeles, Los Angeles, CA.*

Parkinson's disease (PD) is the second most common neurodegenerative disease and is caused by a combination of genetic and environmental factors. The main hallmarks of PD include loss of dopaminergic neurons in the substantia nigra, aggregation of the protein alpha-synuclein leading to the formation of toxic Lewy bodies, and neuroinflammation. Epidemiological studies have reported a positive association between exposure to air pollutant (AP) and incidence of PD. We hypothesize that AP exposure activates microglia, interferes with alpha-synuclein processing and contributes to neuronal injury. Transgenic zebrafish (ZF) embryos were utilized to determine the effect of a major component of AP, diesel exhaust particulate extract (DEPe), on microglia's interactions with alpha-synuclein and their role in neurotoxicity. DEPe exposure led to a significant loss of dopaminergic neurons in the ZF brain and activation of microglia, seen morphologically and through preliminary rtPCR quantification of expression of inflammatory cytokine genes. Reduction of microglia using morpholino oligonucleotides did not alter DEPe-induced neuron loss. However, microglia were also activated with overexpression of GFP-tagged human alpha-synuclein in the ZF brain, and were found to engulf it, suggesting that they play a role in synuclein homeostasis and contribute to the neuroinflammatory response. ZF embryos treated with DEPe also had altered light-cycling behavior. These data suggest that microglia may not play a direct role in DEPe-induced neuron loss in our ZF model, but do play a role in clearing aggregated alpha-synuclein and contributing to neuroinflammation in PD. Current studies are focusing on the effects of DEPe-induced microglial activation on alpha-synuclein kinetics since both of these processes have been implicated to play a pathological role in PD. Additionally, we are utilizing a rat cortical cell culture model to confirm these findings, as well as begin to study the role that another key glial cell, astrocytes, play in DEPe's neurotoxicity. Ultimately, these studies will help elucidate the mechanisms by which AP contributes to neurodegeneration in PD.

1441 Multiplex Analysis in a *Drosophila* Gene-Environment Model Identifies Interactions among LRRK2, Rotenone, and α-Synuclein

S. Sarkar, G. Maor, and M. B. Feany. *Harvard Medical School, Boston, MA.*

Epidemiological studies strongly support a role for environmental factors, particularly pesticide exposure, in the pathogenesis of Parkinson's disease (PD). Genetic risk factors, including penetrant single gene mutations and risk factors identified from genome-wide associated studies (GWAS) also contribute to PD risk and progression, but available model systems are limited in their ability to interrogate gene-environment crosstalk *in vivo* and at scale. Here we use *Drosophila* as a model system to understand complex gene-environment interactions in PD. We developed a multiplex model in *Drosophila* in which we knocked down GWAS candidate genes in neurons in a robust new α-synucleinopathy model and exposed the flies to environmental neurotoxicants. We identified an interaction between LRRK2, rotenone and α-synuclein. Expression of the disease-causing Lrrk-G2019S mutant in the presence of rotenone and alpha-synuclein induced behavioral deficits and mitochondrial dysfunction. Further, super resolution microscopy analysis revealed that the interaction of LRRK2, α-synuclein and rotenone leads to hyperstabilization of actin cytoskeleton. We have previously shown that LRRK2 has actin severing activity and previous studies have implicated the GTPase domain in regulating actin severing. We next expressed a GTPase domain mutant, Lrrk-Q1003H, designed to mimic the human protective mutant LRRK2-R1398H. Interestingly, expression of the LRRK2 protective mutant attenuated behavioral deficits mediated by LRRK2-rotenone-synuclein interactions. Further, expression of the protective mutant also attenuated the actin stabilization and mitochondrial deficits. Together, using our novel multiplex model in *Drosophila* we have identified an interaction between LRRK2, α-synuclein, and rotenone which is modulated by actin stabilization and mitochondrial dysfunction. Our findings have implication towards development of a personalized approach for drug discovery and lead identification.

1442 Mitochondrial Mechanisms of Harmane-Induced Dopaminergic Neurotoxicity in *C. elegans*

S. R. Sammi, C. S. Nieves Rivera, and J. R. Cannon. *Purdue University, West Lafayette, IN.*

Harmane (1-methyl-9H-pyrido[3,4-b]indole) is heterocyclic aromatic amine (HAA) that is a known tremorigen, and is also linked to Parkinson's disease (PD). It is found in cooked meat, roasted coffee beans, and tobacco. Our previous research showed that harmane produces selective dopaminergic neurotoxicity evidenced by decreased mitochondrial viability, elevated superoxide levels, and morphological alterations consistent with neurodegeneration. Given, that mitochondria are the primary target organelle, the goal of this study was to determine the mitochondrial mechanisms of neurotoxic action. Inhibition of 2-oxoglutarate carrier (OGC) ameliorated harmane-induced DA neurotoxicity. Specifically, OGC inhibition decreased harmane-induced effects on neuronal morphology and mitochondrial content. The effects appeared to be harmane specific since OGC inhibition failed to protect toxicity from other insults. Thus, we have identified OGC as critical to mediating harmane neurotoxicity. Further, N-acetyl cysteine, an antioxidant that also activates mitochondrial complexes and is a precursor for glutathione (GSH) ameliorated harmane neurotoxicity. Conversely, inhibition of glutamate cysteine ligase, a key enzyme in GSH biosynthesis increased neurodegeneration. Together, these data suggest that GSH levels are critical to harmane-induced DA neurotoxicity. In support of previously observed harmane-induced increases in superoxide, the mitochondrial targeted superoxide dismutase mimetic, XJB-5-131 ameliorated DA cell loss. Taken together, our findings suggest that OGC could be a possible entry port of harmane into mitochondria and that targeted scavenging of superoxide is beneficial. Additionally, our data also indicate the critical role of GSH to harmane neurotoxicity. HAAs are a widespread dietary exposure. Mounting data suggest HAA-induced neurotoxicity and our findings implicate specific mitochondrial mechanisms.

1443 Carnosine Reduces Toxic Effects of Manganese on Mitochondrial Membrane Potential

R. Wallach, T. Bowman, M. A. Carroll, and E. J. Catapane. *Medgar Evers College, Brooklyn, NY.*

Manganese (Mn) is an essential metal that at excessive brain levels causes manganism, which is similar to Parkinson's disease. The toxic mechanism of action is not fully understood. Proposed mechanisms suggest Mn causes oxidative stress and mitochondrial dysfunction causing damage to dopamine neurotransmission. Previously we showed Mn reduced mitochondrial O_2 consumption in gill of *Crassostrea virginica* and that two proposed treatments for manganism, EDTA and p-aminosalicylic acid (PAS), protected against this. We also showed Mn disrupts mitochondrial membrane potential of *C. virginica* gill lateral cells (GLC). We hypothesize the neurotoxic effects of Mn on GLC mitochondria membrane potential can be blocked by carnosine, an antioxidant with potential neuroprotective properties. To test this we used the mitochondrial selective fluorescent probe TMRM (tetramethylrhodamine methyl ester perchlorate) to study mitochondrial membrane potential in GLC. GLC were treated with 2.5μM TMRM, then exposed to either Mn (125 μM) alone, carnosine or PAS (125 μM) alone, Mn with carnosine (125 μM each), or Mn with PAS, and compared to control GLC. Mitochondrial fluorescence was viewed on a Leica fluorescence microscope with epilume illumination with a 50 watt HBO mercury excitation lamp and Texas Red filters (Ex 560 nm, Em 630 nm). Photomicrographs were taken with a Leica DFC400 camera at 100X and 200X at 0, 10 and 20 min. All sections were photographed with the same camera and microscope settings. GLC mitochondrial fluorescence intensity (FI) was measured with ImageJ from NIH. Control GLC fluoresced brightly indicating a strong mitochondrial membrane potential. GLC treated with carnosine or PAS alone had FI similar to controls. Mn treatment caused a 40% reduction in FI over the 20 min period, while GLC co-treated with Mn and PAS showed no loss. Carnosine was less effected than PAS in blocking Mn because carnosine co-treatments still allowed Mn to cause a 15% loss in FI compared to controls. This study showed PAS and carnosine have protective effects against Mn on GLC mitochondrial membrane potential, with carnosine being less protective than PAS. These findings should be of interest to those exploring possible therapeutic treatments for manganism. *This work was supported by grants NIGMS-2R25GM06003, NIH-K12GM093854-07A1 and PSC-CUNY 62344-00-50.*

1444 Carnosine Reduces Neurotoxic Effects of Manganese on an Oyster Gill Cilio-Inhibitory Dopamine System

J. Quintuna, C. Ramirez, E. Georges, M. A. Carroll, and E. J. Catapane. *Medgar Evers College, Brooklyn, NY.*

Manganese (Mn), a neurotoxin causing manganism a Parkinson's-like disease, disrupts dopamine (DA) neurotransmission. The neurotoxic mechanism is not fully resolved. Lack of effective treatment for manganism is a major obstacle for clinical management. Gill lateral cell (GLC) cilia of *Crassostrea virginica* are controlled by serotonin-DA innervations. DA is cilio-inhibitory; serotonin cilio-excitatory. Previously we showed acute and short-term Mn treatments block cilio-inhibitory effects of DA. This neurotoxic action of Mn is reversed by p-aminosalicylic acid and taurine. Recent reports suggest the dipeptide carnosine (*beta*-alanyl-L-histidine) is worth investigating as a neuroprotective agent for manganism because of its efficacy in other neurodegenerative diseases. We hypothesize carnosine will reduce neurotoxic actions of Mn on cilio-inhibitory effects of DA in *C. virginica* GLC. We conducted acute experiments testing DA on excised gill treated with Mn (10^{-4} M) in the presence or absence of carnosine (10^{-4}M). Cilia activity of GLC was measured by stroboscopic microscopy. Cilia of control GLC that were first activated by serotonin (10^{-5}M) responded normally to DA (10^{-6}-10^{-4}M) with the appropriate decrease in cilia beating from about 20 beats/sec to about zero. Mn disrupted the DA induced cilio-inhibitory dose response and carnosine treatments reduced this neurotoxic effect, generating a cilio-inhibitory response similar to DA without Mn. We also conducted short-term experiments in which *C. virginica* were treated with Mn (100 µM) for 2, 3 and 5 days with or without carnosine (100 µM). Control animals were sham treated. For each treatment period, co-treating animals with carnosine and Mn reduced the neurotoxic effect of Mn on the cilio-inhibitory DA system, generating cilia responses similar to sham treated controls. The study showed that in *C. virginica* carnosine reduced the neurotoxic effects of Mn on the cilio-inhibitory DA system. The findings are helpful in furthering the understanding of the neurotoxic mechanism of Mn and provides evidence suggesting carnosine should be further investigated as a potential therapeutic agent for manganism. *Supported by grants 2R25GM06003 of NIGMS, K12GM093854-07A1 of NIH and 62344-00-50 of PSC-CUNY.*

1445 G Protein-Coupled Inwardly Rectifying Potassium Channel (GIRK) and Control of Gill Lateral Cell Membrane Potential and Cilia Response of *Crassostrea virginica*

S. Small, A. Johnson, M. Eid, E. J. Catapane, and M. A. Carroll. *Medgar Evers College, Brooklyn, NY.*

Crassostrea virginica gill lateral cell (GLC) cilia are controlled by serotonin-dopamine innervations. Dopamine (DA) is cilio-inhibitory and hyperpolarizes the plasma membrane. Serotonin is cilio-excitatory and depolarizes. GLC DA receptors are D2-like (D2R). D2R activation opens G protein-coupled inwardly-rectifying potassium channels (GIRK) causing hyperpolarization. It is unknown if GLC have GIRK and if hyperpolarization is involved in cilio-inhibition of DA. We hypothesize GIRK is present in GLC and activation hyperpolarizes GLC and slows cilia beating. We conducted immunohistofluorescence (IHF) studies with GIRK antibodies and tested a GIRK inhibitor and activator on changes in plasma membrane potential while simultaneously measuring cilia beating using stroboscopic microscopy. Plasma membrane potential was measured using $DiBAC_4(3)$ and a microspectrum analyzer. IHF showed GIRK present in GLC. ML297 a GIRK activator hyperpolarized the membrane but had no effect on cilia beating. $BaCl_2$ a GIRK inhibitor had no effect on membrane potential or cilia beating. However applying DA after $BaCl_2$ decreased cilia beating but did not hyperpolarize the membrane indicating $BaCl_2$ was effectively blocking GIRK channels. In other experiments gills were treated with manganese (Mn), a neurotoxin causing manganism, a Parkinsons-like syndrome. In *C. virginica* Mn interferes with cilio-inhibition of DA, blocking both hyperpolarization and cilio-inhibitory in GLC. In the present study Mn had no effect on the GIRK activator or inhibitor, suggesting the toxic effect of Mn on the DA system is not involved in altering GIRK activity but rather activation of D2R. The study differentiates steps of D2R signaling pathway involved with cilia beating from those controlling plasma membrane potential. It also showed Mn does not affect GIRK activity in GLC. This is important because the mechanism of Mn neurotoxicity is not fully resolved and lack of effective treatment for manganism in humans is a major obstacle for clinical management. The findings are helpful in furthering understanding of D2R signaling pathway and Mn neurotoxicity, and provides evidence to guide future studies on therapeutic agents for manganism. *Supported by grants 2R25GM06003 of NIGMS, NIH K12GM093854-07A1 and PSC-CUNY 62344-00-50.*

1446 Effects of Manganese on Cilio-Inhibitory Actions of Dopamine D2 Agonists in Gill Lateral Cells of *Crassostrea virginica*

T. Foster, K. Baxter, K. Ernest, E. J. Catapane, and M. A. Carroll. *Medgar Evers College, Brooklyn, NY.*

Gill lateral cell (GLC) cilia of *Crassostrea virginica* are controlled by serotonin-dopamine innervations. Dopamine (DA) is cilio-inhibitory; serotonin cilio-excitatory. Manganese (Mn) a neurotoxin causing manganism a Parkinson's-like disease is characterized by aberrant DA neurotransmission. The mechanism of Mn neurotoxicity is not fully resolved. Lack of effective treatment for manganism is a major obstacle for clinical management. Previously our lab showed Mn disrupts cilio-inhibitory actions of DA in *C. virginica* and that post-synaptic DA receptors on GLC are D2-like (D2R). Since Mn interferes with D2R signal transduction pathway preventing normal cilio-inhibitory response, we hypothesized Mn would interfere with the pathway when D2R agonists are used. We tested dose responses of three different D2R agonists (piribedil, N-propyl piperidine and ergocryptine) on excised gill to determine their efficacy on reducing GLC cilia beating in the presence or absence of Mn. Results for each agonist also were compared to gill treated with or without Mn using the natural ligand DA. In the absence of Mn, each agonist was cilio-inhibitory, with N-propyl piperidine being the most effective, reducing beating rates similar to DA. Repeating the experiments with Mn (10^{-5}M) present caused a moderate reduction in cilio-inhibitory effectiveness of ergocryptine and piribedil, but did not cause a reduction in the cilio-inhibitory ability of N-propyl piperidine. The results support our hypothesis that Mn interferes with the cilio-inhibitory actions of D2R agonists, however not all three agonists were equally affected. Since cilio-inhibitory actions of two of the three agonists were impaired by Mn the results suggest Mn toxicity may not be targeting the DA molecule itself, but rather interfering with one or more steps of the D2R signal transduction pathway. In addition the three agonists had different cilio-inhibitory effectiveness and therefore likely to have different D2R binding capacities on GLC. This may explain their varied response to Mn, especially if Mn is directly interfering with ligand binding or activation of D2R. This study helps further the understanding of the neurotoxic mechanism of action of Mn and may be valuable in searching for therapeutic treatments for manganism. *Supported by grant NIGMS-2R25GM06003, NIH-K12GM093854-07A1 and PSCCUNY-62344-00-50.*

1447 LRRK2 Activation as a Common Feature of Parkinson's Disease-Associated Environmental Toxicants

J. Massa, K. E. Johnson, E. K. Hoffman, K. Farmer, J. T. Greenamyre, and B. R. De Miranda. *University of Pittsburgh, Pittsburgh, PA.*

Environmental contaminants that cause mitochondrial dysfunction are associated with increased Parkinson's disease (PD) risk, such as pesticides rotenone and paraquat, and organic solvents trichlorethylene (TCE) and tetrachloroethylene (PERC). Despite the structural diversity of these environmental contaminants, they are each implicated as inducers of cellular oxidative stress. Recently, we reported that the protein kinase LRRK2, the most commonly inherited mutation in familial PD, exhibited aberrant kinase activity within dopaminergic neurons of the substantia nigra (SN), in rats exposed to rotenone or TCE. This toxicant-induced elevated LRRK2 kinase activity resulted in neuronal pathology that mirrored inherited *mutations* in LRRK2, such as vesicular trafficking dysfunction, endolysosomal impairment, and protein accumulation. Based on these data, we hypothesized that LRRK2 activation is induced by oxidative stress produced by environmental mitochondrial toxicants, which may influence cellular pathology, and contribute to the degeneration of dopaminergic neurons. We assessed this by comparing wild-type (WT), endogenous LRRK2 activation measured using a novel, validated proximity ligation assay (PLA) in a dopaminergic cell line (N27-A) following *in vitro* exposure to rotenone, paraquat, TCE or PERC. Each of these toxicants significantly induced LRRK2 kinase activity corresponding with elevated reactive oxygen species (ROS), measured by the fluorescent ROS indicator dye, dihydroethidium (DHE; $p < 0.001$). To assess whether LRRK2 mutations increase susceptibility to environmental toxicant exposure, we measured toxicant-induced ROS in CRISPR-edited 293 HEK cells that express the most commonly inherited LRRK2 mutation (G2019S). ROS production was elevated at baseline in LRRK2-G2019S HEK cells, and significantly exacerbated following application of either rotenone, paraquat, TCE, or PERC compared to WT ($p < 0.0001$). Interestingly, LRRK2 knockout HEK cells were robustly protected from toxicant-induced ROS production. Similarly, the small-molecule LRRK2 kinase inhibitor MLi-2 protected both dopaminergic and HEK cells from toxicant-induced oxidative stress. Collectively, these data indicate a role for LRRK2 interaction with common environmental contaminants that are associated with increased PD risk, and represents a possible point of susceptibility for individuals with inherited LRRK2 mutations.

1448 Manganese Exposure Stimulates the Release of Exosomes Containing Misfolded α-Synuclein by Impairing Endosomal Trafficking and Autophagic and Lysosomal Protein Degradative Machinery

D. Rokad, D. S. Harischandra, S. Sarkar, D. Luo, V. Lawana, D. Kim, H. Jin, V. Anantharam, A. Kanthasamy, and A. G. Kanthasamy. *Iowa State University, Ames, IA.*

Environmental exposure to excessive manganese (Mn) increases the risk of chronic neurological diseases, including Parkinson's disease (PD). Aggregated α-synuclein (αSyn) is a key pathophysiological characteristic of PD. Oligomeric αSyn can be released from neurons by exosomes, facilitating the spread of misfolded proteins to neighboring cells, triggering a neurotoxic response. We discovered that Mn enhances the release of misfolded αSyn via exosomes from dopaminergic neurons, but the underlying molecular mechanisms are unclear. To understand the Mn-induced release of exosomal αSyn, we examined how Mn modulates endosomal protein trafficking and misfolded protein degradation. We exposed MN9D dopaminergic neuronal cells stably expressing human wild-type (WT) αSyn (MN9D-αSyn) to Mn (300 μM) for 24 h. Mn significantly suppressed expression of the key endosomal recycling protein Rab11a, both at the protein and mRNA levels, suggesting Mn downregulates endosomal recycling mechanisms, thus forcing late endosomes to mature into multivesicular bodies (MVBs). Moreover, ectopic expression of WT Rab11a significantly mitigated exosome release in untreated and Mn-exposed MN9D-αSyn cells, whereas ectopic expression of mutant Rab11a (S25N) increased exosome release. Intriguingly, our qRT-PCR, Western blot, and ICC analyses also revealed that Mn exposure upregulated mRNA and protein levels of Rab27a, a key endosomal protein that mediates exosome release through fusion of MVBs with the plasma membrane, suggesting Rab27a upregulation contributes to Mn-induced exosome release. Since aggregated αSyn get degraded via autophagic/lysosomal pathway, we examined if Mn impairs this pathway to promote exosomal αSyn release. Our Western blot analysis of from *in vitro* and *in vivo* studies shows Mn upregulated autophagosomal marker Beclin-1, but downregulated lysosomal marker LAMP2, suggesting impairment of autophagolysosome formation following Mn exposure. Results from other key lysosome assays, such as ICC, LysoTracker staining and Cathepsin D assay confirmed Mn-induced lysosomal dysfunction. Together, these novel findings demonstrate Mn compromises endosomal trafficking, autophagic/lysosomal impairment, thereby promoting exosomal release of misfolded αSyn. *NIH ES026892, NS088206, Eugene Linda Lloyd chair.*

1449 Drp1 Inhibition Attenuates Autophagy Impairment Induced by Alpha-Synuclein and Neurotoxicants

R. Z. Fan, C. Sportelli, M. Guo, J. Pinnell, and K. Tieu. *Florida International University, Miami, FL.*

Gene-environment interactions play an important role in the pathogenesis of Parkinson's disease (PD). Enhanced neurotoxicity has been documented when α-synuclein (α-syn) is combined with neurotoxicants. Impairment in autophagy-lysosomal function resulting in misfolded and aggregated α-syn protein may account for such neurotoxicity. We report here that blocking dynamin-related protein 1 (Drp1) improved autophagy flux in mammalian cell models of α-syn, paraquat (PQ) and manganese (Mn), leading to reduced protein aggregation when α-syn was combined with these toxicants. To block Drp1 function, we used three complementary approaches: siRNA-Drp1, overexpression of Drp1-dominant negative and the small molecule mitochondrial division inhibitor-1 (mdivi-1). By using autophagy reporter HeLa cells with stable expression of mRFP-GFP-LC3 treated with human α-syn preformed fibrils (PFF) and by quantifying immunoreactivity of LC3 and p62 in N27 neuronal cells with stable inducible expression of α-syn, we observed that Drp1 inhibition abolished autophagy impairment induced by α-syn. Consistent with its role in improving autophagy function, Drp1 inhibition reduced proteinase K-resistant α-syn aggregates, as well as exosome release and spread of α-syn pathology from neurons to neurons and from microglia to neurons. To gain additional mechanistic insights into this protection, we assessed mTOR activity by quantifying the levels of phosphor-4E-BP1, which is a downstream substrate of mTOR, in stable α-syn N27 cells. We observed that α-syn activated mTOR, and strikingly, knocking down Drp1 inhibited mTOR activity to an equivalent extent of rapamycin, an mTOR inhibitor. Through investigation of the effects of PQ and Mn on autophagy, we observed a striking blockade of autophagy flux by these toxicants at concentrations much lower than their LC_{50} values. We also confirmed that, in models in which α-syn was combined with either PQ or Mn, proteinase K-resistant α-syn aggregation was significantly reduced by Drp1 inhibition. In summary, our data support a common and prominent role of impaired autophagy in genetic and toxicant induced cell models relevant to parkinsonism. Furthermore, our observation that Drp1 inhibition improved autophagy flux in these models is novel and significant.

1450 Mitochondrial and Autophagolysosomal Dysfunction Induced by Heterocyclic Aromatic Amine Exposure Is Modulated by Neuromelanin Formation

V. Lawana, S. Um, A. Chandran, J. H. Shannahan, and J. R. Cannon. *Purdue University, West Lafayette, IN.*

Neuromelanin is a pigmented product of dopamine catabolism present in human dopamine neurons in the substantia nigra. However, most preclinical PD models (i.e., rodents and *in vitro* cultures) lack neuromelanin. Thus, the role of neuromelanin in environmentally induced neurotoxicity is generally ignored. Our lab and others demonstrated a selective dopaminergic neurotoxic potential of a group of chemicals produced from high-temperature meat cooking, known as heterocyclic aromatic amines (HAA). Further, we recently showed that two HAAs, 1-methyl-9H-pyrido[3,4-b]indole (harmane) and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP), induce dose-dependent toxicity in human SH-SY5Y neuroblastoma cells; where neuromelanin formation (through ectopic tyrosinase expression) increased intracellular HAA levels and several metrics of HAA-induced toxicity. The primary goal of the present research was to elucidate pathogenic mechanisms by which neuromelanin formation modulates HAA-induced neurotoxicity. Post HAA exposure, SH-SY5Y cells (with and without neuromelanin formation) were evaluated for oxidative stress, autophagic flux, and mitochondrial function/morphology. Our data show that SH-SY5Y cells exposed to harmane and PhIP induced concentration-dependent oxidative stress, loss of mitochondrial membrane potential and lysosomal degeneration. The magnitude of each of these changes was significantly increased in neuromelanin forming cells. Additionally, using the Seahorse MitoStress assay, we demonstrated that neuromelanin-forming SH-SY5Y cells have heightened susceptibility to HAAs, with respect to mitochondrial function. For harmane, functional alterations were also associated with mitochondrial morphological changes. Lastly, we showed that harmane treatment disabled autophagic flux by increasing autophagy and reducing lysosomal activity, promoting dysfunctional mitophagy. Taken together, our data show a pivotal role of neuromelanin in modulating specific pathogenic pathways that underlie HAA-mediated neurotoxicity. Our data also suggest that, in general, dopaminergic neurotoxicity should be evaluated in the presence of neuromelanin to increase the translational potential of laboratory studies.

1451 The Role of Inflammatory Mouse lncRNA AK039862 in PQ-Induced Proliferation and Migration Inhibition through the Pafah1b1/Foxa1 Pathway in Co-culture Environments

J. Wu[1], Y. Zhang[1,2], W. Shao[1], F. Zheng[1], P. Cai[1], Z. Guo[1], S. Wu[1], and H. Li[1]. *[1]Fujian Medical University, Fuzhou, China; and [2]Second Military Medical University, Shanghai, China.*

Emerging evidence has suggested a significant role of long non-coding RNAs (lncRNAs) in neurodegenerative diseases, including Parkinson's disease (PD). It has been identified that particular lncRNAs have a potential effect on PD progression induced by neurotoxins (such as paraquat) through damage and inflammatory responses to dopaminergic/microglia cells. However, the specific role and mechanisms of LncRNA in PQ-induced PD disease progression remain unclear. In the present study, we focus on the comprehensive effect of particular lncRNA in mixed and sophisticated brain environments. We found the interesting individual and interacted features of lncRNA AK039862 are involved in PQ-induced cellular functional effects through using two non-contact co-culture models to better simulate the coexistence of dopaminergic cells and microglia. First, we detected that AK039862 was involved in the neuronal injury process in PQ-treated mice and determined its regulatory mechanism *in vitro*. Interestingly, we found PQ significantly inhibits cell proliferation and migration *in vitro*. Further research indicates PQ-induced decreased expression of AK039862 can rescue microglia proliferation and migration via the AK039862/Pafah1b1/Foxa1 pathway. Meanwhile, AK039862/Pafah1b1/Foxa1 pathway also participated in the interaction between microglia and dopaminergic cells with PQ treatment in two non-contact co-culture models. In summary, our findings elucidated the role of AK039862 in PQ-induced neurodegeneration via Pafah1b1/Foxa1 pathway, and revealed the complex and diverse functions of inflammatory AK039862 in the communication between microglia and dopaminergic cells. *Project supported by the National Natural Science Foundation of China (Grant No. 81573195).*

1452 Paraquat Primes the Microglial NLRP3 Inflammasome via the Voltage-Gated Proton Channel Hv1

C. Kim[1], M. Neal[1], A. Boyle[2], L. Wu[3], and J. R. Richardson[1]. *[1]Florida International University, Miami, FL; [2]Kent State University, Kent, OH; and [3]Mayo Clinic, Rochester, MN.*

Paraquat (PQ) is one of the most widely used herbicides and can increase the risk of developing Parkinson's disease (PD) by ~2.5 times. PQ treatment induces PD-like symptoms with selective nigrostriatal degeneration, aggregation of α-synuclein, and increased neuroinflammation in the rodent brain. PQ-mediated microglial activation leads to dopaminergic neurotoxicity, but its mechanism is not well-established. Hvcn1/Hv1 is a voltage-gated proton channel selectively expressed in microglia and other immune cells. It has been shown to be required for NADHP-oxidase (NOX)-dependent production of reactive oxygen species (ROS) under the pathological conditions. The purpose of this study was to determine the role of Hv1 in paraquat-induced neuroinflammation and neurodegeneration. Using a bioinformatic approach of published microarray data, we found that *HVCN1* mRNA levels were significantly elevated in the substantia nigra of post-mortem samples from PD patients compared to age-matched controls. Direct PQ treatment on the BV2 mouse microglial cell line and primary mouse microglia (PMG) induced *Hvcn1* mRNA levels by 2-3-fold. This was accompanied by significant increases in ROS levels and mRNA expression of the *Nlrp3* inflammasome. PMG isolated from global Hv1 knockout (KO) mice displayed significantly reduced production of ROS and mRNA levels of *Nlrp3* and *Il1b* following PQ treatment. We used western blotting to observe and quantify the protein levels of NLRP3, as well as the inflammasome-related proteins cleaved IL-1β and cleaved caspase-1. The levels of NLRP3 protein and cleavage of the IL-1β and caspase-1 protein were increased after PQ treatment of the PMG. These effects were abolished in the Hv1 KO PMG. Following a single injection of 10 mg/kg PQ to C57BL/6J mice, levels of *Hvcn1* mRNA and IL-1β protein were increased by 6-fold and 2-fold in the striatum, respectively. This effect was abolished in Hv1 KO mice. These data demonstrate that direct PQ treatment primes the microglial NLRP3 inflammasome through the voltage-gated proton channel Hv1.

1453 A Differential Gene Expression Study of Two Siblings with Genetic Risk for Parkinson's Disease

M. D. Neely[1], H. N. Cukier[2], L. M. Prince[3], H. Kim[3], C. T. Mahapatra[3], A. Griswold[2], D. M. Dykxhoorn[2], and A. B. Bowman[3]. *[1]Vanderbilt University Medical Center, Nashville, TN; [2]John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; and [3]Purdue University School of Health Sciences, West Lafayette, IN.*

Parkinson's disease (PD) is characterized by the loss of dopaminergic (DAergic) neurons in the substantia nigra. As a complex, multifaceted disorder, accumulating evidence substantiates the role of gene-environment interaction in PD etiology. We have previously reported a case of two siblings harboring identical compound heterozygous *PARK2* mutations that exhibited markedly different clinical phenotypes. The older brother displayed symptoms of parkinsonism by his mid-20's while the younger brother showed exercise-induced dystonia in his mid-30's with no further clinical progression through his late 40's. Neural progenitor cells (NPCs) derived from induced pluripotent stem cell (iPSC) lines generated from both siblings showed an increased sensitivity to copper and manganese. Hence, we set out to investigate the differential gene expression profile of iPSC-derived neurons from the two siblings that may account for the observed phenotypic difference. In the present study, we generated four independent iPSC clones from each sibling, differentiated them into floor plate DAergic lineages, and performed RNA-sequencing. The expression profiles were evaluated at days 11 and 25 of differentiation. Following comprehensive transcriptomic profiling, we chose 14 genes to validate by qRT-PCR from those differentially expressed between the brothers. Genes were selected based on those known to be associated with PD or changes in PD environmental risk, such as SLC18A2, GSTT1, and HLA-DRB5. Lineage-specific markers were also examined to ensure successful differentiation. We report that the qRT-PCR validation was in good agreement with results obtained from RNA-sequencing, with 11 and 12 of 14 genes validated in day 11 and 25, respectively. Of these PD associated genes, there were substantial differences in expression levels between the siblings' DAergic neurons ranging from 2-fold to even higher. Findings from this study will provide us with information to help explain the phenotypic discordance in the two siblings. Finally, further analyses will advance our understanding of how gene-environment interactions may increase an individual's susceptibility to or provide resistance from the onset of PD.

1454 Toward Understanding Intrinsic Characteristics of Dopaminergic Degeneration

M. R. Miah[1], P. Chen[1], N. Aranoff[2], A. B. Bowman[3], and M. Aschner[1]. *[1]Albert Einstein College of Medicine, Bronx, NY; [2]Yeshiva University Stern College for Women, New York, NY; and [3]Purdue University, West Lafayette, IN.*

The selective loss of dopaminergic (DAergic) neurons is a hallmark of Parkinson's disease (PD) whether etiology is idiopathic, genetic or toxicant related. The mechanisms underlying this specific DAergic neurodegeneration remain elusive. 6-hydroxydopamine (6-OHDA) has been extensively used to model specific DAergic neurodegeneration. Levodopa, a precursor to dopamine (DA) that can pass through the blood-brain barrier, is clinically used to resolve some of the symptoms of PD by increasing DA production in remaining DAergic neurons. Several studies have reported the presence of 6-OHDA in both rat and human brains as well as in the urine of levodopa-treated PD patients. While suggested in the literature, the role of DA in potentiating the unique susceptibility of DAergic neurons is not thoroughly investigated or substantiated. We aim to test the hypothesis that DA is necessary and sufficient to render DAergic neurons susceptible to 6-OHDA. To pursue this, we took advantage of the genetically tractable *Caenorhabditis elegans* (*C. elegans*) worm model and expressed green fluorescent protein (GFP), tyrosine hydroxylase (*cat-2*) and/or the DA reuptake transporter (*dat-1*) into ADF serotonergic neurons while removing native tryptophan hydroxylase (*tph-1*) and the serotonin reuptake transporter (*mod-5*). This novel approach allows us to investigate the role of DA and its transporter on neurodegeneration in a completely different phenotypic cell background (neoDAergic neurons) in a live organism. Here, we show that the genetic knockout of DA production and the DA transporter in *C. elegans* protects against 6-OHDA-induced DAergic neurodegeneration. Increasing DA production by increasing cat-2 transcription in native DAergic neurons made these neurons more susceptible to 6-OHDA. We establish that wildtype ADF neurons showed no significant degeneration upon treatment with 6-OHDA. Interestingly, however, subjecting our neoDAergic ADF neuron expressing strain to 6-OHDA showed significant degeneration in these altered neurons. Investigating gene expression differences between native DAergic neurons and neoDAergic ADF neurons in the next steps of the study can further parse out the intrinsic characteristics of DAergic neuron susceptibility. Together our study shows DA is necessary and sufficient in conferring neuronal susceptibility to 6-OHDA.

1455 Acquired Dysregulation of Dopamine Homeostasis Reproduces Features of Parkinson's Disease

M. L. Bucher, C. W. Barrett, C. J. Moon, A. D. Mortimer, J. T. Greenamyre, and T. G. Hastings. *University of Pittsburgh, Pittsburgh, PA.*

Dopamine has the potential to act as an endogenous neurotoxin when its vesicular sequestration is impaired and it undergoes oxidation and enzymatic metabolism - two cytosolic processes that generate reactive oxygen species and reactive metabolites. Dysregulation of dopamine has been hypothesized to contribute to the enhanced vulnerability of nigrostriatal dopaminergic neurons to degeneration in Parkinson's disease. Here, we present findings from a novel *in vivo* rat model of acquired dysregulation of dopamine sequestration in nigrostriatal dopaminergic neurons through viral-mediated small-hairpin RNA interference targeting endogenous vesicular monoamine transporter 2 (VMAT2) expression. Utilizing an adeno-associated (serotype 2) virus (AAV2-shVMAT2), viral-mediated interference of VMAT2 expression resulted in a loss of VMAT2 protein expression in transduced dopaminergic cell bodies in the substantia nigra with a corresponding loss of VMAT2 protein in the striatal terminals, an increase in dopamine metabolism, and deficits in dopamine-mediated behaviors. This model results in nigrostriatal dopaminergic neurodegeneration that can be rescued through reintroduction of exogenous VMAT2, demonstrating that dysregulation in dopamine sequestration via loss of VMAT2 is sufficient to cause neurodegeneration. Analysis of pathogenic mechanisms of degeneration within viral-transduced dopaminergic neurons identified oxidative damage of macromolecules evidenced by a 26.29% increase in 4-hydroxynonenal (paired t-test, n=9, $p<0.05$) and a 27.36% increase in 3-nitrotyrosine (paired t-test, n=9, $p<0.05$). Proximity ligation assay was used to quantify a 28.35% increase in autophosphorylation of the Parkinson's disease-associated kinase LRRK2, which indicates increased LRRK2 activation (paired t-test, n=4, $p<0.05$). As an additional measure of LRRK2 activity, the amount of phosphorylated Rab10, a substrate of LRRK2, was quantified with a 23.52% increase in phosphorylated Rab10 (paired t-test, n=4, $p<0.05$). Although there was no significant increase in total α-synuclein, there was a 42.85% increase in phosphorylated α-synuclein (paired t-test, n=4, $p<0.05$) as well as a 90.9% increase in the interaction between α-synuclein and mitochondrial protein import protein TOM20 (paired t-test, n=3, $p<0.05$), which

indicates the formation of aberrant α-synuclein. This model demonstrates that a progressive acquired loss of VMAT2 expression in adulthood is sufficient to induce Parkinson's disease associated pathogenic mechanisms of degeneration and provides a novel model to test therapeutic interventions for Parkinson's disease.

1455a Effects of Formaldehyde Exposure on Human Neural Cell Using 3D Model *In Vitro*

P. Wu. *New York University, New York, NY.* Sponsor: C. Jin

Alzheimer's disease (AD), as a chronic neurodegenerative disorder characterized by rapidly progressive cognitive dysfunction and behavior impairment, is the most common form of dementia which accounts for 60 to 70 percent of cases. Pathologically, AD is characterized by severe atrophy and neuronal loss, extracellular neuritic plaques composed mainly of aggregated amyloid-β (Aβ), and intracellular neurofibrillary tangles consisting of hyperphosphorylated tau protein. Multilevel complex interactions between genetic, epigenetic, and environmental factors contribute to the occurrence and progression of AD. Formaldehyde (FA) is the simplest of the aldehyde which is a widespread environmental organic pollutant. Recent studies suggested that elevation of FA in the body by endogenous and/or exogenous exposure may play important roles in AD development. To investigate the role of FA exposure in AD development and progression in human cells *in vitro*, a three-dimensional (3D) human neural cell culture model for AD was used. This model was able to recapitulate key events of AD pathology including β-amyloid plaques and neurofibrillary tangles. Immortalized human neural progenitor cells (ReNcell VM (ReN)) were virally transfected with AD-related mutant genes including mutant APP and/or PSEN1 and enriched based on GFP and/or mCherry signals by Fluorescence-activated cell sorting (FACS). In order to mimic the restrictive environment of human brain and allow Aβ deposition and aggregation, the FACS-sorted ReN cells were differentiated into neurons and maintained in a 3D Matrigel culture system. The AD Model and primary ReN cells were treated with different concentrations of FA as well as vehicle control for 16 weeks. Expression of Aβ40 and Aβ42 were measured in 4, 6, 12 16 weeks by ELISA and cytotoxicity was evaluated by LDH (Lactate Dehydrogenase) activity assay. The results revealed that FA significantly elevates expression of Aβ40 and Aβ42 in a concentration-dependent manner both in AD model and ReN cells. It indicated that FA exposure may play a critical role in AD development and progression. Further study of the mechanisms involving in FA and Aβ, tau protein, histone modifications, chromatin assembly will be explored, which may provide more clues of AD etiology and new insight into AD potential therapeutic targets.

1456 Non-Dioxin-Like Polychlorinated Biphenyls Affect the Sensory System Leading to a Delayed Escape Response in Zebrafish Larvae

N. R. Brun, J. M. Panlilio, J. J. Stegeman, and J. V. Goldstone. *Woods Hole Oceanographic Institution, Woods Hole, MA.*

Polychlorinated biphenyls (PCBs) are persistent legacy contaminants that bioconcentrate in fish and other predators. Fish are a major dietary source of exposure for humans. One of the most abundant PCBs found in aquatic biota and in human maternal plasma and amniotic fluid is the non-dioxin-like PCB153, yet its biological activity is not well understood. There is increasing evidence that PCB153 targets the nervous system and may be responsible for behavioral deficits following exposures in early development. In this study, we used the zebrafish larvae to investigate the effects of the non-dioxin-like congeners PCB153 and PCB138 on the neural circuitry during development, in comparison to the dioxin-like PCB126. We tested behavioral effects in PCB-treated fish by assessing the larval escape response. Our results show that in 6-day old larvae exposed to PCB153 or PCB138, the response latency times (M = 58.0 ms, SD= 30.7, and M = 57.0 ms, SD = 33.5, respectively), were dramatically greater than the latency in controls (M = 20.9 ms, SD = 20.0), $F(3, 747)$ = 125.4, $p<0.0001$. Notably, PCB126 does not alter the latency (M = 19.2 ms, SD = 20.1). The escape response involves a neuronal circuit with detection of the signal in auditory hair cells and other sensory neurons, and transmission to the Mauthner cells and reticulospinal neurons. By using transgenic zebrafish lines, immunohistochemistry, and electrical stimulation, which bypasses the sensory system and directly activates Mauthner neurons, we were able to show that the Mauthner cells are present (in all of the 50 samples inspected) and functionally transmit information downstream of the circuit ($t(87)$ = 1.045, p = 0.2989). Morphological analysis of hair cells and innervating neurons is currently underway. Non-dioxin-like PCBs may be disrupting synaptic transmission to the Mauthner cell by inducing swelling of afferent neurons and modulating neurotransmission. This study advances understanding of the mechanism of action of a ubiquitous environmental contaminant, providing mechanistic insight into a process affecting rapid escape from predators (ecological relevance) and proper neuronal development (human health relevance). *NIH 5P42ES007381 - The Boston University Superfund Research Program.*

1457 microRNA-124 Protects Neural Cells against Arsenic-Induced Endoplasmic Reticulum Stress and Cytotoxicity *In Vitro* and Is Associated with Neurodevelopmental Outcomes in Children

H. Park, R. Sun, R. A. Panganiban, D. C. Christiani, and Q. Lu. *Harvard T.H. Chan School of Public Health, Boston, MA.*

Arsenic (As) exposure adversely affects neurodevelopment in children. Accumulation of misfolded proteins leads to endoplasmic reticulum (ER) stress response, if not relieved, cell death. Despite the potential role of ER stress for As-induced neurotoxicity, the underlying mechanisms remain poorly understood. This study aimed to identify the roles of microRNA(miR)-124, a novel ER stress suppressor, in the regulation of As-induced ER stress response and cytotoxicity in neural cells. We further aimed to link these *in vitro* findings to neurodevelopmental outcomes in children who were exposed to As. Using Quantitative RT-PCR and Cyquant assay, we showed that miR-124 protects against As-induced cytotoxicity in neural cells with concomitant suppression of As-induced ER stress. In addition, As-induced cytotoxicity was exacerbated in miR-124 knockouts generated by CRISPR-based gene editing compared to scramble control. Furthermore, we identified two miR-124 SNPs rs67543816 (p=0.0003) and rs35418153 (p=0.0004) that are significantly associated with a mental composite score calculated from the Bayley Scales of Infant Development III in Bangladesh children. Our study implicates As-induced ER stress as a crucial mechanism for the detrimental effects of As on neural cell function and neurodevelopment and identifies miR-124 as a potential preventative and therapeutic target against detrimental effects of As exposure in children.

1458 Effect of Placental-Derived Mesenchymal Stem Cells on Fetal Brain Developmental Defects Caused by Maternal LPS-Induced Intrauterine Inflammation

C. Tseng[1], C. Wu[1], C. Chen[2], and M. Chao[1]. *[1]Chung Yuan Christian University, Taoyuan, Taiwan; and [2]Mackay Memorial Hospital, Taipei, Taiwan.*

Maternal bacterial infections during pregnancy represent a significant risk factor in preterm as well as neuropsychiatric disorders with a presumed neurodevelopmental deficit. One of the downstream syndrome, neuroinflammation, has been reported to be highly associated with numbers of neurological and pathological diseases, like schizophrenia, cerebral palsy, and autism. Our previous published data has been used lipopolysaccharide (LPS) as a model of clinical bacterial infection in pregnant animals like many other reports. We found that LPS induced counteracted pregnancy loss and alterations in thickness and lamination of the neocortex *in vivo*. It is due to LPS-induced inflammation response, which is proved by application of N-acetyl-cysteine (NAC). However, the NAC is debatably used in clinical in pregnant subjects. Accordingly, mesenchymal stem cells (MSCs) are considered as a substitute therapeutic agent. MSCs are pluripotent cells that are present in multiple tissues, including bone marrow, adipose tissue, skin, muscle, blood, and placenta. It has been proved that MSCs can interact with cells of both the innate and adaptive immune systems, and thus act as a possible clinical therapy for immune-mediated diseases, such as osteogenesis imperfecta, severe graftversus-host disease (GvHD), and Crohn's disease. Therefore, it is conceivable that MSCs could protect the fetal brain against LPS caused inflammatory response. MSCs were directly infused into fetal abdomen or placenta at a density of 1×10^5 cells at 15 days of gestation age, and one hour later a dose of 25 μg/kg LPS was injected into pregnant rats intraperitoneally. To label the new generating neurons, 5-bromodeoxyuridine solution (BrdU, 50 mg/kg/day in PBS) was injected subcutaneously from 16 to 18 days of gestation age. Twenty-four hours later, the pregnant rats were sacrificed, and maternal hematology, cytokine and ROS production were analyzed. H&E staining and immuno-labeling of cortical laminate markers, such as Ctip2, Satb2, were used to investigate the fetal brain morphology and laminal development. Indeed, we found that LPS-induced toxicity could be ameliorated in the presence of MSCs, including in recovery of hemoglobin level and WBC number, an increase of cortical thickness, and prevention of abnormal Satb2 cortical lamination. In the first place, this study describes the initial efforts to evaluate the likely therapeutic effects of MSCs on LPS-induced developmental failure.

1459 Neonatal Exposure to Organophosphorus Flame Retardant TDCPP Induces Hippocampal Injury via Microglia-Mediated Inflammation

Y. Wei, and X. Zhong. *Sun Yat-sen University, Guangzhou, China.*

Tris(1,3-dichloro-2-propyl) phosphate (TDCPP) is a phosphorus-based flame retardant common in consumer goods and baby products. Neurodevelopmental toxicity is a major concern of OPFRs' adverse health effects. However, the mechanism and early response for TDCPP-induced neurotoxicity are largely unknown. This study investigates the role of microglia-mediated neuroinflammation in TDCPP-induced neurotoxicity in mouse hippocampus and primary culture cells. C57BL/6 pups were administered with TDCPP (0, 5, or 50 mg/kg/day) via oral gavage from postnatal days 10 to 38 (28 days). The results showed that TDCPP exposure for 28 days altered the gene expression of neuronal markers *Tubb3, Nefh, Nes* and *Mbp*, and led to apoptosis in the hippocampus. The mRNA levels of pro-inflammatory factors *Il-1β, Tnfa* and *Ccl2* dose-dependently increased in the hippocampus at both 24 hours and 28 days following exposure, accompanied by microglia activation characterized by an amoeboid-like phenotype. In *in vitro* studies using the primary microglia isolated from neonatal mice, exposure to TDCPP (0-100 μM) for 24 hours resulted in cellular activation. It also increased the expression of genes responsible for inflammatory responses including surface markers and pro-inflammatory cytokines in a dose-dependent fashion. Neurite outgrowth of primary mouse hippocampal neurons was inhibited by treatment with the conditioned medium harvested from microglia exposed to TDCPP. These results reveal that neonatal exposure to TDCPP induces neuronal damage in hippocampus through microglia-mediated inflammation. The study suggests that microglia is a sensitive responder for OPFRs exposure.

1460 *D*-Amphetamine, but Not Desipramine, Impairs Sustained Attention and Short-Term Remembering in Mice Exposed to Low but Not High Doses of Methylmercury during Adolescence

D. Kendricks, and M. C. Newland. *Auburn University, Auburn, AL.*

Methylmercury (MeHg), a known environmental neurotoxicant, has been previously shown to alter behaviors related to development of dopamine systems, such as observed impairments in choice and behavioral flexibility. Other behaviors related to development of dopamine systems, such as attention and memory, which are components of attention-deficit/hyperactivity disorder, may also be targets of MeHg's toxicity. Because adolescence is the final period for dopamine development prior to adulthood, changes in sustained attention and memory as a result of adolescent MeHg exposure were observed here using a mouse model. Mice were exposed to 0, 0.3, or 3ppm MeHg throughout adolescence and trained in a visual signal detection task in adulthood. Behavior was probed with dopaminergic and noradrenergic agonists, *d*-amphetamine and desipramine, in order to determine the specificity of MeHg's effects. MeHg did not alter baseline responding on the visual signal detection task but behavior for the 0 and 0.3ppm exposure animals was disrupted by the highest dose of *d*-amphetamine, 1.0mg/kg. Animals exposed to 3ppm MeHg were not impaired by any dose of *d*-amphetamine. Further, desipramine did not impair behavior for any animals in this task supporting hypotheses that performance in this task is specifically mediated by dopamine activity. Because animals exposed to 3ppm MeHg were not affected by *d*-amphetamine, this study suggests that interactions between MeHg and *d*-amphetamine are nonmonotonic.

1461 Zebrafish Larval Locomotor Activity Is Depressed by Lack of Swim Bladder inflation or Dimethyl Sulfoxide

B. N. Hill[1], D. L. Hunter[2], and S. Padilla[2]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; and [2]US EPA, Research Triangle Park, NC.* Sponsor: T. Shafer

The US Environmental Protection Agency (US EPA) is evaluating alternative methods to screen and prioritize chemicals for developmental neurotoxicity. Assessing larval zebrafish photomotor response is recognized as a higher throughput testing strategy to identify neurotoxic chemicals. Usually, dead and malformed embryos are not included in the analyses of the larval zebrafish behavior, but, often, swim bladder inflation status is not assessed or reported. In our studies, we have determined that the photomotor responses of control larvae without inflated swim bladders is reduced >50% during the light phase of testing as compared to locomotor activity of control larvae with inflated swim bladders. Another variable, dimethyl sulfoxide (DMSO), a commonly used vehicle for administering chemicals, has been recently reported (Teixidó *et al*. 2018) to affect swim bladder inflation and locomotor activity in larval zebrafish, however larvae without inflated swim bladders appeared to have been included in that behavioral analysis. The main objective of the present study was to determine whether those behavioral changes noted by Teixidó and coworkers were a result of impaired swim bladder inflation or solely due to DMSO exposure. Embryonic zebrafish were developmentally exposed to a range (0.05-1.5%, v/v) of DMSO and, at 6 days post-fertilization, swim bladder inflation and locomotor activity were assessed. Larvae developmentally exposed to the highest DMSO concentration (1.5%) showed decreased incidence of swim bladder inflation, whereas locomotor activity for larvae with inflated swim bladders was altered at DMSO concentrations as low as 1%, a concentration used in some developmental neurotoxicity assays. These results indicate that DMSO can affect both swim bladder inflation and locomotor activity, but the effect on locomotor activity is the more sensitive endpoint. Therefore, caution should be taken when interpreting reports that include larvae without inflated swim bladders or utilize DMSO concentrations near 1% as both of these variables can influence behavior results. *This abstract may not necessarily reflect official Agency policy.*

1462 Lead Exposure Alters the Neurogenic Potential of Pluripotent Stem Cells

C. Mansel, S. Fross, and B. Vohra. *William Jewell College, Liberty, MO.* Sponsor: B. Vohra, American Society for Pharmacology and Experimental Therapeutics

Lead (Pb) is a teratogen that poses health risks after acute and chronic exposure. Developing fetuses are particularly sensitive to maternal blood lead levels because lead can freely pass through the placental membrane. Although lead's effect on late-stage embryonic development has been studied extensively, only a few studies have examined how lead affects stem cell determination and differentiation. In our present study, we sought to investigate how lead affects the retinoic-acid induced determination and differentiation of pluripotent stem cells into neurons. To achieve this end, we cultured P19 stem cells with 1-3μM Pb^{2+} and measured lead's effect on neurosphere formation, cytotoxicity, cell proliferation, and stem cell differentiation into neurons and glial cells. Moreover, we explored the mechanism of this affect by measuring N-cadherin and Sox2 expression after lead treatment. We discovered that lead exposure significantly decreased both the number and size of neurospheres by as much as 50% through an increase in cytotoxicity which decreased the number of alive cells by 40% after 48hrs when compared to the control. Moreover, lead exposure decreased expression of N-cadherin during the determination process by over 50% and significantly increased the number of Sox2-positive cells when lead was added during the determination process by over 60% when compared to the control. We also found that the negative effect of lead exposure on neuronal differentiation of stem cells did not significantly differ when we exposed the cells to lead during the process of determination or differentiation. However, lead exposure affected glial cell differentiation in a stage-specific manner by inhibiting glial cell differentiation when lead was added during determination and promoting glial cell differentiation when lead was added during the differentiation process. In summary, lead exposure during the development process may alter the differentiation potential and survival of neuronal stem cells and likely affects the overall development of the nervous system in developing embryos.

1463 2,3,7,8 Tetrachlorodibenzo-[p]-Dioxin-Induced Activation of the Aryl Hydrocarbon Receptor Alters Brain Morphology and Disrupts Oligodendrocyte Precursor Development

N. R. Martin[1], J. C. Gawdzik[2], S. E. Martin[1], A. L. Rodd[1], and J. S. Plavicki[1]. *[1]Brown University, Providence, RI; and [2]University of Wisconsin–Madison, Madison, WI.*

The aryl hydrocarbon receptor (AHR) is a ligand-activated transcription factor with roles in the development and function of the nervous system. Environmental contaminants such as dioxin (TCDD; 2,3,7,8 tetrachlorodibenzo-[p]-dioxin), polycyclic aromatic hydrocarbons (PAH), and polychlorobiphenyls (PCB) activate AHR and produce transcriptional changes that disrupt central nervous system development (CNS) and alter behavior. Our goal is to determine how AHR activation in zebrafish leads to hyperactivity by assessing changes in brain development and function. Developmental toxicology in studies in mice have demonstrated that a single prenatal exposure to TCDD disrupts CNS myelination by oligodendrocytes. Myelin insulates axons and is necessary for effective communication between neurons and impairment is associated with neurodegenerative disorders such as cerebral palsy and

multiple sclerosis. In the zebrafish hindbrain, the transcription factor Sox9b directs development of oligodendrocyte precursor cells. Our preliminary data indicate that toxicant-induced AHR activation (1 ppb TCDD; waterborne at 4 hours post-fertilization (hpf) for 1 hour) results in the downregulation of *sox9b* in the developing zebrafish brain. We hypothesize that AHR agonist exposure disrupts oligodendrocyte development due to impaired expression *sox9b*. Using fluorescent immunohistochemistry and confocal microscopy, we found that early exposure to TCDD altered brain morphology and resulted in a change in oligodendrocyte precursor number. To elucidate the roles of sox9b in early oligodendrocyte development, we have generated a dominant negative Sox9b (dnSox9b) to manipulate Sox9b function in developing zebrafish employing the Gal4/UAS system. Our preliminary results indicate that inhibiting Sox9b function significantly alters brain morphology and reduces oligodendrocyte number. Together, these studies demonstrate the effects of AHR activation on oligodendrocyte development and facilitate our understanding of how environmental contaminant exposure impact neurodevelopment.

PS 1464 Population Variability in Neurotoxicity Outcomes Modeled *In Vitro* with Diversity Outbred Neural Progenitor Cells

D. You[1], M. Behl[1], T. Choi[2], L. Page[2], L. Everett[3], M. Balik-Meisner[3], D. Porter[2], K. Witt[1], R. Paules[1], and A. H. Harrill[1]. *[1]NIEHS, Research Triangle Park, NC; [2]Predictive Biology, Carlsbad, CA; and [3]Sciome LLC, Research Triangle Park, NC.*

Developmental neurotoxicity (DNT) is critical, yet challenging, health effect of chemicals to study. To date, there are few screens for DNT and existing assays do not incorporate sufficient genetic diversity to capture variation in DNT susceptibility across individuals in a diverse human population. To overcome these challenges, Diversity Outbred (DO) mice were created as a population resource composed of genetically distinct individuals, mimicking the diversity of the human population. DO mice allow investigators to generate toxicodynamic variability factors (TDVFs) that can replace default uncertainty adjustment factors for risk assessment. Here, we utilized 200 neural progenitor cells (NPCs) derived from DO mice to assess the population-wide variability upon exposure to six chemicals with DNT potential (0-100 µM): rotenone, dieldrin, estradiol, methyl mercury, 2,2′,4,4′,5-pentabromodiphenyl ether or isopropylated phenyl phosphate. Cell viability was measured at 114 h post-exposure. We observed wide distributions of the cytotoxicity EC10 for rotenone and methyl mercury, indicating that genetic variants contributed to interindividual sensitivities to these agents. Chemical-specific TDVFs were calculated to quantitatively assess population variability in toxic response using Bayesian statistics. The TDVFs for rotenone and methyl mercury were greater than default uncertainty factor, indicating that the reference dose for these chemicals may not adequately protect genetically sensitive subpopulations. In addition, mouse-derived TDVFs were comparable to human cell-derived TDVFs, suggesting that DO-derived TDVFs adequately capture human variability. TempO-Seq transcriptomic analysis, along with machine learning, is ongoing to determine mechanisms underlying and biomarkers associated with susceptibility to methyl mercury toxicity. Taken together, this population-based *in vitro* assay using DO NPCs provides a data-driven estimate for interindividual toxicodynamic variability suitable to inform risk assessment and more precise determination of human reference doses.

PS 1465 Embryonic and Larval Zebrafish (*Danio rerio*) Developmental Toxicity following Zinc Exposure

S. H. Pradhan, M. A. Coogan, and C. M. Sayes. *Baylor University, Waco, TX.*

The widespread application of emerging nanomaterials has made it necessary to question the potential adverse effects of nanoparticles released into the environment. The size and unique properties of nanoparticles have proven beneficial as ingredients in consumer products, but the literature has linked exposure to certain nanoparticles with adverse health effects ranging from oxidative stress to developmental toxicity and genotoxicity in aquatic environments. Zinc is an essential trace element and plays an important role in aquatic physiological processes, but in excess can display toxic effects. Bioaccumulation of zinc oxide nanoparticles (ZnO_2NP) has been observed in the gills of adult zebrafish, resulting in increased presence of reactive oxygen species (ROS). The toxicity of zinc derivatives ($ZnCl_2$ and ZnO_2, ZnO_2NP) has been attributed to the dissolution of the zinc ions as opposed to a nanoparticle-mediated toxicity. This study measures developmental toxicity in embryo and larval zebrafish (up to 18 dpf) with $ZnCl_2$ and ZnO_2NP at 0ppm, 0.25ppm, 0.50ppm, 0.75ppm, 1.00ppm, and 1.25ppm dosing concentrations in order to elucidate the potential effects of nanoparticle toxicity. Endpoints being measured include escape and avoidance behaviors, length, spinal angles, and ocular distance. Biochemical assays are also applied to measure mitochondrial activation and RTqPCR for genomic endpoints. Higher levels of avoidance behavior were observed following ZnO_2NP exposure when compared to $ZnCl_2$, while length, spinal angles, and ocular distance results were similar for both toxicants. Biochemical assays revealed increased mitochondrial activity with the nanoparticle when compared to chloride. RTqPCR revealed changes in SOD1, Bcl-2, Pink1 and p53. Bcl-2 and Pink1, genes related to mitophagy, suggesting the role of the mitochondria in zinc toxicity. In order to further confirm the toxicant role of the nanoparticle in zinc toxicity, further studies should include investigation of zero valent zinc nanoparticles along with dissociation of ZnO_2NP and $ZnCl_2$ into Zn (II).

PS 1466 The Use of Genetically Encoded Calcium Indicators to Understand the Effects of Neurotoxic Compounds on Neuronal Function

N. R. Martin, S. E. Martin, and J. S. Plavicki. *Brown University, Providence, RI.*

Zebrafish are an outstanding model for studying the molecular mechanisms underlying brain development. Researchers have leveraged the throughput capabilities of the model to screen the neurotoxic potential of a large number of compounds. These powerful screens provide a readout of dysfunction, but do not identify the regional changes in brain activity that mediate the observed behavioral changes. Here, we describe how genetically encoded calcium indicators can be used to perform functional neuroimaging in zebrafish and how we can use functional neuroimaging to gain insight into how neurotoxicant exposure affects brain health. To visualize changes in regional brain activity following toxicant exposure, we are using the CaMPARI transgenic zebrafish line. CaMPARI, which stands for **Ca**lcium **M**odulated **P**hoto**a**ctivatable **R**atiometric **I**ntegrator, is a photoconvertible protein that permanently converts cells with high calcium from green to red in the presence of 405 nm light. In the transgenic line we are using, CaMPARI is driven by a differentiated neuron-specific promoter. Since neuronal firing is accompanied by an influx of calcium, following photoconversion the more active cells will appear red, while less active cells will remain green. To photoconvert CaMPARI in freely behaving fish, we modified our Noldus DanioVision behavioral unit to include a 405 LED. As an initial proof-of-concept experiment, we acutely exposed zebrafish larvae at 4 days post fertilization (dpf) to either (1) the GABA-inhibitor pentylenetetrazol (PTZ), (2) the anesthetizing agent MS-222, or (3) untreated embryo rearing medium. As expected, PTZ exposure increased motor activity and calcium signaling, whereas the acute exposure to MS-222 decreased motor behavior and neuronal activity. After successfully generating an experimental pipeline for photoconversion and analysis, we exposed larvae to varying concentrations of perfluorooctanesulfonic acid (PFOS), a pervasive toxicant that has been shown to produce hyperactivity in low doses in larval zebrafish and has also been shown to alter juvenile zebrafish behavior. Chronic exposure to PFOS (32 µM and 16 µM; from 4 hpf until the time of photoconversion) resulted in a significant global increase in neural activity and either hyper- or hypoactivity depending on the PFOS dose. We are currently examining the effects of different per- and polyfluoroalkyl substances as well as known neurotoxicants on neuronal activity. Moving forward we will collaborate with computational biologists to analyze regional differences in activity within individuals to identify the systems levels changes that are produced by toxicant exposure. Together, our functional neuroimaging studies paired with behavioral analysis will provide insight into the effects of neurotoxicants on brain function and provide a means for determining if different regional patterns of brain activity can produce similar behavioral responses.

PS 1467 Mutations Link Polycyclic Aromatic Hydrocarbon Exposure to Neurodevelopmental Diseases

B. H. Baker, and B. L. Pearson. *Columbia University, New York, NY.*

Polycyclic aromatic hydrocarbons (PAHs) are a mutagenic class of chemicals produced from burning organic matter. Inhalation and ingestion are the most common routes of exposure to PAHs, which are ubiquitous in air pollution, cigarette smoke, and burnt food. While epidemiologic studies show a clear association between PAHs and neurodevelopmental diseases, the underlying mechanisms are poorly understood. One possibility is environmentally induc*ed mutations*, which are well known to underlie cancer, but are seldom studied in the context of neurodevelopmental disease. Once metabolically activated by phase I enzymes, PAHs form mutation-inducing DNA adducts. To characterize mutational signatures relevant to cancer, Kucab and colleagues (2019, PMID 30982602) performed whole genome sequencing (WGS) of PAH dosed human induced pluripotent stem cells. We used this WGS dataset to explore the ability of PAHs to mutate neurodevelopmental genes. To determine if the genes mutated by PAHs were enriched for nervous system processes,

we performed gene ontology analysis of PAH-induced coding sequence variants. To determine if PAH-caused *mutations* promote specific nervous system diseases, we compared the number of PAH mutations in high-confidence gene sets for several diseases with 1,000 bootstrapped control gene sets from the genome. Out of 13 enriched gene ontology terms, 8 were closely related to neurodevelopment. Compared to control gene sets, there were 3.6-fold more mutations in autism genes, 4.0-fold more mutations in schizophrenia genes, and 3.0-fold more mutations in attention deficit hyperactivity disorder (ADHD) genes. Alzheimer's and amyotrophic lateral sclerosis (ALS) genes were mutated at similar rates to control genes. When the analysis was restricted to protein coding sequence mutations, autism and schizophrenia genes were mutated significantly more than randomly sampled genes, while ADHD, Alzheimer's, and ALS genes were not. Disparities in the mutability of genes may depend on gene length, gene expression, chromatin structure, and other genomic properties. Ultimately, we show increased susceptibility of neurodevelopmental genes to PAH induced *mutations*, which underscores the role of the environment in neurodevelopmental disease. Environmental exposures may be responsible for a large proportion of *de novo* mutations underlying sporadic cases of autism and schizophrenia.

1468 Identifying Key Events That Drive Neurotoxicity in Larval Zebrafish with Transcriptomic Dose-Response Modeling

X. Howey[1], T. Tal[2], S. Gaballah[1], C. Wood[1], L. Bertotto[1], and L. Wehmas[1]. *[1]US EPA, Research Triangle Park, NC; and [2]Helmholtz Centre for Environmental Research, Leipzig, Germany.*

Gene expression data from short-term *in vivo* studies shows efficacy in quantifying concentration-dependent effects that inform toxicity outcomes, particularly for chemicals with limited toxicity data such as Per- and Polyfluoroalkyl Substances (PFAS). Here, zebrafish were exposed to 4.4-44.8 µM potassium perfluorohexane-1-sulfonate (PFHxS), 0.28-5.0 µM perfluorooctane sulfonic acid (PFOS), 0.25-5.0 µM Heptachlor (control for developmental neurotoxicity; DNT) or 0.4% DMSO daily from 0-5 days post fertilization (dpf). Automated behavioral assessments on 6 dpf revealed hyperactivity for all compounds at non-teratogenic concentrations. To identify key events that drive DNT, zebrafish were exposed to 7.87-25.1 µM PFHxS, 0.88-2.8 µM PFOS, 0.49-1.57 µM Heptachlor, or 0.4% DMSO. RNA was isolated from head tissue collected at 4 and 5 dpf, before the onset of hyperactivity, for sequencing (NextSeq 500). Differentially expressed genes were identified using Gene Specific Analysis (Partek Flow) and mapped to human orthologs for analyses (IPA). PPAR was predicted as a major regulator for all chemicals. Enrichment in neurologic-related pathways, including axonal guidance signaling and dopamine feedback, was also identified. Dose estimates from transcriptomic benchmark dose modeling (BMD_T, BMDExpress 2.0) identified median BMD_T values of 18 µM (PFHxS), 2 µM (PFOS), and 1 µM (Hetachlor) at 4 dpf and 10 µM (PFHxS), 1 µM (PFOS), and 1 µM (Heptachlor) at 5 dpf. Median BMD_T values were comparable to *in vivo* lowest observed effect concentration (LOEC) values for hyperactivity: 14 µM PFHxS, 0.88 µM PFOS, or 0.88 µM Heptachlor. This approach demonstrates that transcriptomic points of departure can be linked to hyperactivity (i.e. a functional DNT toxicity outcome) in larval zebrafish to ultimately inform mode of action delineation and enhance chemical risk assessments. *This abstract does not necessarily reflect US EPA policy.*

1469 Development of Automated Neurotoxicity Assay in Juvenile Mice

T. Endo[1,2], S. Benner[3], H. Lipp[4], and C. Tohyama[2]. *[1]Phenovance Research and Technology LLC, Kashiwa, Japan; [2]University of Tsukuba, Tsukuba, Japan; [3]Hamamatsu University School of Medicine, Hamamatsu, Japan; and [4]Neurospex, Zurich, Switzerland.*

The immature brain in the developing period is known to be vulnerable to environmental chemicals. However, reliable and efficient behavioral testing methods to directly assess the toxicological effects on cognitive function in juvenile animal models are limited. Here, we aimed to develop an automated and standardized method for assaying cognitive behavior of juvenile mice, as early as weaning, up to adult mice. Methods: We utilized IntelliCage (TSE Systems/New Behavior), an automated behavioral testing system, by customizing its hardware to suit the size of juvenile mice at different stages. A total of 24 juvenile mice (12 males and 12 females) were prepared using 15 pregnant mice of C57Bl/6N strain. To minimize the possible litter effects, one or two offspring of the same sex were obtained from each dam. On postnatal day 21, the mice were weaned, implanted with a microchip, and group-housed in the IntelliCage. The cognitive behavior of the mice was continuously assessed using a self-paced behavioral flexibility test (SP-FLEX) protocol until the mice became 8 weeks old. This test required mice to acquire place learning and shuttling rule and adapt to serial reversals, to obtain water reward effectively. The present method using a customized IntelliCage was found to detect juvenile mouse behaviors (corner visit, nose poke, and licking) without complications. All 3-week-old mice fulfilled the criteria of acquisition of the original place learning and shuttling rule (30% of correct response rate) within the first 48 h, and completed at least 15 reversal phases within the first 2 weeks. In addition, sexually-dimorphic behavioral choice tendencies in the SP-FLEX was found to emerge during the first 2 weeks. All the above results including the sexual difference found in juvenile mice are similar to those typically observed in adults over 8 weeks old. We successfully developed an automated cognitive assay for juvenile mice up to adult mice. This method can be applied to examine the safety of chemical agents in the juvenile period and to investigate the detailed time course of typical/atypical cognitive-behavioral development in mice. *This study was supported by JSPS KAKENHI JP18H03036.*

1470 Using Zebrafish to Study Birth Defects: The Effect of Valproic Acid during Embryonic Neurogenesis

M. A. Muhsen[1], J. Youngs[1], A. Riu[2], and M. Bondesson[1]. *[1]Indiana University Bloomington, Bloomington, IN; and [2]University of Houston, Houston, TX.*

Valproic acid (VPA) is an anticonvulsant drug used to treat certain types of epilepsy. Several reports have shown that VPA has teratogenic effects during pregnancy. Fetal exposure increases the risk for birth defects, including neural tube defects (NTDs) and other congenital malformations, as well as learning difficulties and behavioral problems. We investigated neurotoxic effects of VPA exposure using zebrafish as a model organism. Different transgenic (Tg) fish embryos were exposed to increasing concentrations of VPA from 6 hours post fertilization. Tg (ngn1: eGFP) was used to visualize neural tube development in zebrafish embryos. Tg (mnx1: GFP) was used to study motor neurons and neurite sprouting. Tg (nestin: eGFP) was used to study neuroepithelial stem cells and neural progenitor cells. Our results showed that VPA exposure resulted in NTDs, motor neuron abnormalities and neurite sprouting defects. Additionally, VPA decreased the fluorescence of neuronal progenitor cells in early developmental stages, indicating fewer cells. We further investigated whether Vitamin B9 (Folic Acid, FA) could rescue the VPA-induced perturbations. Our preliminary results indicated that FA treatment did not rescue the number of the neuronal progenitor cells. We conclude that VPA exposure induces specific neurotoxic effects in developing embryos, and that zebrafish is a promising model to study these effects and to screen for countermeasures.

1471 Evaluation of Chemical and Nonchemical Interactions on Neurological Development of Rat Offspring

T. E. Beasley[1], K. L. McDaniel[1], W. M. Oshiro[1], J. N. Franklin[1], V. C. Moser[2], and D. W. Herr[1]. *[1]US EPA, Research Triangle Park, NC; and [2]US EPA (Retired), Research Triangle Park, NC.*

Exposure to chemicals and non-chemical factors that occur during susceptible stages of neurodevelopment have been associated with several adverse outcomes in children, including cognitive deficits, anxiety, and depression. However, it is unclear as to how exposure to both chemical and non-chemical factors may impact brain development. To better understand these potential interactions, we exposed pregnant Long-Evans rats to Manganese (Mn), a reported neurodevelopmental toxicant, through drinking water (0, 2, or 4 mg/ml) from gestational day (GD) 7 to postnatal day (PND) 22. Half of the animals were perinatally exposed to a variable stress paradigm from GD13 to PND9. Measurements of somatic development and behavior were then quantified in the offspring to evaluate the impacts of Mn alone, and when combined with maternal stress. Mn concentrations in the drinking water provided to the dams were measured as < 0.001, 1.95 and 3.93 mg/ml respectively. Our results indicate no evidence of maternal toxicity was observed, and all dams gained weight at the same rate. Maternal stress and/or Mn exposure did not affect litter size but PND22 pup weight was significantly reduced in the 4 mg/ml Mn-exposed group. Water consumption was decreased in the Mn exposed dams in a dose-dependent manner but was not altered by the stress paradigm. The efficacy of the manipulations to increase maternal stress levels was determined using serum corticosterone (Cort) as a biomarker. A baseline concentration was established prior to treatment (GD7) and then measured at subsequent time points (GD16, PND9). Baseline Cort levels were low and similar in all treatment groups. As expected, Cort levels were elevated in all the Stress groups on GD16 when compared to the Non-Stress groups. A preliminary analysis of Mn tissue concentrations revealed levels elevated similarly in the brain and blood of Mn-exposed pups at PND2. Similarly, PND23 Mn-exposed dams also showed increased Mn concentrations in the brain, blood and liver; the addition of stress did not significantly alter the Mn levels in these tissues.

Taken together, these results show that maternal stress did not exacerbate the effects of Mn exposure on these measurements. *This abstract does not necessarily reflect US EPA policy.*

1472 Assessing Adult Cognitive and Motor Function in Three Genotypes of Mice Exposed to Benzo[a]pyrene during Early Brain Development

K. Clough, J. Mullaguru, E. DeBurger, K. Jenkins, V. Ferguson, T. Forrest, and C. P. Curran. *Northern Kentucky University, Highland Heights, KY.*

Benzo[a]pyrene (BaP) is a carcinogenic polycyclic aromatic hydrocarbon commonly found in traffic-related air pollution, tobacco smoke, and grilled foods. BaP is linked to learning deficits and to neurodevelopmental delays in human and animal studies. We are using a mouse model to determine if genetic differences increase susceptibility to BaP exposure during early brain development. Mice lacking the CYP1A2 metabolic enzyme and wild type control mice were exposed to BaP from gestational day 10 (GD10) through weaning at postnatal day 25 (P25). A battery of cognitive and motor function tests were performed when the mice reached young adulthood (P60). We used a pole climb test to assess motor function, open field locomotor to assess activity levels, and novel object recognition to assess non-spatial visual learning and memory. We found a significant main effect of genotype in the earlier intervals with higher spontaneous activity in *Ahr^{d}Cyp1a2(-/-)* mice compared with the other two lines ($P < 0.05$). There was a significant gene x treatment interaction with the time to turn ($P < 0.05$) with BaP-exposed *Ahr^{b}Cyp1a2(+/+)* wild type mice having longer latencies whereas BaP-exposed *Ahr^{d}Cyp1a2(-/-)* mice had shorter latencies than corn oil-treated controls ($P < 0.05$). There were no significant differences in the time to descend the pole. There was a significant gene x treatment interaction with *Ahr^{d}Cyp1a2(-/-)* exposed mice showing impairments in object recognition memory ($P < 0.01$).

1473 Developmental Exposure to Non-Aroclor PCB 11 Affects Maternal Gestational Weight Gain, Male Offspring Birth Weight, and Hippocampal Apoptosis in Neonatal Mice

C. R. Klocke[1], H. Lehmler[2], and P. J. Lein[1]. *[1]University of California Davis, Davis, CA; and [2]University of Iowa, Iowa City, IA.*

Commercial production of polychlorinated biphenyls (PCBs) has been banned for decades and environmental levels of congeners present in Aroclor mixtures have been declining. However, recent studies have identified the presence in environmental and biological samples of other PCB congeners that were not present in the original commercial mixtures. PCB 11 (3,3'-dichlorobiphenyl) is one such congener that has been identified in air, water, dairy products, seafood, and meat. Elevated levels of PCB 11 have been detected in the serum of women at increased risk of having a child with a neurodevelopmental disorder (NDD). Previous *in vitro* studies using primary rat hippocampal and cortical neuron-glia co-cultures have shown PCB 11 enhances dendritic arborization and axonal growth at concentrations as low as 1 fM without affecting cell viability. Similar changes in these late stages of neuronal maturation have been noted in ASD patients. However, whether PCB 11 also influences earlier stages of neurodevelopment, such as neuronal apoptosis, which are also implicated in ASD pathogenesis has not yet been tested. There is also a paucity of data as to whether the developmental neurotoxicity of PCB 11 observed *in vitro* is recapitulated *in vivo*. Given that the diet is a major route of PCB exposure, we tested whether dietary exposure to environmentally relevant levels of PCB 11 during gestation and lactation in mice would affect hippocampal apoptosis in the neonatal period. Wild-type female C57BL/6J mice ($N = 5$/group) were given PCB 11 solubilized in peanut oil and mixed into peanut butter at doses of 0.1 or 1.0 mg/kg$_{BW}$/day beginning 14 days (d) prior to mating and continuing through gestation (19-20 d) and lactation (21 d). A vehicle control (VEH) group was given peanut butter with peanut oil alone. Unexpectedly, we observed that 1.0 mg/kg PCB 11 significantly increased maternal weight during both pre-conception and gestational dosing periods. Birth weight, postnatal weight gain, and anogenital distance (AGD) of male offspring in the 1.0 mg/kg group were also significantly increased, but not in any other group. At postnatal day (PND) 4, 1 male and 1 female pup from each litter were euthanized to quantify apoptosis. There was a significant increase in the total number of apoptotic cells in the hippocampus labeled via TUNEL staining in the 0.1 mg/kg group of both sexes. Taken together, these data indicate PCB 11 disrupts neurodevelopment in neonatal mice by increasing apoptosis and suggest a potential role of PCB 11 in endocrine disruption, evidenced by alteration of both maternal and male offspring weight and AGD. *Supported by NIEHS (R01 ES014901-09S1A1).*

1474 Maternal Exposure to Organophosphate Flame Retardants Alters Locomotor and Anxiety-Like Behavior in Male and Female Adult Offspring

K. Wiersielis, S. Adams, A. Yasrebi, K. Conde, and T. Roepke. *Rutgers, The State University of New Jersey, New Brunswick, NJ.*

Endocrine disrupting compounds (EDC) are compounds found in our environment that interrupt typical endocrine function. A particular group of EDCs are flame-retardants due to their interaction with steroid and nuclear receptors in *in vitro* investigations. Humans are consistently exposed to flame-retardants daily as they are used in everyday items such as plastics, clothing, toys, and electronics. In the past, polybrominated diphenyl ethers have been used, however, since 2004, they have been replaced with organophosphate flame-retardants (OPFR) as the major flame-retardant chemical. The effects of maternal or developmental exposure to OPFR on behavior are currently underexplored. Yet, previous research in rodent models utilizing a commercial flame-retardant mixture containing OPFR reported alterations in anxiety like behavior in the elevated plus maze (EPM). Here we asses anxiety-like behavior in the open field test (OFT), the Light/Dark box (LDB), as well as, the EPM in adult offspring that were maternally exposed to OPFR or oil controls. Outcomes from the OFT and LDB indicate that males and females maternally-exposed to OPFR exhibit altered locomotor activity. Results of the EPM were sex-specific as we did not observe an effect in females; however, effects in males differed depending on treatment condition. Males maternally-exposed to OPFR exhibited an anxiolytic-like phenotype in contrast to their vehicle counterparts. This effect in OPFR-treated males was not due to alterations in locomotor activity. Our research illustrates that there are sex- and treatment-dependent effects of OPFR exposure on locomotor and anxiety-like behaviors in a mouse model.

1475 Manganese Consumption and Moderate Perinatal Stress: Complex, Persistent, and Sex-Dependent Changes in Neurobehavior as Assessed by Acoustic Startle Reflex, Prepulse Inhibition, and Choice Reaction Time in Rats

W. M. Oshiro[1], T. E. Beasley[1], K. L. McDaniel[1], V. C. Moser[2], and D. W. Herr[1]. *[1]US EPA, Research Triangle Park, NC; and [2]US EPA (Retired), Research Triangle Park, NC.*

The developmental effects of chemicals that co-occur in vulnerable populations with elevated physical and psychological stress is of increasing concern to risk assessors. In order to assess causality of these factors we developed a rodent model of co-occurring perinatal manipulations and conducted a series of assessments to evaluate behavioral and cognitive functions. Manganese (Mn), a potential neurodevelopmental toxicant, was delivered in drinking water (0, 2, or 4 mg/ml Mn) to pregnant, Long Evans rats from gestational day (GD) 7 to postnatal day (PND) 22. A variable paradigm designed to physically or psychologically challenge the dams was applied to half of the animals from GD13 to PND9. Here we report behavioral assessments performed in adult offspring. The acoustic startle reflex (ASR) and habituation differed between males and females, but no effects of stress or Mn were observed. Assessments of prepulse inhibition (PPI) of the ASR yielded a significant interaction between Stress, Mn, and prepulse intensity. Additional analyses suggested the 2 Mn group differed between stress groups at the 3 dB prepulse. Preliminary data from cued and uncued choice reaction time (CRT) assessments revealed female rats in the stressed group had longer decision times (0 and 4 Mn) and movement times (0 and 2 Mn), while reaction times in males was not affected. Choice accuracy in female rats was not affected by Mn but uncued accuracy was reduced by stress. Male accuracy on the cued task was reduced by Mn but not stress. Finally, premature responding was not affected by any treatment in either sex. This data supports a relationship between persistent perturbations of behavioral processes following early transient environmental perinatal stress and Mn exposure. The behavioral changes of these measures are complex, sex specific, and dependent on the specific task. *This abstract does not necessarily reflect US EPA policy.*

1476 One Size Does Not Fit All in Thyroid Disruption: Distinct Thyroid Hormone Profiles and Adverse Outcomes after Developmental Exposure to PTU (Propylthiouracil), DE-71 (Brominated Flame Retardant), and OMC (Octyl Methoxycinnamate)

M. Axelstad[1], L. Ramhøj[1], M. Scholze[2], J. Köhrle[3], and A. Kortenkamp[2]. *[1]Danmarks Tekniske Universitet, Kgs. Lyngby, Denmark; [2]Brunel University London, London, United Kingdom; and [3]Charité—Universitätsmedizin Berlin, Institut für Experimentelle Endokrinologie, Berlin, Germany.*

Correct thyroid hormone economy is crucial for mammalian brain development. In humans, even mild, non-clinical hypothyroxinemia during pregnancy has been linked to reduced IQ and increased risk of neurobehavioral disorders in the offspring. Several groups of environmental chemicals can interfere with thyroid hormone economy, which raises concern about their potential to disrupt human brain development. Here, we tested how developmental exposure to three thyroid-disrupting chemicals with differing mechanisms of action could affect thyroid hormone economy and cause adverse outcomes. We exposed 104 pregnant Sprague Dawley rats from gestational day (GD) 7 to postnatal day (PD) 22 to either corn oil (vehicle control), the anti-thyroid drug PTU (1 or 2.5 mg/kg/day), the UV-filter OMC (375 or 500 mg/kg/day) or a commercial mixture of brominated flame retardants DE-71 (20 or 40 mg/kg/day). Serum hormones (T3, T4 and TSH), body-, and organ weights were measured in dams and offspring at different times during the study. Our results showed that the three different compounds showed a distinct pattern of effects on liver, thyroid and brain, which seemed closely related to their primary mechanism of action. PTU exposure increased thyroid gland weight, DE-71 caused liver weight increases whereas reductions in brain weights were seen in OMC exposed offspring. The three compounds also caused very different effects on thyroid hormone economy and the hormone effect patterns varied in dams and offspring over the time course of the study. Thus, in developmental toxicity studies it is important to assess thyroid hormone economy at several time points throughout the study, in order to obtain better understand the chemically induced changes and to best protect humans from the adverse effects of thyroid hormone disruption. Future studies should focus on elucidating the origin of the different effect patterns and link them to possible adverse effects on the developing brain.

1477 Triclosan Impairs Mitochondrial Form and Function in the *Xenopus laevis* Tadpole Nervous System

A. H. Thomson, H. G. Sturgeon, and C. K. Thompson. *Virginia Polytechnic Institute and State University, Blacksburg, VA.*

Mitochondrial health is critical for normal brain development, and in a toxic environment mitochondria reduce energy production, undergo mitophagy, and exclude themselves from their vast network. Recent studies have shown that triclosan, a widely used antibacterial and antifungal agent, acts as a mitochondrial uncoupler, which causes damage to the mitochondrial membrane, inhibiting energy production. The impact of triclosan on mitochondrial function in whole animals has not been thoroughly investigated, however. We performed a series of *in vivo* experiments designed to assess the impact of triclosan on mitochondrial form and function in *Xenopus laevis* tadpoles, with emphasis on the nervous system. We injected tadpole brains with TMRM, a fluorescent reporter of mitochondrial membrane potential. After two hours, we imaged the brain using high resolution confocal microscopy to obtain a baseline level of TMRM fluorescence, then immediately treated tadpoles with either triclosan (concentrations from 50μM to 0.1μM), the well-characterized uncoupler FCCP (0.5μM), or control, and then continued imaging the brain once every five min for 30 min. We found that 50μM triclosan significantly decreased TMRM fluorescence in mitochondria in the end feet of radial glial cells in ~ 15-20 min; lower concentrations operated over a longer time course. Preliminary experiments with injections of MitoTracker show that mitochondrial networking is substantially disrupted 20 min post onset of treatment with triclosan, similar to treatment with FCCP. Ongoing experiments with globally isolated tadpole mitochondria using Seahorse are assessing triclosan's impact on overall energy production by measuring oxygen consumption rates. In addition, the same batch of isolated mitochondria are being used in experiments using blue native-PAGE to assess sub-mitochondrial structures called supercomplexes. These aggregates consist of the major components of the electron transport chain and contribute to respiration efficiency. In toxic environments supercomplexes become disassociated, adversely affecting mitochondrial function. In summary, our results demonstrate that triclosan can act as a mitochondrial uncoupler in neural tissue of live animals.

1478 Folic Acid and Methionine Levels Affect Neural Differentiation and Compound Toxic Potency in the Neural Embryonic Stem Cell Test (ESTn)

V. C. de Leeuw[1,2], M. van Nieuwland[1,3], and A. H. Piersma[1,2]. *[1]Rijksinstituut voor Volksgezondheid en Milieu (RIVM), Bilthoven, Netherlands; [2]Institute for Risk Assessment Sciences, Utrecht, Netherlands; and [3]Radboudumc, Nijmegen, Netherlands.* Sponsor: H. Heusinkveld

One of the challenges in the transition to animal-free testing is making sensible *in vitro* to *in vivo* extrapolations. However, culture conditions may affect the sensitivity of the *in vitro* test. In this study the influence of two important nutrients in culture medium that are part of one-carbon metabolism, folic acid (FA) and methionine (Met), was examined in the neural embryonic stem cell test (ESTn). ESTn mimics neural differentiation, from gastrulation until neural maturation. Both FA and Met are important for proper closure of the neural tube and affect differentiation of ESTn. Both FA and Met showed a dose-dependent effect on differentiation as assessed by morphological scoring. Low concentrations of Met enhanced cytotoxicity while ESTn deprived of FA showed only reduced differentiation without affecting cell viability. Interestingly, the concentrations of FA or Met for optimal neural differentiation were higher than normally present in the culture medium. Next, ESTn with slightly lowered FA (from 9 to 5.25 μM) or Met (from 20.1 to 16.31 μM) medium levels were exposed to methotrexate (MTX), a known developmental neurotoxicant that interferes with the one-carbon cycle. Lower FA and Met concentrations were chosen in such a way that ESTn differentiated with 90% efficiency relative to the control medium. Exposure to MTX at ID_{50} as determined in ESTn in control medium (39 nM) led to severe disruption of morphology in presence of low FA or Met, showing that ESTn became more sensitive to MTX toxicity. Exposure to a lower MTX concentration (13 nM) did not affect morphology but did increase protein expression of pre-neural tube marker E-cadherin and neural crest cell marker Twist2 in lower Met, but not in lower FA or control medium. In conclusion, both nutrients are important for proper differentiation and sensitivity of ESTn, and Met seems to be more essential in this regard than FA. In addition, it is suggested that the concentration of FA and Met in the medium may not be the optimal concentrations for ESTn. This study illustrates that basic culture conditions affect the read-out of *in vitro* tests, and therefore the outcome of *in vitro* to *in vivo* extrapolations.

1479 Evaluating Neonatal Reflexes in Mice Exposed to Benzo[a]pyrene during Early Brain Development

T. Parton, A. Parton, J. Mullaguru, K. Jenkins, E. DeBurger, K. Clough, and C. Curran. *Northern Kentucky University, Highland Heights, KY.*

Polycyclic aromatic hydrocarbons (PAHs) are a major component traffic-related air pollution, cigarette smoke and produced during baking and grilling food. They are a risk factor for learning and memory deficits in children exposed *in-utero* or during early life. We used the prototypical PAH benzo[a]pyrene to determine if there is genetic susceptibility to PAH-induced developmental neurotoxicity. Using a mouse model with variations in the aryl hydrocarbon receptor and CYP1A2, we compared monoamine neurotransmitter levels in offspring of dams treated with 10mg/kg/day benzo[a]pyrene. Negative geotaxis and righting reflex are innate behavioral responses in mice that require normal vestibular sensory abilities and neuromuscular control. In this study, we compared three genotypes of mice, *Ahr^{d}Cyp1a21(-/-)*, *Ahr^{b}Cyp1a2(-/-)* and wild type *Ahr^{b}Cyp1a2(+/+)* mice. Mice were treated with 10mg/kg/day BaP or the corn oil vehicle from gestational day 10 to weaning at postnatal day 10. The surface righting reflex was measured at P5, P7 and P10. Negative geotaxis was assessed at P7, P10 and P14. For the righting reflex, there was a trend for a significant gene x treatment interaction on postnatal day 5 (P5) with BaP-exposed pups from both *Cyp1a2(-/-)* lines have longer latencies ($P = 0.1$). There was a significant main effect of genotype on postnatal day 7 (P7) with both *Cyp1a2(-/-)* lines having shorter latencies than wild type mice. There were no significant differences on P10. For negative geotaxis, there were no significant differences at postnatal day 7 (P7). There was a significant main effect of treatment on P10 with BaP-exposed pups having shorter latencies than pups from corn oil-treated dams ($P < 0.01$). There was a significant main effect of genotype on P14 with *Ahr^{b}Cyp1a2(-/-)* knockout pups having longer latencies compared with the other two genotypes ($P < 0.05$).

1480 Effects of Developmental Exposure to Manganese and Nonchemical Environmental Factors on Learning and Memory, Social Interaction, Motor Activity, and Anhedonia

K. L. McDaniel[1], T. Beasley[1], W. Oshiro[1], V. Moser[2], and D. Herr[1]. *[1]US EPA, Research Triangle Park, NC; and [2]US EPA (Retired), Research Triangle Park, NC.*

Manganese (Mn), a toxicant that naturally occurs in the environment, has been shown to produce neurotoxic effects on the developing young when levels exceed physiological requirements. To evaluate the effects of this chemical in combination with non-chemical factors pregnant Long-Evans rats were treated with 0, 2, or 4 mg/ml Mn in their drinking water from gestational day (GD) 7 to postnatal day (PND) 22. Half of the dams received a variable stress protocol from GD13 to PND9. (Beasley et al. abstract). One male and 1 female offspring from each litter was tested on a selection of behavioral tasks beginning at PND17. Motor activity was measured in figure-eight mazes at PND 17, 29, and 79 (different group of animals at each age). Learning and memory was examined on PND34 using a Novel Object Recognition (NOR) task; social interaction was tested at PND 48 in a separate set of offspring. Anhedonia, a measure of depression, was assessed at PND53 by comparing the preference for chocolate milk versus water. In the NOR task, for males, the 4 mg/ml Mn no stress group showed a lower percentage of visits to the novel object compared to the 0 and 2 mg/ml Mn no stress groups. In females, the 2 mg/ml Mn stress and 4 mg/ml Mn no stress groups spent a greater percentage of time at the novel object than the 0 mg/ml Mn no stress group. The 4 mg/ml Mn no stress group also spent more time at the novel object than the 4 mg/ml Mn stress group. Preliminary observations show no changes on motor activity, social interaction, or anhedonia tests. There were statistically significant interactions between Mn and stress but the effects differ by sex and endpoint. These data indicate that other factors, extraneous but coexistent with chemical exposures, should be considered in the evaluation of chemical risk. *This abstract does not necessarily reflect US EPA policy.*

1481 A Robust Protocol for the Differentiation of Stem Cells to a Neuronal-Glial Co-culture to Assess Developmental Neurotoxicity

V. de Leeuw, C. Van Oostrom, A. Piersma, H. Heusinkveld, and E. Hessel. *Rijksinstituut voor Volksgezondheid en Milieu (RIVM), Bilthoven, Netherlands.*

There is a high need for animal-free, human-relevant *in vitro* models to assess developmental neurotoxicity (DNT) potential of chemicals. Essential in this major effort is to have reliable protocols that mimic parts of neural development, preferably performed within a short time period. This study presents a robust and reproducible protocol to differentiate human stem cells, both embryonic and induced pluripotent stem cells, into neural progenitor cells (NPC). Within the course of two weeks this is followed by differentiation into a co-culture of a variety of neuronal cells and astrocytes that presents spontaneous network activity. Gene expression of markers typical for cell differentiation were regulated as expected: stem cell marker *POU5F1* decreased dramatically during differentiation, while neural progenitor marker *NEUROG1* peaked at the neural progenitor stage. Neural markers *TUBB3* and *MAP2* increased steadily over time and astroglial marker *GFAP* increased strongly only between the NPC and neural stage. Gene expression results could be confirmed with immunostainings. Gene and protein markers for synapses (*PSD95, SYNPR*) and transporters (*SLC17A6, SLC32A1*) increased in the last stage of differentiation, which was also functionally reflected by spontaneous network activity measured on a multi-well micro-electrode array. The results were reproducible across different banks and cellular origin, and a neural network is formed within two weeks This hESC model can be employed to study the effects of chemicals on the *in vitro* differentiation of human NPC into a neuronal - glia co-culture, representing an essential process in human brain development. The differentiation protocol is reproducible and relatively easy to perform and is relevant for regulatory purposes.

1482 RyR-Active Polychlorinated Biphenyls (PCBs) Cause Neurobehavioral Deficits in Larval Zebrafish

B. Yaghoobi[1], G. W. Miller[1], E. B. Holland[2], X. Li[3], D. Harvey[1], S. Li[1], H. Lehmler[3], and P. J. Lein[1]. *[1]University of California Davis, Davis, CA; [2]California State University, Long Beach, CA; and [3]University of Iowa, Iowa City, IA.*

Despite being banned since the late 1970s, PCBs continue to pose significant risk to the developing nervous system. Early life stage (*in utero* or during infancy) exposure to PCBs is associated with increased risk of neuropsychiatric disorders. A common neuropathologic feature of neuropsychiatric disorders is altered patterns of dendritic arborization in central neurons, and we have previously demonstrated that non-dioxin-like (NDL) PCB congeners alter dendritic arborization in the developing mammalian brain via sensitization of ryanodine receptors (RyR). Structure activity relationships (SAR) of RyR sensitization by PCBs (both NDL and dioxin-like congeners) have been determined using tissues from not only mammalian tissues but also rainbow trout (*Oncorhynchus mykiss*) muscle tissue. However, whether this SAR translates to developmental neurotoxicity (DNT) of PCBs *in vivo* has yet to be tested. To address this gap, we are evaluating the DNT of PCBs 28, 66, 84, 95, 138, and 153 in the zebrafish model. We first confirmed that these PCB congeners exhibited differing RyR activity in zebrafish muscle ranging from negligible (PCB 66) to moderate (PCB 153) to high (PCB 95) activity. We then tested the effects of static embryonic exposure to each of these PCB congeners on photomotor behavior. Enzymatically dechorionated embryos were exposed to varying concentrations (0.1-10 μM) of these six congeners from 6 to 120 h post-fertilization (hpf). Embryos were observed daily by stereomicroscope for mortality and gross malformations and behavioral assessments were conducted at 72, 96, and 120 hpf. The body burden of each PCB was measured by gas chromatography. At the concentrations tested, none of these PCBs caused death or overt teratology. A subset of these PCB congeners altered photomotor behavior in larval zebrafish, and the SAR for PCB behavioral effects mirrored the SAR for RyR sensitization. Quantification of PCB levels in larval zebrafish ruled out the possibility that congener-specific effects on behavior were due to differential uptake of PCB congeners. These data support the hypothesis that RyR sensitization contributes to the *in vivo* DNT of PCBs. *This work was supported by the NIEHS (grants ES014901 and ES011269).*

1483 Iodine Insufficiency Exacerbates Structural Defect in Rat Brain following Developmental Exposure to Ammonium Perchlorate

M. E. Gilbert, K. Bell, C. Riutta, J. Ford, and K. L. O'Shaughnessy. *US EPA, Research Triangle Park, NC.*

Iodine is required for thyroid hormone (TH) synthesis, severe deficiencies in iodine leading to hypothyroidism. As TH is necessary for brain development, maintaining iodine status is especially important during pregnancy. Perchlorate is an environmental contaminant that interferes with iodine uptake and reduces TH production. As such, pregnant women with iodine deficiency (ID) may be particularly susceptible to perchlorate exposure. In this study we examined how dietary ID and perchlorate exposure, alone and in combination, affect serum TH profiles in pregnant rats and their progeny. As a measure of neurodevelopmental insult, offspring were examined on postnatal day 14 (PN14) for the presence of a periventricular heterotopia, a known TH-dependent phenotype within the brain. Naïve female rats were maintained on either an iodine-replete (Control) or ID diet for a minimum of 4 wks; this ID regimen reducing serum T4 by 35%. Animals were bred and on gestational day 6, half of each group was exposed to 0 or 300 ppm perchlorate in the drinking water. Serum T4 in newborn pups was decreased 20% by ID or perchlorate, differences that were ameliorated by PN6. In contrast, serum T4 in offspring of dams exposed to both ID and perchlorate was decreased by 57% in the neonate, with further reductions by PN14. Heterotopia were not observed in pups from ID or control dams. Perchlorate-exposure induced small heterotopia in more than half of the animals examined (6 of 10). In contrast, large heterotopia were observed in all pups (12 of 12) born to dams exposed to the combination of ID and perchlorate. Quantification of heterotopia revealed a severe defect (mean volume of 0.0542 mm^3). These data indicate that neurodevelopmental effects of perchlorate exposure are not only unmasked but greatly exacerbated under conditions of dietary iodine insufficiency, conditions that result in permanent structural defects in the developing brain. *Does not reflect US EPA policy.*

1484 Benzalkonium Chloride Disinfectants Induce Apoptosis and Activate the Integrated Stress Response in a 3D *In Vitro* Model of Neurodevelopment

J. M. Herron, H. Tomita, C. C. White, T. J. Kavanagh, and L. Xu. *University of Washington, Seattle, WA.*

Benzalkonium chlorides (BACs) are a class of disinfectants widely used in food processing, health care, and residential settings. Recent studies demonstrated that BAC exposure leads to an increased incidence of neural tube defects *in utero* and increased apoptosis of neural progenitor cells (NPCs) at high concentrations *in vitro*. We previously found that BACs alter cholesterol and lipid homeostasis in cultured neuronal cells and in brains of neonatal mice exposed to BACs *in utero*. However, the effects of BACs on neurodevelopment as a result of altered cholesterol biosynthesis has not been investigated. Here we investigate the effects of BACs on neurospheres, free floating structures of NPCs, which are used as a three-dimensional *in vitro* model of neurodevelopment. We chose a short-chain BAC (BAC-C12) and a long-chain BAC (BAC-C16) to cover the structural and biological effect variations of the BACs. Thus, NPCs were isolated from embryonic mouse brains at embryonic day 13.5-14.5 and cultured in suspension to allow the formation of neurospheres until day *in vitro* 4 (DIV4). The neurospheres were then grown until DIV7 in the presence or absence of various concentrations of BACs ranging from 1 to 100 nM. Consistent with our previous work in a neuronal cell line, we observed potent inhibition of cholesterol biosynthesis at the step of Dhcr7 by the short-chain BAC-C12 at 50 nM, but not by BAC-C16. Interestingly, neurospheres exposed to either BAC decreased in size, which was not observed in neurospheres exposed to AY9944, a known Dhcr7 inhibitor, suggesting that cholesterol biosynthesis inhibition is not responsible for the reduction in neurosphere growth. Using immunocytochemistry, we found that both BACs decreased the number of proliferating cells and increased the number of apoptotic cells. To further explore the mechanisms underlying the similar biological actions of both BACs, we carried out RNA sequencing on neurospheres exposed to each BAC at 50 nM for 24 hours, which revealed activation of the integrated stress response by both BACs, including upregulation of *Trib3* (a mediator of ER stress-related neuronal apoptosis), *Asns* (asparagine synthetase), and *Slc7a11* (a transporter that mediates the intracellular level of cysteine). Overall, these results add to a growing body of literature that BACs may have detrimental effects on neurodevelopment. *Supported by NIH Grants P30ES007033, T32ES007032 and R01HD092659.*

1485 Trace Fear Conditioning in Adult Offspring after Concurrent Perinatal Exposure to Variable Environmental Events and Manganese

J. N. Franklin, B. N. Chorley, V. C. Moser, W. M. Oshiro, T. E. Beasley, K. L. McDaniel, and D. W. Herr. *US EPA, Research Triangle Park, NC.*

Developmental exposure to variable stressors may alter learning and memory formation in offspring. Our research examines if exposure to nonchemical environmental events during development influences the effects of a concurrent chemical exposure. The current study examined if perinatal exposure to variable nonchemical environmental events and/or exposure to manganese (Mn) in drinking water alters learning after a trace fear conditioning (TFC) protocol. Pregnant Long-Evans rats were exposed to a series of unpredictable environmental events, which have been shown to increase maternal corticosterone levels. These events were presented daily from gestational day (GD) 13 through postnatal day (PND) 9. Groups of control and environmentally manipulated dams were exposed to 0, 2, or 4 mg/mL of Mn in drinking water from GD7 through PND22. Starting at PND97, male and female offspring were trained with a TFC protocol. TFC consisted of pairing a compound light and tone cue followed by a 30 sec. trace period and a foot shock (1mA, 0.5 sec. duration). Five pairing sessions occurred on the training day where all groups displayed reduced movement after each pairing. The next day context learning was assessed by placing rats back into the training chamber and measuring activity without cues. Cue learning was also tested on the day after training by measuring activity in a novel chamber where the light and tone cue were presented. Data suggests that all groups displayed reduced movement indicative of learning during context testing. No significant treatment effects were noted for perinatal environmental manipulations, Mn, or concurrent exposure to both when compared to control offspring motor activity. Ongoing research will look for transcriptional changes in the hippocampus and amygdala of these adult offspring after learning TFC. *This abstract does not necessarily reflect US EPA policy.*

1486 Perinatal Exposure to Propylthiouracil (PTU), but Not DE-71, Induces Heterotopia in the Brain Despite Similar Effects on Serum T4 Levels

L. Ramhøj[1], A. Kortenkamp[2], M. Scholze[2], T. Svingen[1], J. Köhrle[3], and M. Axelstad[1]. *[1]Danmarks Tekniske Universitet, Kgs. Lyngby, Denmark; [2]Brunel University London, London, United Kingdom; and [3]Charité—Universitätsmedizin Berlin, Institut für Experimentelle Endokrinologie, Berlin, Germany.*

Thyroid hormones (TH) are crucial for brain development and low maternal serum thyroxine is associated with adverse effects in their children. These effects can manifest as lower IQ, delayed motor development and increased risk of neurobehavioral disorders such as autism and schizophrenia. Concurrently, a number of environmental chemicals can interfere with thyroid hormone availability and action, raising concerns that these chemicals can disturb thyroid hormone balance and adversely affect child brain development. Propylthiouracil (PTU) exposure of pregnant and lactating rats decrease serum thyroxine (T4) levels in dams and offspring, and induce a range of effects in the offspring's brain. Here, we show that offspring of PTU-exposed dams had periventricular heterotopia, a congenital malformation of the brain. These are irreversible clusters of ectopic neurons in the corpus callosum, which form, in a dose dependent manner, as a result of reduced perinatal T4 levels. We compared heterotopia formation after PTU exposure with that of two other suspected thyroid disrupters: the UV-filter octyl methoxycinnamate (OMC) and a mixture of brominated flame retardants (DE-71). Only PTU induced heterotopia, even though DE-71 reduced T4 levels in the offspring to a similar degree (~75% reduction). Expression of a battery of thyroid hormone responsive genes was analyzed in the pup cortex as potential biomarkers of concurrent TH action. PTU reduced gene expression in a dose-dependent manner, whereas the low serum T4 levels in DE-71 offspring did not alter expression levels. On the other hand, OMC altered gene expression at a time when there was no change in TH levels. This suggests that circulating serum T4 levels, altered by environmental chemicals, are not necessarily reflecting thyroid hormone action in the brain. In order to protect the fetus and the developing child from thyroid hormone disrupting chemicals, future studies should elucidate both adverse effects and the conditions allowing for effects to eventuate.

1487 A Mouse Neural Organoid Model Generated in Multi-Well Plates on Synthetic Hydrogels for Developmental Toxicity Applications

C. S. Lebakken, G. Kaushik, W. Richards, and S. Visuri. *StemPharm, Madison, WI.*

There is a vital need to create physiologically relevant *in vitro* models that can predict developmental toxicity mechanisms. As the developing brain consists of multiple cell types including progenitor cells, neurons and astrocytes, all interacting and supporting each other, we propose that an organoid model containing these cells, formed in a developmentally regulated manner would be an important *in vitro* model. A mouse model serves as a good starting point for several reasons: 1) The developmental timing of the mouse brain is rapid and we can achieve organoids expressing complex phenotypes and astrocytes in the course of a four week experiment, and 2) There is ample *in vivo* data publicly available with neurotoxin treatment of mice for comparison purposes. We have differentiated mouse embryonic stem (ES) cells to neural progenitor cells and then plated these on a custom-designed, synthetic polyethylene glycol (PEG) hydrogel substrates in culture conditions designed to enable formation of neural organoids. Organoids at day 20 were characterized using neuronal (βIII tubulin, MAP2, DCX) and astrocyte (GFAP) markers. We have utilized RNA-Seq approaches and gene-set enrichment analysis (GSEA) to investigate the effect of different substrates (for example, our optimized synthetic hydrogel vs. the complex animal-derived material, Geltrex®) in the development of neural organoids and observed that the synthetic hydrogel substrate significantly upregulated biological pathways such as central nervous system differentiation, synaptic transmission, neuron maturation and synapse formation over Geltrex®. In addition, we validated our *in vitro* model using previously published *in vivo* mouse dataset by Lein *et al.* (Nature, 2007) and found that the described neuron marker gene set was significantly upregulated in mouse neural organoids cultured on the synthetic hydrogel. We then tested the model by treating it with a small set of neurotoxic compounds (Chlorpyrifos, Valproate, Lead Acetate and BDE-99) at IC_{50} concentrations for four days. We observed significant higher LDH cytotoxicity in chemical treatments compared to the control. RNA was extracted from organoids for transcriptomic analysis, which is currently in progress. By quantifying the outputs such as change in gene expression and cytotoxicity, our *in vitro* model will aid pathologically- and physiologically relevant predictions of developmental toxicity.

1488 A Tiered Skin Irritation Safety Assessment of a Face Cream Product

F. Louie[1], K. M. Towle[1], E. S. Fung[2], L. G. Yang[1], J. S. Kozal[1], L. C. Garnick[1], and A. D. Monnot[1]. *[1]Cardno ChemRisk, San Francisco, CA; and [2]Cardno ChemRisk, Aliso Viejo, CA.*

The US Food and Drug Administration (FDA) does not require specific testing to demonstrate the safety of personal care and cosmetic products or their ingredients. Recently, a tier-based assessment was proposed by Cardno ChemRisk to assess the skin irritation potential of personal care and cosmetic products. This safety evaluation framework was applied to two newly formulated face cream products prior to them being commercially available to consumers. The first tier utilized the Organization for Economic Co-operation and Development (OECD) QSAR Toolbox to perform an *in silico* evaluation of the skin irritation potential of the product ingredients. Subsequently, we reviewed ingredient-specific safety reviews from the Consumer Ingredient Review (CIR), European Chemicals Agency (ECHA), and Scientific Committee on Consumer Safety (SCCS) to identify any ingredients with potential skin irritation hazards. For the tier two analysis, the OECD 439 EpiDerm Skin Irritation Test (SIT) was performed to evaluate the skin irritation potential of the face cream product utilizing a reconstructed human epidermis. Tier one results showed that out of the 85 evaluated ingredients, 8 ingredients (BHA, BHT, menadione, methyl miristate, phenoxyethanol, tocopherol, avobenzone, isopropyl palmitate) received an *in silico* structural alert for skin irritation, and an additional 17 ingredients (arnica montana flower extract, carbomer, cetearyl alcohol, lemon peel oil, disodium EDTA, eucalyptus globulus leaf oil, fragrance, isododecane, lavender oil, rosemary leaf oil, sodium lactate, sorbitan olivate, stearic acid, stearyl alcohol, cholesterol, sodium hydroxide, and tetrasodium EDTA) were identified as potentially associated with skin irritation based on previous safety evaluation reviews. However, based on the results from *in vitro* testing (tier two), the face cream product was classified as a non-irritant. This study demonstrates the value of a tiered testing approach for personal care and cosmetic products, as the presence of a potential ingredient hazard does not necessarily constitute a risk.

1489 Incorporation of Particle Deposition and Clearance in the Development of Occupational Exposure Limits (OELs) for Active Pharmaceutical Ingredients (APIs) with Minimal Oral Bioavailability

K. Sachdeva, A. Ader, and J. Gould. *SafeBridge Consultants Inc., Mountain View, CA.*

Inhalation is the primary route of exposure in the workplace and key in the considerations in setting of an OEL. Conventional assumptions are that the entire dose that is inhaled remains in the lung and can be absorbed systemically. This may be more accurate for small molecules (MW <1 kDa) but is generally not applicable for larger molecules (i.e., proteins or oligonucleotides). The deposition of these biologic-type APIs can influence their ultimate fate and potential pharmacological action either systemically or locally in the respiratory tract. An examination of the deposition of respirable and inhalable particles was modeled to identify a relevant fraction that could then be used in setting OELs. The Multiple Path Particle Dosimetry (MPPD) model (V3.04 2002-2016) was utilized to understand the percent deposition of 1.5, 2.5, 4, 7, 10 and 50 µm mass median aerodynamic diameter (MMAD) particles to the pulmonary (PU), tracheobronchial (TB) and head regions of the respiratory tract under active and at rest conditions. For each region, the highest percentage deposition was identified at approximately 17%, 16%, and 98% for particles with a MMAD of 4 µm, 7 µm and 50 µm, respectively. From a literature review, the percentage of particles not rapidly cleared from the PU, TB, and head regions was estimated to be approximately 100%, 75% and 20%, respectively. Both factors were combined to identify a relevant fraction of 17% (PU), 12% (TB) and 20% (head), which is assumed to have a potential to remain in the lung region long enough to impart pharmacological or toxic effects. These values can be used to estimate a relevant dose to portions of the respiratory tract. For example, for an immunomodulatory drug that targets B-lymphocytes that is present in the PU, TB and head, one could estimate a worst-case relevant fraction of 50%, which would be applied to adjust the inhaled dose in the OEL determination. This would be a dose capable of causing direct lung effects and would be a reasonable point of departure. Understanding the relevant fraction of the total inhaled dose, provides a realistic, if somewhat conservative estimate of the exposure for hazard characterization and risk assessment purposes.

1490 Derivation of a Health-Based Screening Value for Fentanyl on Indoor Surfaces

B. Kelman[1], M. Halverson[1], C. Chan[1], N. Moore[1], T. Dodd[2], and C. Robbins[1]. *[1]J.S. Held, Redmond, WA; and [2]J.S. Held, New Orleans, LA.*

Fentanyl is a potent synthetic opioid that is 50-100 times more potent than morphine. Routes of exposure for therapeutic use are transdermal patches, transmucosal lozenges/sprays, and injectable formulations. Oral and transmucosal therapeutic doses in humans begin at approximately 0.0025 mg/kg; transdermal doses range from 0.0125 to 0.1 mg/hr. Increased clandestine fentanyl production operations in residential structures present potential health concerns. The low amount required to induce adverse effects and high dermal/mucosal uptake are concerning for remediation of illicit fentanyl production facilities. In the United States, there is currently one remediation standard which is based on analytical detection limits (California). There are currently no guidelines available to assist stakeholders in determining whether fentanyl is present at levels that could impact human health or to conclude whether cleanup efforts were successful from a health-based perspective. We derived health-protective screening values (HBSVs) for fentanyl on residential surfaces after remediation utilizing surface wipe sampling. Following CalEPA's approach in their methamphetamine remediation derivation, we utilized any effect induced by the drug as an adverse effect and possibly a critical effect. We considered exposure paradigms including incidental ingestion and dermal contact with dust residues present on indoor surfaces for different age groups. Inhalation exposures were not considered significant due to fentanyl's extremely low volatility and data from similar cleanups (methamphetamine houses) indicating re-suspension of material was unlikely post-remediation. Exposure modeling results indicate that dermal absorption from floor contact followed by hand-to-mouth behavior of young children (6 months to less than 2 years) was the most important factor for establishing a screening value for surfaces. We found no published acceptable daily intake levels; in lieu of this, provisionary advisory levels produced by the EPA for oral exposures (0.00086 mg/kg-d) and dermal clinical studies for transdermal exposures were used as the bases for our derived HBSV. The resulting derived HBSV for fentanyl on surfaces was 0.0002 mg/100 cm^2.

1491 Derivation of Health-Based Exposure Limits (HBEL) for a Drug Substance, Naproxen Sodium

J. Gould, M. Olson, and R. Sussman. *SafeBridge Consultants Inc., New York, NY.*

HBELs, such as a Permitted Daily Exposure (PDE) and an Occupational Exposure Limit (OEL), are routinely developed for active pharmaceutical ingredients (APIs) by pharmaceutical companies, but are seldom published by expert panels or regulatory agencies. APIs differ from other chemicals in that APIs are designed to impart a physiological change in an individual and there are generally robust API-specific human data sets. Specific guidance for API HBEL development was published by International Society of Pharmaceutical Engineers and European Medicines Agency. Naproxen sodium, a propionic acid derivative and an approved non-steroidal anti-inflammatory drug (NSAID), was selected because the HBEL values for this API are of high importance since naproxen is used frequently as a surrogate for industrial hygiene (IH) performance testing. The purpose of this work is to demonstrate the appropriate incorporation of clinical and other data into an OEL and PDE derivation and provide clear justification for each point of the assessment. To develop the OEL and PDE, the publically available non-clinical and clinical pharmacodynamics, pharmacokinetic and toxicological data were collected and evaluated. Both the critical effect for humans (the lowest clinical dose) and a nonclinical study [lowest-observed-adverse-effect level (LOAEL) for developmental toxicity] were selected as points of departure. Adjustment Factors, aligned with the above guidance, including F1 (interspecies), F2 (intraspecies) with a calculated chemical specific adjustment factor, F3 (subchronic to chronic), F4 (severity of effect) and F5 (LOAEL to no-observed-adverse-effect level [NOAEL]) were considered and then applied to the POD. A bioavailability factor (α), accumulation factor (S) and modifying factor (MF) are described. The assumptions leading to determination of HBEL values are compared and contrasted. While the data set for deriving the PDE and the OEL are the same, the HBEL values differ based on differential considerations for protection of worker and patient health. In general, the OEL does not equal PDE divided by 10. Overall, an HBEL incorporates all available data; while nonclinical data serve a valuable comparative purpose, as clinical data are usually more conservative and more relevant for the human risk assessment involved in determination of HBELs.

1492 Human Health Risk Assessment for Pulegone, a Carcinogenic Flavor Chemical in Mint- and Menthol-Flavored Electronic Cigarette Liquids and Smokeless Tobacco Products

S. V. Jabba, and S. Jordt. *Duke University, Durham, NC.*

In 2018, FDA banned six flavor chemicals from addition to food, due to their carcinogenicity in animals. One of these compounds, pulegone, was detected in US-marketed mint/menthol-flavored e-liquids and smokeless tobacco products (SLT). In contrast, the tobacco industry minimized pulegone content in menthol cigarettes. Since FDA proposed to exempt mint/menthol-flavored e-cigarettes from sales restrictions, the human health risk associated with pulegone in these products needs to be assessed. Margin of Exposure (MOE), a risk parameter used by FDA for assessing carcinogenic risk of food additives, was calculated by dividing the FDA-provided no-significant-adverse-effect-level (NOAEL) of pulegone at which no carcinogenicity was reported (13.39mg/kg-bw/d) by the Estimated-Exposure-Dose (EED) for humans from use of mint/menthol-flavored e-cigarette or SLT products. EEDs were based on pulegone concentrations in products and daily amount consumed by users (light user-5ml e-liquid/10g SLT; moderate-10ml e-liquid/20g SLT; heavy-20ml e-liquid/30g SLT). Pulegone MOE was compared between mint/menthol-flavored e-cigarettes, SLT products and menthol cigarettes. The carcinogenicity risk is inversely proportional to MOE, with a threshold of 10,000; thus, MOE's below 10,000 require risk-mitigating interventions. Depending on daily consumption rates, MOEs ranged between 325-6,012 for e-cigarettes and 549-1,646 for SLT, all significantly below the threshold of 10,000, indicating increased risk for users. Predicted pulegone exposure in e-cigarette users was 44-1,608 times higher, and in SLT users 126-1,319 times higher than in menthol cigarette smokers. Users of mint/menthol-flavored e-cigarettes and SLT are exposed to pulegone levels significantly higher than the FDA considers unacceptable for food intake. Exposures from e-cigarettes and SLT are several orders of magnitude higher than from combustible menthol cigarettes. FDA is advised to prioritize reduction of pulegone levels to mitigate carcinogenic risk before endorsing mint/menthol-flavored e-cigarettes for harm reduction. Inaction will further increase health risk for users from continued exposures to carcinogenic pulegone.

1493 Application of the Dermal Sensitization Threshold Concept to Chemicals Classified as High Potency Category for Skin Sensitization Assessment of Ingredients for Consumer Products

T. Nishijo[1], A. Api[2], F. Gerberick[3], M. Miyazawa[1], D. W. Roberts[4], R. J. Safford[5], and H. Sakaguchi[1]. *[1]Kao Corporation, Tochigi, Japan; [2]Research Institute for Fragrance Materials, Woodcliff Lake, NJ; [3]GF3 Consultancy LLC, West Chester, OH; [4]Liverpool John Moores University, Liverpool, United Kingdom; and [5]B-Safe Toxicology Consulting, Northants, United Kingdom.*

Skin sensitization evaluation is a key part of the safety assessment of ingredients in consumer products, which may have skin sensitizing potential. The dermal sensitization threshold (DST) concept, which is based on the concept of the thresholds of toxicological concern, has been proposed for the risk assessment of chemicals to which skin exposure is very low level. There is negligible risk of skin sensitization if a skin exposure level for the substance of interest was below the reactive DST which would protect against 95% of protein-reactive chemicals. For the remaining 5%, the substance with the defined knowledge of chemical structure (i.e., High Potency Category (HPC) rules) needs to be excluded from application. However, the DST value for chemicals classified as HPC has not yet been proposed. In this study, we calculated the 95th percentile probabilities estimate from distributions of skin sensitization potency data of 116 HPC sensitizers from the expanded data set using the publicly available LLNA data from the OECD Toolbox database and the national toxicology program interagency center for the evaluation of alternative toxicological methods (NICEATM) database. As a result, we derived a novel DST for chemicals classified as HPC (HPC DST) of 1.5 μg/cm^2. This value presents a useful for the default approach for unidentified substances in ingredients considering, as a worst case scenario, that the unidentified compound may be potent skin sensitizer. Finally, we developed a novel risk assessment workflow incorporating the HPC DST.

1494 Utility of Subchronic Transcriptional Points of Departure for Agrochemical Chronic/Carcinogenic Risk Assessment

Z. Yan[1], E. Costa[2], L. Murphy[2], E. Bianchi[2], J. Howell[3], D. Anderson[3], P. Mukerji[3], K. Johnson[2], S. Gehen[2], and C. Terry[2]. *[1]Corteva Agriscience, Zionsville, IN; [2]Corteva Agriscience, Indianapolis, IN; and [3]Corteva Agriscience, Newark, DE.*

Although transcriptional data have been used to inform toxicity modes of actions, use of these data for human health risk assessment is not yet widely accepted. It was hypothesized that a subchronic transcriptome-based point of departure (POD) derived from target organ (e.g., liver) effects would approximate the apical endpoint POD from a chronic and cancer bioassay. In separate studies, male rats were dosed orally with four pesticide active ingredients: triclopry, inatreq, sulfoxaflor and pronamide for 13 weeks. Liver and/or kidney transcriptomes were analyzed by RNA sequencing, and a biological effect POD (BEPOD) was derived using BMDExpress. All apical endpoints with treatment-related effects observed in previously conducted rat and mouse cancer bioassays were analyzed using benchmark dose (BMD) methods to establish noncancer and cancer PODs. A comparison of rat BEPOD values with rat apical PODs for the noncancer and cancer apical endpoints showed the apical PODs and BEPODs were within 2-fold, specifically, 1.33, 1.69, 1.13, 1.62-fold, whereas mouse apical PODs and rat BEPODs were within 10-fold, i.e., 8.80, 0.15, 2.10 and 5.23-fold for four agrochemicals. Furthermore, the liver BEPOD was within 10-fold of the apical POD even for agrochemicals without apical liver effects. Our results are consistent with previous findings using environmental chemicals and suggest BEPODs from rat subchronic studies might be used to estimate apical PODs from rat and mouse chronic and cancer bioassays. To this end, a framework is proposed to incorporate shorter-term BEPODs into overall weight of evidence to estimate a chronic and cancer bioassay POD, thus enabling the potential to conduct a chronic/carcinogenic risk assessment without performing a chronic and cancer bioassay.

1495 Glyphosate Risk Assessment to Assess Proposition 65 Requirements for Pesticide Applicators and Construction Workers: Risk Communication Case Study

A. Holbrow Verwiel[1], D. Proctor[2], and M. Suh[2]. *[1]ToxStrategies Inc., San Rafael, CA; and [2]ToxStrategies Inc., Mission Viejo, CA.*

Glyphosate, the active ingredient in Roundup™, has had wide-spread use for many decades, but its listing under California's Proposition 65 law has raised the need to assess warning requirements. Risk communication challenges are heighted by widespread media coverage of large litigation judgements and controversial scientific opinions. To assess the need to warn and provide informed messages regarding potential hazards related to a large herbicide application and subsequent construction project, exposure to herbicide applicators applying glyphosate at the maximum recommended application rate for turf, post-application exposure to construction workers, as well as to surrounding residents and recreators, were quantitatively assessed. A unique site-specific construction scenario was evaluated involving removal of turf and topsoil, traffic on treated soil and burying treated media as fill. For applicators, exposure levels, non-cancer hazard, and potential cancer risks were calculated using EPA's Occupational Pesticide Handler Exposure Calculator for two application scenarios including mixing, loading, and applying herbicides using a hand sprayer, and using a tractor ground boom. To evaluate construction worker exposures, the EPA Regional Screening Level Calculator for construction worker activities was used to assess exposure. Relevant exposure pathways included soil ingestion, dermal contact, and inhalation of resuspended dust. Dead grass and soil samples were collected three days following the final application, and the levels of glyphosate in treated turf were approximately 200 mg/kg. The calculated exposures for all scenarios were at least 2,000-times lower than the No Significant Risk Level (NSRL) (1,100 μg/day). The non-cancer hazard index for construction workers was 0.009, well below the target level of 1, and that for applicators was 0.02. These results indicated that warnings were not required, and risk communication messaging effectively lessened concerns of potential health risk and liability for future litigation.

1496 Volatile Organic Compounds Measured in US Indoor Residential Air from Smoking and Nonsmoking Homes and Implications for Public Health

L. Gloekler[1], L. G. Liang[2], S. L. More[3], N. Binczewski[1], M. T. Hoang[1], and A. K. Madl[1]. *[1]Cardno ChemRisk, Aliso Viejo, CA; [2]Cardno ChemRisk, San Francisco, CA; and [3]Cardno ChemRisk, Portland, OR.*

Volatile organic compounds (VOCs) are commonly found in the indoor residential environment from major sources such as tobacco smoke, building materials, and household consumer products. Factors that can influence the extent of exposure in a home include presence of a basement, attached garage, ventilation, and building age. A total of 22 studies were evaluated and data for indoor air concentrations and personal exposures to 14 common VOCs were pooled across a wide range of United Stated residential homes. Sampling times reported in the studies ranged from 2.5 hours to 6 months. VOC concentrations were compared between smoking and non-smoking homes and evaluated against available acute and chronic governmental health benchmark levels for non-cancer endpoints. Specifically, acute (8-hour) and chronic Agency of Toxic Substances and Disease Registry (ATSDR) Minimal Risk Levels (MRLs) and US Environmental Protection Agency (EPA) (8-hour) acute exposure guideline levels (AEGLs). Weighted averages of indoor area samples ranged from 0.72 μg/m^3 to 44.79 μg/m^3 for all VOCs. Weighted averages of personal samples ranged from 0.53 μg/m^3 to 41.29 μg/m^3. Seven VOCs that are common constituents of cigarette smoke were 1.3 to 3.3 times higher in the indoor air of smoking versus non-smoking homes. In contrast, indoor concentrations of chloroform were twice as high in non-smoking homes, potentially due to alternative sources in the home. The indoor concentration of toluene was not different between smoking and non-smoking homes. The weighted average concentration of each VOC was between 2 and 49,000 times lower than acute health benchmark levels, and 2 to 1,440 times lower than chronic health benchmark levels, except for formaldehyde and benzene. The weighted indoor average of formaldehyde in non-smoking homes was 23 μg/m^3, 2.35 times higher than the ATSDR MRL of 9.8 μg/m^3. Similarly, the weighted average indoor concentration of benzene in smoking homes was 1.17 times higher than the respective ATSDR MRL (11.17 μg/m^3 vs. 9.57 μg/m^3). The analysis of the data suggest that most indoor VOC exposures experienced in residential homes will not pose a risk to human health with respect to acute and chronic non-cancer effects.

1497 Application of a Multifaceted Read-Across Approach in the Determination of an Oral Reference Dose for Cyclopentanone

K. D. Cox, B. Hughes, and V. Bhat. *NSF International, Ann Arbor, MI.*

General population exposure to cyclopentanone occurs through its use as an intermediate in the synthesis of nylon and rubber materials found in drinking water systems. Cyclopentanone is also found in nature, in foodstuffs, and is commercially used in fragrances and flavoring ingredients. An oral risk assessment was needed to establish allowable drinking water levels. Cyclopentanone exhibits low acute oral toxicity with an acute oral LD_{50} ≥1179 mg/kg. Repeated-dose data on cyclopentanone were limited to two non-guideline inhalation studies and a developmental study in rats. Deficiencies in study design or reporting precluded use of these studies for derivation of criteria; however, outside of a finding of mitral cell degeneration, no treatment-related adverse effects were reported. Due to lack of standardized, repeated-dose toxicology studies for cyclopentanone, a read-across approach, using cyclohexanone as a surrogate, was used to determine an oral reference dose (RfD). The selection of cyclohexanone as a surrogate for cyclopentanone was supported based on a weight of evidence approach including the application of QSAR software as well as comparison of available toxicity data, physical-chemical properties, and metabolic pathways. The main metabolic pathway for cyclopentanone, cyclohexanone and other cyclic ketones in general, involves reduction to the secondary alcohol followed by glutathione conjugation and, to a lesser extent, sulfur containing metabolites prior to urinary excretion. From the available repeated-dose toxicity data for the surrogate, cyclohexanone, a critical effect of reduced body weight gain (30-35%) was identified from a two-year drinking water study in F344 rats. The resulting $NOAEL_{HED}$ of 119 mg/kg-day served as the point of departure. Using a total uncertainty factor of 100x (3x interspecies, 10x intraspecies, 3x database), an oral RfD of 1 mg/kg-day was determined for cyclopentanone. The resulting Total Allowable Concentration in drinking water was 8000 μg/L.

1498 Health Assessment of Etocrylene Present in Paints and Coatings

C. Chan, N. Moore, and B. Kelman. *J.S. Held, Redmond, WA.*

Etocrylene (CAS number 5232-99-5), a UV energy-absorbing stabilizer commonly used in paint and coating formulations, was identified by chemical analysis (Fourier transform infrared spectroscopy and gas chromatography/mass spectroscopy) to be responsible for a hazy coating observed on the surfaces of a particular brand of cabinetry doors. We assessed the risk of adverse health effects in consumers from exposure to etocrylene on surfaces of cabinetry doors. To determine a maximal exposure to etocrylene from cabinet doors, we considered: 1) the amount of etocrylene "dust" on a standard sized panel of cabinet door (6 mg on a 256 in^2 cabinet door), 2) the average cabinet door surface area of a large-size home (150 ft^2), 3) 100% exposure level, 4) 100% absorption and bioavailability of exposed etocrylene, and 5) the average body weight of a child (18.6 kg) and adult (80 kg). Based on the above assumptions, an individual adult and child would be exposed up to 6.3 and 27 mg/kg body weight, respectively, in a large home. Our review of the literature found very limited studies on the health effects of etocrylene. There is no peer-reviewed literature on the health effects of etocrylene on humans. There is a report of human test subjects exposed to 5% (weight/volume) solution of etocrylene in corn oil via a patch/epicutaneous test that observed no sensitization reactions in test subjects. The health effects of etocrylene have been investigated in a limited number of *in vitro* and animal *in vivo* studies (with exposure levels of at least 1 g/kg body weight). Results of these studies indicate etocrylene is not a sensitizer, mutagenic, irritating to the eye and skin, or a reproductive or developmental toxicant. The no observable effect levels (NOELs) from the reviewed *in vivo* and *in vitro* studies were used as the basis for a margin of exposure calculation. Results indicate the margins of exposure associated with the exposure assumptions outlined previously are about 160 for an adult and 37 for a child. Margin of exposures of this magnitude based on NOELs and upper limit exposure scenarios indicate that no adverse health effects were expected from the levels of etocrylene present on cabinetry doors.

1499 Optimized Safety Assessment of Chemical Sensitizers

N. Peter, J. Lichter, M. T. Schellenberger, and B. Blömeke. *Universität Trier, Trier, Germany.*

Small chemicals can induce tolerance or sensitization following dermal exposure. Activation of dendritic cells (DC) is an important step in the induction of skin sensitization, and the chemical's potential for DC activation can be evaluated *in vitro* using THP-1 cells, as surrogate DC, in the human cell line activation test (h-CLAT). However, the DC response to chemicals in the skin environment is also modulated by chemical-exposed keratinocytes. We found that THP-1 cells show an increased response (upregulation of activation markers CD86 and/or CD54) to sensitizing chemicals when exposed in coculture with HaCaT keratinocytes. In the past, combining results of a blind study in COCAT (cocultured activation test) with earlier results (in total 26 skin sensitizers) found that all 26 sensitizers were correctly identified, offering a highly accurate hazard prediction. In this study, we applied our optimized COCAT protocol and tested additional 30 molecules, consisting of 50 % fragrances. The fragrance molecules comprised different LLNA classes (ECETOC - Technical Report No. 87, 2003), 1 molecule classified as strong, 4 as moderate and 5 as weak. Concentration-dependent responses and determination of the lowest concentration needed to reach positivity (ECΔ) for CD86 and/or CD54 were received for 80 % of tested molecules, as for some molecules there were interferences. Applying our established protocol, a chemical is tested from 7.8 to 4000 μM and is considered a sensitizer if in ≥ 2 out of 3 runs at least one marker reaches its threshold for positivity (ΔMFI ≥ 10.8 for CD86 or ΔMFI ≥ 300 for CD54). Concentrations inducing positivity varied between 101 μM for trans-2-hexenal and 3932 μM for anisylalcohol, offering a dynamic range to grade sensitizers according to their potency. Comparing our results with available LLNA data found Diethylenetriamine to be categorized false-negative in COCAT, while hazard was correctly predicted for 20 of 21 testable sensitizers. These data underline the superior capacity of COCAT for hazard identification of skin sensitizers.

1500 Exposure to Environmentally Relevant Concentrations of Hexavalent Chromium Does Not Induce Ovarian Dysfunction in Mice

C. Thompson[1], D. Donahue[2], Y. Costecalde[2], G. Hill[2], G. Chappell[3], M. Suh[4], and M. A. Harris[1]. *[1]ToxStrategies Inc., Katy, TX; [2]Integrateed Laboratory Systems Inc., Research Triangle Park, NC; [3]ToxStrategies Inc., Ashville, NC; and [4]ToxStrategies Inc., Mission Viejo, CA.*

Exposure to hexavalent chromium [Cr(VI)] in drinking water has been reported to adversely affect ovarian follicles in mice. Exposure to high concentrations of Cr(VI) (>=250 ppm) for 20 days was reported to decrease follicle counts, whereas exposure to 5 ppm for 90 days is reported to cause structural anomalies in follicle membranes examined by electron microscopy. Effects at >=250 ppm Cr(VI) were likely confounded by overt toxicity, whereas the effects at 5 ppm were subjective and not quantified in any way. Nevertheless, the purported structural effects in electron micrographs currently serve as the basis for a maximum allowable dose level (MADL) derived by the state of California under Proposition 65 (8.2 µg/day) even though there is limited evidence that exposure to higher levels of Cr(VI) affect reproductive health in rodents. To address these findings, we exposed B6C3F1 mice to 0.1 to 150 ppm Cr(VI) in drinking water for 90 days in a GLP-compliant study to examine the potential for effects on follicle health. As expected, water consumption and bodyweight were reduced in the two highest exposure groups due to poor palatability. Counts of small, medium, large, and total follicles were not altered in any exposure group, nor was the percentage of follicular atresia altered. No evidence of morphological changes were apparent in any treatment group by light microscopy. There were no microscopic changes in the adrenal glands, pituitary gland, thyroid/parathyroid glands, mammary glands, vagina, or corpus and cervix uteri. With the exception of the pituitary gland, there were no treatment-related effects on organ weights. The NOAEL for follicle toxicity (150 ppm) leads to a MADL of ~2900 µg/day. Although this MADL is more scientifically defensible than the current MADL, the current study calls into question whether a MADL should be based on follicular toxicity given the lack of effects at 150 ppm and the frank toxicity that is likely associated with exposure to higher Cr(VI) concentrations.

1501 Decreasing Uncertainty in Existing MRL Values and Derivation of New MRL Values in the Absence of New Health Effects Data via Use of Updated Methodologies

K. Zaccaria[1], L. Ingerman[1], C. Harper[2], and S. Ingber[2]. *[1]SRC Inc., North Syracuse, NY; and [2]CDC/ATSDR, Atlanta, GA.*

Updates of ATSDR's minimal risk levels (MRLs) are most often prompted by the availability of new health effects data. However, recent profile updates have demonstrated the importance of reviewing existing MRLs against current risk assessment methodologies, even if newer data have not been identified. Most notably, the continued development and refinement of benchmark-dose (BMD) modeling methodologies provide more accurate dose estimates for point-of-departures (PODs) used in MRL derivation. Additionally, use of human equivalent concentrations (HEC) as PODs instead of administered concentrations decreases the uncertainty in the MRL (e.g. reduces the total uncertainty factor [UF] needed to derive MRLs). Here, we present three profiles with revised/new MRLs derived solely based on updated methodologies: 1,2-dichloropropane (1,2-DCP), endrin, and bromodichlormethane (BDCM). For 1,2-DCP, the acute and intermediate MRLs (both existing and provisional) are based on nasal lesions reported at all tested concentrations by Nitschke and Johnson (1983) and Nitschke et al. (1988), respectively. For the acute inhalation MRL, use of a HEC value as the POD instead of administered concentrations decreased the POD from 100 ppm to 1.8 ppm and decreased the interspecies UF from 10 to 3. For the intermediate inhalation MRL, use of the $BMDL_{HEC}$ value of 0.05 ppm as the POD instead of the administered LOAEL value of 15 ppm removed the LOAEL-to-NOAEL UF of 10 and decreased the interspecies UF from 10 to 3. For endrin, the existing profile did not derive an acute oral MRL because ATSDR considered the available POD for the critical effect (neurotoxicity) a serious LOAEL. At the time, ATSDR did not have BMD modeling capabilities – which allow estimations of PODs below serious LOAELs – and use of a serious LOAEL as a POD for MRL derivation goes against ATSDR practices. However, with current BMD methods, ATSDR identified a BMDL value of 0.06 mg/kg/day for neurotoxicity, which was then used for MRL derivation. For BDCM, ATSDR revised the acute oral MRL using updated BMD methodology, which identified a previously unavailable, better-fit model for the data. This decreased the POD from 10 mg/kg/day, based on the multistage 2-degree model, to 7.15 mg/kg/day, based on the dichotomous hill model. Collectively, these examples demonstrate how the application of updated methodology alone produced more accurate and protective MRLs.

1502 Ethylene Oxide: Cancer Evidence Integration and Dose-Response Implications

J. S. Kozal[1], M. J. Vincent[2], W. J. Thompson[3], A. Maier[2], G. S. Dotson[2], E. A. Best[4], and K. A. Mundt[3]. *[1]Cardno ChemRisk, San Francisco, CA; [2]Cardno ChemRisk, Cincinnati, OH; [3]Cardno ChemRisk, Boston, MA; and [4]Cardno ChemRisk, Boulder, CO.*

Ethylene oxide (EtO) is a highly reactive chemical used as a sterilizing agent and a feedstock for producing other chemicals. IARC and EPA classified EtO as a known human carcinogen. EPA concluded, "Overall, confidence in the hazard characterization of EtO as 'carcinogenic to humans' is high" and derived a published inhalation unit risk (IUR) value (3×10^{-3} per (µg/m^3 EtO). The IUR is calculated from a supralinear dose-response (DR) model based on transformed relative risk estimates from two epidemiological studies. However, neither of these studies demonstrated any increased risk of breast cancers or lymphohematopoietic malignancies (LHM) compared to the general population. EPA also derived IURs from three chronic rodent bioassays; these IURs indicate a 100-fold lower potency than the IUR based on human data. We examined the EPA's reliance on a mutagenic mode of action (MOA) to establish that EtO is a human carcinogen and considered possible DR patterns. Toxicological studies and studies of early effect biomarkers in animals and humans indicated no clear relationship between EtO and LHM or breast/mammary cancers. Only one chronic study of leukemia in female Fisher rats demonstrated a clear monotonic DR; however, this strain is recognized to have a high background rate of leukemia and may not be an appropriate model for human leukemogenicity. Overall, the animal data were inadequate to define the actual DR shape or predict tumor response at very low doses with any confidence. Per EPA policy, a linear low-dose extrapolation approach should be used for a mutagenic MOA. DR analysis of selected key events in the MOA in humans and animals indicated high uncertainty in DR shape. There is no indication that a low-dose extrapolation approach other than linear is justified. Further, comparison of the range of no observable adverse effect levels (NOAELs) for the key events from humans and animals revealed substantial range overlap and did not suggest a 100-fold difference in cancer potency reflected by EPA-derived IURs. We conclude that the epidemiology does not demonstrate that EtO is a human carcinogen and that the toxicological data do not support deviation from linear low-dose extrapolation or a two order of magnitude interspecies difference in cancer potency. Thus, the current EPA IUR for EtO clearly overstates human cancer risks.

1503 Factors Influencing Dose-Response Assessment (DRA) for Monovalent Inorganic Phosphate Compounds (MIP)

K. Salinas, H. Carlson-Lynch, and M. Odin. *SRC Inc., East Syracuse, NY.*

Phosphorus (P) is ubiquitous in nature and an essential constituent of all living organisms. Humans are exposed to P naturally in the diet and by widespread use of MIP, such as orthophosphate (H_3PO_4) and its sodium and potassium salts, in fertilizers, food additives, consumer products, and water treatment. Animal data, and more limited human data, suggest the occurrence of adverse health effects associated with excessive P intake and/or high levels of P in serum. DRA for MIP faces challenges: 1) Physiological levels of P are tightly regulated. Homeostatic mechanisms maintain serum P levels within a narrow range, even in the presence of wide variations in intake. As a result, studies that evaluate health effects associated with serum P levels may not be useful for DRA. 2) Dietary intake of phosphates is difficult to quantify, and the bioavailability of phosphates varies widely with source (10-30% plant, 40-60% animal, 80-100% MIP). Most of the dietary intake studies do not account for different sources of P in the diet, and none provide estimates of intake from MIP. Therefore, dietary intake studies may not be useful for DRA. 3) Human colonoscopy preparation studies provide a known dose of defined material (sodium phosphate) to subjects but include exposure for only one day. There is considerable uncertainty in extrapolating from effects of a single day to subchronic or chronic exposure. 4) Animal toxicity studies are abundant, but few of the available studies include information on concurrent calcium intake, a key determinant of phosphate bioavailability, limiting the candidate points of departure for RfD derivation. 5) P is an essential nutrient. Doses that are below nutritional needs may lead to deleterious effects. The recommended daily intake (RDI) for P may not be a lower bound on the RfD for MIP because the RDI includes P from less bioavailable organic sources in addition to inorganic sources (MIP). 6) A significant proportion of the US population may exhibit conditions or characteristics that increase their susceptibility to phosphate toxicity. For example, chronic kidney disease (CKD) impairs the body's ability to excrete excess P, leading to hyperphosphatemia. People with CKD are typically prescribed phosphate binders and/or instructed to reduce their intake of dietary P below the values recommended for healthy persons. FDA recommends against the use of MIP to treat constipation in infants and children under 5, unless under physician supervision, due to their enhanced susceptibility.

1504 Development of Reproductive Toxicity Criteria for 4-Vinyl-Cyclohexene and Its Metabolite Vinyl Cyclohexane Diepoxide

J. Ator[1], Z. Guerrette[2], B. Reid[2], and M. H. Whittaker[1]. *[1]ToxServices LLC, Washington, DC; and [2]ToxServices LLC, Ann Arbor, MI.*

4-Vinyl-cyclohexene (VCH) is a 1,3-butadiene dimer that primarily serves as an industrial intermediate in, for example, polymer synthesis; it may be present in various products as a residual, potentially resulting in consumer exposure. CYP450-mediated bioactivation of VCH to epoxides results in ovotoxicity, with vinyl cyclohexane diepoxide (VCD) being the most potent epoxide in terms of ovarian follicular depletion. Mice are more sensitive to VCH's ovotoxicity compared to rats following inhalation or oral exposure, reflecting their greater rate of epoxide formation. Subchronic to chronic dermal or oral exposure to VCD results in uterine atrophy, ovarian follicular atrophy, and ovarian tubular hyperplasia in B6C3F1 mice. Sprague-Dawley rats also show loss of ovarian follicles following intraperitoneal injection of VCD. Based on these data, both VCH and VCD are included on the State of California's Proposition 65 list as female reproductive toxicants. However, no safe harbor Maximum Allowable Dose Level (MADL), which serves as the basis for quantitative Proposition 65 regulatory compliance determinations, has been developed for either chemical. We developed an MADL for VCH based on a Texas Commission on Environmental Quality (TCEQ) risk assessment that identified a 250 ppm inhalation-route point of departure (POD), equivalent to 44.6 ppm after adjusting for less-than-continuous exposure, for ovarian atrophy in B6C3F1 mice. Inter-route extrapolation from the adjusted exposure concentration in air to a corresponding daily dose, using default female mouse body weight and inhalation rate values, yielded a VCH dose of 321 mg/kg/day. This daily dose was multiplied by the OEHHA-established female human body weight of 58 kg and then divided by 1,000, in accordance with OEHHA guidelines, to obtain a MADL of 18.6 mg/day for VCH. For VCD, we performed a dose-response assessment to identify the POD upon which to base its MADL. Across VCD studies in rats, mice, and non-human primates, the highest NOAEL that is lower than the lowest LOAEL is an i.p. NOAEL of 5 mg/kg/day from a 4-week rat study that identified ovarian atrophy. As was done for VCH, the POD for VCD was multiplied by the 58 kg default female body weight and divided by 1,000 to obtain an MADL of 290 µg/day. These MADLs will aid risk assessors to limit potential reproductive harm from VCH or VCD present in consumer products by supporting California Proposition 65 regulatory compliance determinations.

1505 Exposure to 1,4-dioxane above the Metabolic Saturation Threshold Induces a Mitogenic Key Element in the Mouse Liver Cancer Mode of Action

M. Lafranconi[1], R. Budinsky[2], L. Corey[3], L. Haws[4], J. Klapacz[2], G. Chappell[5], and R. Golden[2]. *[1]Environmental Resources Management, Cincinnati, OH; [2]Dow Chemical Company, Midland, MI; [3]Intertox Inc., Seattle, WA; [4]ToxStrategies Inc., Austin, TX; and [5]ToxStrategies Inc., Asheville, NC.*

The US EPA has completed two risk evaluations of 1,4-Dioxane (1,4-DX) carcinogenicity, an IRIS assessment in 2013 and the recently published, draft TSCA risk evaluation in 2019, where human cancer risks related to rodent liver tumors were characterized using the default non-threshold model. The available evidence for the rodent liver tumor response better aligns with a threshold-dependent, tumor promotion Mode of Action (MOA) but early key events (KEs) in this MOA have not been well defined for the mouse model. To address this, we conducted a study in female B6D2F1/Crl mice. Mice consumed drinking water containing 0, 40, 200, 600, 2,000 or 6,000 ppm 1,4-DX (targeted at 0, 10, 50, 150, 500 and 1,500 mg/kg/day, respectively) for up to 90-days. Blood levels of 1,4-DX and its major metabolite, 2-hyrdoxyethoxyacetic acid (HEAA), were determined to characterize the time course of absorption and clearance of 1,4-DX. Indices of hepatic proliferation, histopathology, mRNA analysis and BrdU incorporation were used to characterize the time course and magnitude of a proposed KE (proliferation) resulting from exposure to 1,4-DX. There was a dose and time dependent increase in blood levels of HEAA with a supralinear increase in 1,4-DX blood concentration with exposure to 6,000 ppm demonstrating saturation of metabolic clearance. There was a corresponding, and previously unreported, increase in liver weight and BrdU incorporation in the absence of cytotoxicity and genotoxicity indicating a direct mitogenic stimulus triggered by 1,4-DX accumulation. These data advance the understanding of early KEs in the MOA for 1,4-DX and confirm previous reports of a threshold MOA based on metabolic saturation and accumulation of parent compound.

1506 Probabilistic Risk of Decreased Levels of Triiodothyronine following Chronic Exposure to PFOS and PFHxS in Drinking Water

M. Öberg[1], A. Silva[1], J. Ringblom[1], C. Lindh[2], K. Scott[2], and K. Jakobsson[3]. *[1]Karolinska Institutet, Stockholm, Sweden; [2]Lunds Universitet, Lund, Sweden; and [3]Göteborgs Universitet, Gothenburg, Sweden.*

High concentrations of perfluorinated alkyls (PFAS) have been found in drinking water and in human serum due to contamination from industrial production sites or extensive use of firefighting foams. In many places the identified levels are found to be above the guidance levels and there is a need to characterize the risk in terms of probability for adverse health effects. We performed an integrated probabilistic risk assessment combining the serum levels of perfluorooctane sulfonic acid (PFOS) and perfluorohexane sulfonic acid (PFHxS) measured in residents of a heavily contaminated area in Sweden with data from a subchronic toxicity study where Cynomolgus monkeys were exposed to PFOS. The critical outcome was defined as a 10% decrease in total triiodothyronine (T_3) hormone levels. The 5th and 95th percentile of human serum concentrations for the residents (n = 1,845) were 63.3 - 830.9 ng/mL (PFOS) and 45.0 - 795.5 ng/mL (PFHxS). A benchmark dose analysis was employed to describe the dose-effect relationship in animals and extrapolation distributions were used to estimate the corresponding human benchmark dose for decreased T_3 levels. The median probability of critical exposure (PoCE), following a combined exposure to PFOS and PFHxS, was estimated to be 2.1% (90% C.I. 0.4% - 13.1%). A separate gender based analysis showed that the risk was mainly distributed among women (PoCE = 3.9%, C.I. 0.8% - 21.6%), with an estimated PoCE for men of 0.08% (C.I. 0.02% - 2.85%). As the initial deterministic risk characterization, based on the same key study and similar level of adversity, indicated an exposure close to the tolerable daily intake of 150 ng/kg/day, this study exemplifies a shift of narrative following the use of a probabilistic approach as a tool for risk assessment.

1507 Derivation of No-Significant-Risk-Levels (NSRLs) for 4-Vinylcyclohexene and 4-Vinylcyclohexene Diepoxide

Z. Guerrette, J. Ator, B. Reid, and M. H. Whittaker. *ToxServices LLC, Washington, DC.*

4-Vinylcyclohexene (VCH) and 4-vinylcyclohexene diepoxide (VCD) are listed on the State of California's Proposition 65 List as known to the State to cause cancer and reproductive toxicity. The cancer listings are based on the results of National Toxicology Program (NTP) two-year bioassays. Oral dosing with VCH led to dose-related increased incidences of skin and preputial gland tumors in male rats, lymphoma and lung tumors in male mice, and ovarian and adrenal tumors in female mice. Dermal dosing with VCD resulted in dose-related increased incidences of dermal tumors in each sex of each species and ovarian tumors in female mice. Preneoplastic ovarian lesions were detected in mice dosed with VCH and VCD. Industries are obligated to comply with Proposition 65 labeling requirements and drinking water discharge prohibition for products sold in California, unless they are able to demonstrate that VCH and VCD levels in their products result in consumer exposures below specific safe harbor levels, specifically No Significant Risk Levels (NSRLs) for carcinogens. As the State of California has not published NSRLs for VCH or VCD, we derived NSRLs based on NTP tumor data in accordance with California Office of Environmental Health Hazard Assessment guidelines. Additionally, as VCD is a metabolite of VCH, we sought to compare the carcinogenic potential of these chemicals. The Carcinogenicity Potency Project Database (CPDB) identified a TD50, the dose producing a 50% tumor incidence, of 106 mg/kg/day for VCH based on the increased ovarian tumor incidence identified for mice in the NTP study. We linearly extrapolated the TD50 to a probability of one excess cancer case in an exposed human population of 100,000 (10^-5 cancer risk), resulting in a NSRL of 123 µg/day for VCH. As the CPDB identified no TD50 for VCD, we performed benchmark dose (BMD) modeling via the US EPA's BMD Software to derive BMDs for the tumors detected in the NTP rodent bioassays of VCD. The resulting CSFs were scaled to human equivalent doses (HEDs) using body weight scaling. The most conservative HED from models with appropriate statistical fit corresponded to combined skin tumors in male rats. A VCD cancer slope factor (CSF) was derived from the BMD for skin tumors, and a NSRL of 4.9 µg/day was calculated using this CSF and a 10^-5 cancer risk. These NSRLs can be used as part of risk and safety assessments to evaluate compliance with Proposition 65 requirements for consumer products containing VCH and/or VCD and sold in California.

1508 Risk Analysis of Current Ozone Levels in New Delhi, India

A. K. Sharma[1], R. Khare[2], and G. Kaur[1]. [1]*Shoolini University, Solan, India; and* [2]*Symphony Technologies, Pune, India.*

In today's world, air is full of toxic gases resulting in adverse effects. In the last decade, increased combustion of igneous fuels results in progressive change in the atmospheric composition. Ozone is the most steady and unmanageable air pollutant in urban air and an ideal candidate causing damage to respiratory system as previously reported. The site of damage after prolonged ozone exposure is the alveolar region. Levels as low as 50 ppm can result in decreased levels of ascorbic acid, uric acid and glutathione, resulting in pulmonary obstruction, bronchial hyper responsiveness and airway inflammation. While EPA reports that over 70 million people in the US reside in areas not meeting the one-hour EPA ozone standard, present day estimate of mortality in India owing to lung damage such as COPD due to ozone exposure is about 12000 people (India census 2011). In this study, we assessed the risk using FMEA by utilizing the available regional data in the metropolitan city of New Delhi on ozone and produced risk assessment for the current ozone levels in the Indian sub-continent and determined the at-risk populations. Finally, our data highlights the emerging role of ozone exposure as an air pollutant in the Indian sub-continent.

1509 Assessment of the Relevance of Toxicological Findings in the Development of an Oral Reference Dose for GenX

C. M. Thompson[1], C. Ring[2], L. Pham[3], G. A. Chappell[3], and L. C. Haws[2]. [1]*ToxStrategies Inc., Katy, TX;* [2]*ToxStrategies Inc., Austin, TX; and* [3]*ToxStrategies Inc., Ashville, NC.*

Detection of GenX, an alternative to the long-chain per- and polyfluoroalkyl substances (PFAS), in water sources near production facilities has led to the need for development of toxicity criteria protective of oral exposure. Assessment of available toxicity data (i.e., chronic, subchronic, reproductive, and developmental toxicity studies in rats and mice) demonstrated that although the liver is a primary target organ in both rats and mice, GenX has been reported to cause other effects such as reduced fetal and pup body weight, reduced pup survival, and altered mammary gland development. The strength of evidence and relevance for developmental effects was assessed, including an analysis of confounding effects such as reduced maternal feed intake in high dose groups and transcriptomic evidence for enrichment of altered glucose metabolism and gluconeogenesis. Liver effects in mice were determined to be consistent with peroxisome proliferator-activated Receptor-α (PPARα) activation, including increased liver weight, liver hypertrophy, and increased peroxisomal enzyme activity. Re-evaluation of liver tissue from previously conducted studies in mice (2010) using more current histopathological diagnostic criteria demonstrated that lesions previously diagnosed as 'single cell necrosis' were in fact apoptosis. This was subsequently corroborated by immunostaining for activated caspase-3 as well as transcriptomic pathway enrichment analyses. GenX was also found to increase mitosis in the liver at the same doses as apoptosis, which is consistent of rodent-specific cell cycle changes induced by PPARα activators. The involvement of PPARα and absence of liver necrosis, fibrosis, and inflammation indicate that the mouse liver lesions have limited relevance for risk assessment. Overall, the analyses support development of an RfD based on liver lesions observed in rats exposed for 2 years. Modeling these lesions using both frequentist and Bayesian benchmark dose (BMD) models, resulted in deterministic and probabilistic RfD values for GenX of 0.02 and 0.01 mg/kg/ day, respectively. Incorporation of the more conservative of the two RfD values in standard equations for development of a maximum contaminant level goal yielded an acceptable concentration in drinking water of 70 ppb.

1510 Risk Assessment of Manganese Exposure for Pica Child: Application of PBPK Modeling

D. Proctor[1], C. Ring[2], and G. Song[1,3]. [1]*ToxStrategies Inc., Mission Viejo, CA;* [2]*ToxStrategies Inc., Austin, TX; and* [3]*Covance Inc., Los Angeles, CA.*

Steel slag aggregate used as road cover can contain up to 3% manganese (Mn). Although Mn in slag is not readily released for absorption into the body if incidentally ingested (33% bioaccessibility), we assessed the potential for neurotoxicity associated with a hypothetical child displaying pica behavior. Soil pica is when a young child ingests higher levels of soil than is expected, on the order of 1,000 to 5,000 mg/day or more. Information regarding the prevalence of pica behavior is limited, but it is considered most prevalent among children 1 to 3 years of age, and it is estimated that approximately one-third of children ingest more than 10 grams of soil 1 or 2 days per year. Since no acute toxicity criteria for ingestion of Mn exist, previously published physiologically-based pharmacokinetic (PBPK) models for Mn were used to predict potential uptake of Mn into the brain globus pallidus for two hypothetical exposure scenarios, in addition to daily Mn exposure via diet and inhalation of ambient air. Exposures for a 2-, 3- and 5-year old child were modeled for slag intakes of: 1) 1,000 mg/day for 5 consecutive days, or 2) 10,000 mg twice in one year, occurring 6 months apart. The model predicted that both the peak concentration (Cmax) and Area Under the Curve (AUC) of Mn in the globus pallidus were below the level of concern associated with neurotoxicity. Specifically, the model predicted Cmax ranged from 0.46 to 0.80 ug/g, with AUCs of 208 to 791 ug/g/h, and half-lives of 1-3.5 days. Cmax increased from 9% to 48% but rapidly return to baseline concentrations. The PBPK results suggest that the target brain Mn exposure from pica behavior would be well under the levels associated with neurological effects (AUC > 6000 ug/g/h or Cmax >7 ug/g from chronic intake) and more importantly, the increase is transient. In summary, pica behavior, although probably quite unlikely with steel slag, would not result in the intensity and duration of Mn exposure that could cause neurological effects in children, and these methods can be applied in other Mn health risk assessments.

1511 Occupational Risk Assessment for the New Oxidative Hair Dye 2-methoxymethyl-p-phenylenediamine: Improved Protection of Hairdressers from Allergy Induction

E. Gargano[1], A. A. Gaspari[2], B. Blomeke[3], and C. Goebel[1]. [1]*Coty Inc., Darmstadt, Germany;* [2]*Thomas Jefferson University Sidney Kimmel Medical College, Philadelphia, PA; and* [3]*Universität Trier, Trier, Germany.*

Occupational exposure of hairdressers to the strong sensitizers p-phenylenediamine (PPD) and toluene-2,5-diamine (PTD) through oxidative hair dyes has been associated with the development of allergic contact dermatitis. The PPD and PTD replacement 2-methoxymethyl-PPD (ME-PPD) combines equally excellent hair coloring performance with a moderate a skin sensitizing potency. Quantitative risk assessment (QRA) was applied to comparatively assess the occupational risk of hairdressers to become sensitized to either PPD or ME-PPD containing hair dye products. Hairdressers' hand exposure to ME-PPD was determined by collecting samples following typical routine hair color treatments in commercial salons in Germany using a hand rinse method and HPLC analysis. Published data were available for PPD and PTD. Daily hand exposure concentrations were derived by considering assessment factors for wet work, uneven hand exposure and inter-individual variability for professionals. QRA was conducted by comparing daily hand exposure with the sensitizing potency defined as the No Expected Sensitization Induction Levels (NESIL). For ME-PPD the hairdresser hand exposure level is approximately 100 fold below the NESIL while hand exposure to PPD is 2.7 fold below the NESIL, respectively. In conclusion, QRA reveals that the use of ME-PPD in oxidative hair colors significantly reduces the occupational risk of allergy induction for hairdressers compared to PPD and PTD.

1512 Toxicological Risk Assessment to the Typical Constituents of E-cigarettes in China

J. Guo, P. Shang, H. Wang, H. Liu, and S. Liu. *Zhengzhou Tobacco Research Institute of CNTC, Zhengzhou, China.* Sponsor: R. Meng

Electronic nicotine delivery systems, which is also called e-cigarettes, are devices used for vaporizing e-cigarette smoke liquid that comprises with nicotine, propylene glycol, glycerine, and flavourings. Previous studies suggest that chemical constituents between the aerosol produced by heating e-cigarette liquid and the traditional cigarette smoke are quite different. Specifically, the composition and the release of harmful constituents from e-cigarette are significantly lower. However, there is still a lack of obvious evidence that the risk of human exposure by e-cigarette is seriously reduced when compared with traditional cigarette because of little research. In this work, we randomly select 26 e-cigarette liquids from China market to analyze their harmful constituents and the corresponding release amounts, including nicotine, glycerine, propylene glycol, formaldehyde, acetaldehyde, 2,3-butanedione, butyraldehyde, Propionaldehyde, crotonaldehyde, 2-butyraldehyde, acetone, and acrolein. The technology of risk assessment we used is a scientific evidence-based analytical process. Results indicate that compounds like nicotine, glycerin, propylene glycol, formaldehyde, and acetaldehyde can be detected in all samples, with the release amounts under the level of 0.04, 1.95, 1.47, 0.59, and 0.33 g/puff, respectively, while the detection rates of propionaldehyde, crotonaldehyde, and 2-butyraldehyde were more lower, which can be detected by 19.2%, 11.5% and 11.5% samples, respectively. Both 2, 3-butanedione and butyraldehyde were not detected in the aerosol. The detection rates of acetone and acrolein are 23.1% and 38.5%, with the release

amounts of 0.13 and 0.23 g/puff. We also performed field investigation on 517 e-cigarette consumers living in Beijing, Shanghai, Guangzhou, and Shenzhen cities of China. The smoking parameters were recorded by CReSS Pocket. Results showed that about 95% consumers used the e-cigarette containing tank systems, which can be added the liquid. Their usage frequency of e-cigarettes is about 84.6 puff/day, with a capacity around 87.2 ml/puff. The lifetime average daily dose of each constituent (LADD) from aerosol was calculated by LADD=(C×IR×ED)/(BW×LT), which is then used to calculate HQ by HQ =LADD/RfD, where RfD is the reference dose. According to IRIS of US Environmental Protection Agency (US EPA), the RfDs of formaldehyde, acetone, and acrolein are 2×10^{-1}, 9×10^{-1} and 5×10^{-4}mg/(kg·d) respectively. The finally obtained HQs for formaldehyde, acetone, and acrolein are 4×10^{-3}, 2×10^{-4}, and 6×10^{-1}, respectively, indicating that these hazards might not be expected to be a threat to the public health.

1513 Oral Administration of Hexavalent Chromium Did Not Increase Mutant Frequency in the Small Intestine of *gpt* Delta Mouse

Y. Aoki[1], M. Matsumoto[1], M. Matsumoto[1], K. Masumura[2], and T. Nohmi[2]. [1]*National Institute for Environmental Studies, Tsukuba, Ibaraki, Japan; and* [2]*National Institute of Health Sciences, Kawasaki, Kanagawa, Japan.*

WHO/IARC categorizes hexavalent chromium (Cr[VI]) compounds as Group I human carcinogens. In animal model studies, exposure to the Cr[VI] compound, sodium dichromate, via drinking water for 2 years increased the incidence of tumors of the oral mucosa and tongue in rats and of the small intestine in mice. However, the *in vivo* mutagenicity of Cr[VI] compounds in target organs must be evaluated prior to assessing the cancer risk they pose. We examined the *in vivo* mutagenicity of Cr[VI] in the small intestine, the target organ of tumorgenicity, by using a transgenic mouse gene mutation assay. In our studies, male *gpt* delta mice received sodium dichromate dihydrate in drinking water at tumorigenic doses (85.7 or 257.4 mg/L for 28 days or 8.6, 28.6, or 85.7 mg/L for 90 days). Compared with that in vehicle control mice, *gpt* mutant frequency in the small intestine of Cr[VI]-exposed mice was not increased significantly in either the 28- or 90-day study; in contrast, 28-day oral administration of potassium bromate at a dose of 2.0 g/L as a positive control significantly increased the mutant frequency to three times higher level than that of vehicle control. Our results indicate that Cr[VI] compounds are not mutagenic in target organs, such as the small intestine, at tumorigenic doses, suggesting that non-mutagenic mechanisms, such as cytotoxicity, contribute to the tumorigenicity of Cr[VI] compounds.

1514 Hazard Assessment of Diacetyl and Structurally Related Diketones—A Read-Across Approach

T. Hansen[1], M. Wehr[1], B. A. Kühne[1], D. Ritter[1], J. Knebel[1], J. P. Schimming[2], J. J. Boei[3], P. S. Hiemstra[3], H. Vrieling[3], and S. E. Escher[1]. [1]*Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany;* [2]*Universiteit Leiden, Leiden, Netherlands; and* [3]*Leids Universitair Medisch Centrum, Leiden, Netherlands.* Sponsor: C. Dasenbrock

Diacetyl (2,3-butanedione) is a volatile organic compound with a strong buttery flavor that is commonly used as food flavoring ingredient and in electronic cigarettes. Concerns were raised regarding respiratory disorders (Popcorn Lung) such as bronchiolitis obliterans linked to occupational pulmonary exposure to diacetyl vapors and use of electronic cigarettes. In this read-across study, we investigated the use of new approach methodologies to characterize and differentiate the hazard of diacetyl and other structurally related diketones. For this purpose, three structurally similar groups (α, β and γ diketones) which most likely have different modes of action were included, together with 2 negative compounds aliphatic aldehydes, which do not show any inflammatory response in the available rodent *in vivo* studies. Primary human bronchial epithelial cells (PBECs) were isolated from tumor-free lung tissues from four donors and differentiated into mucociliary epithelial cells at air-liquid interface (ALI) conditions. The cells were exposed to the case study chemicals under (ALI) conditions using the P.R.I.T.® ExpoCube® device for 1h once or repeatedly on three consecutive days. Cellular viability was measured by LDH-leakage and barrier function by measuring the transepithelial electrical resistance (TEER) 24h after the final exposure. Exposure concentrations ranged from 100 to 1840 ppm (diacetyl) and from 50 to 5000 ppm (other diketone analogues). Chemical-induced transcriptomic responses were investigated utilizing targeted RNAseq with the Templated Oligo Detection Assay (TempO-Seq) based on a 3347 gene panel. TempO-Seq analysis revealed up or down regulated differentially expressed genes (DEGs) in a dose and exposure time dependent manner. Analysis of the gene expression patterns indicated that some of these diketones may share a similar mode of action. Translational analyses were carried out to link these *in vitro* data to relevant adverse human outcomes like pulmonary fibrosis and inflammation. *Acknowledgement: This project received funding from the European Union's Horizon 2020 research and innovation program (grant agreement No 681002).*

1515 Using Study Evaluation to Inform Evidence Integration for Chemical Risk Assessment: Application in a Systematic Review of Hexavalent Chromium Male Reproductive Outcomes

E. Yost[1], X. Arzuaga[2], A. Sasso[2], and C. Gibbons[2]. [1]*US EPA, Research Triangle Park, NC; and* [2]*US EPA, Washington, DC.*

In the application of systematic review for chemical risk assessment, study evaluation is used to identify the strengths and weaknesses of the evidence base in a consistent and transparent manner. This can be used to inform evidence integration by identifying factors that may affect the reliability and interpretability of the results. Here, we describe how this principle was applied in a systematic review of the health effects of hexavalent chromium [Cr(VI)], focusing on animal toxicology studies that evaluated male reproductive outcomes. A literature search for studies on the health effects of Cr(VI) was conducted by searching three online databases (PubMed, Web of Science, Toxline) through May 2018, and supplemented by manual searches of key references, gray literature searches, and "backward" searches to identify articles cited by included studies, reviews, or prior assessments by other agencies. Twenty-three animal toxicology studies that examined the effects of Cr(VI) exposure on the male reproductive system were identified. These studies were evaluated by at least two independent reviewers for reporting quality, risk of bias, and sensitivity using a domain-based approach, and were rated as *high* confidence, *medium* confidence, *low* confidence, or *uninformative*. Of these, eight studies were considered *uninformative* due to serious flaws and were excluded. Four studies had no notable concerns and were considered *high* confidence, and eleven had significant concerns across multiple study evaluation domains and were considered *low* confidence. Whereas the *high* confidence studies found that the male reproductive system appeared unaffected by Cr(VI) exposure, the *low* confidence studies found a range of effects including decreased sperm quality and quantity and altered hormone levels. Taken together, the reliability of the observed effects in animals was considered to be compromised by risk of bias and sensitivity concerns; therefore, these findings contributed very little to the overall weight of evidence for male reproductive outcomes. *The views expressed in this abstract are those of the authors and do not necessarily reflect the views or policies of the US EPA.*

1516 Systematic Review of the Potential Respiratory Carcinogenicity of Metallic Nickel in Humans

R. L. Prueitt[1], W. Li[2], R. Chang[1], and J. E. Goodman[2]. [1]*Gradient, Seattle, WA; and* [2]*Gradient, Boston, MA.*

The inhalation of dust containing certain nickel compounds has been associated with an increased risk of lung and nasal cancers in occupational studies of workers who process or refine sulfidic nickel ores and are exposed to relatively high levels of mixtures of water-soluble, sulfidic, oxidic, and/or metallic forms of nickel. Nickel compounds are classified as Group 1 carcinogens by the International Agency for Research on Cancer (IARC), while metallic nickel is classified as a Group 2B carcinogen. IARC has identified metallic nickel as a priority substance for review within the next 5 years. We conducted a systematic review of the potential carcinogenicity of metallic nickel, focusing on cancers of the respiratory tract, which is the target organ for tumors induced by nickel compounds. We evaluated the quality and risk of bias of the relevant epidemiology, experimental animal, and *in vitro* mechanistic studies using the National Toxicology Program's Office of Health Assessment and Translation (OHAT) Risk of Bias Rating Tool. We then used a systematic review protocol based on the OHAT approach to critically assess whether metallic nickel should be considered a human respiratory carcinogen. Our evaluation of the epidemiology evidence indicates that there is no increased risk of respiratory cancers in workers exposed predominantly to metallic nickel. In addition, cross-classification analyses of worker cohorts exposed to multiple forms of nickel indicate that there is no evidence to suggest that metallic nickel exposure resulted in increased respiratory cancer risk. Animal evidence indicates that metallic nickel does not increase the incidence of respiratory tumors in rodents exposed by inhalation. The mechanistic evidence indicates that metallic nickel can induce DNA strand breaks *in vitro*, but is not mutagenic, suggesting that any DNA damage induced by metallic nickel is repaired. Nevertheless, *in vitro* studies are limited in value, as they bypass normal clearance mechanisms and do not consider the low bioavailability of nickel ions from metallic nickel particles in the cell nucleus. After integrating

the evidence from all study types, and applying a standard framework for causality, we concluded that any relationship between metallic nickel exposure and respiratory cancer in humans is not likely to be causal.

1517 Comparison and Analysis of Discrepancies among Commonly Used Cramer Decision Tree Methods in Toxtree Software

E. N. Rogers, A. L. Mihalchik, and S. C. Gad. *Gad Consulting Services, Raleigh, NC.*

The threshold of toxicological concern (TTC) is a practical tool to screen and estimate safe human exposure levels to compounds lacking adequate data for safety evaluation. In the absence of compound-specific toxicological data, approaches, such as the Cramer Classification Scheme, can be utilized to estimate an appropriate exposure level. The Cramer Classification Scheme is a 33-question decision tree used to classify the potential toxicity of non-carcinogenic compounds with limited toxicity data based upon a curated dataset of oral NOAELs. Divided into 3 classes, the Cramer decision tree scheme categorizes organic chemicals as possessing either low (Class I), moderate (Class II), or high (Class III) potential for toxicity. Although it is possible to manually assess compounds using the decision tree, Toxtree software has developed an automated software approach which implements the Cramer decision tree scheme. Two other decision tree methods, Cramer rules with extensions and the revised Cramer decision tree, are also available and utilized by many scientists in order to predict probable toxicological risk of compounds, although standardized regulatory guidance regarding which tree is most appropriate is currently unavailable, especially considering current applications of the TTC to a variety of chemicals and potential human exposure routes and regimens. The Cramer rules with extensions includes 5 additional questions as derived by Munro et al. (1996) to overcome possible misclassification of compounds. By contrast, the revised Cramer decision tree is a shortened scheme which combines several Cramer questions and incorporates additional industry-derived data on metabolism, toxicity and biochemistry of compounds within the dataset. Recently, analysis of several compounds using these various Cramer schemes elicited conflicting data. Evaluation and comparative analysis among examples using the original, extended, and revised versions of the Cramer decision tree are presented in this poster. By presenting these chemical examples with conflicting Cramer classification, it is possible to gain a better understanding of potential risk associated with each compound and influence of classification scheme on prediction outcomes. Analysis of these chemical examples assists in determination of the most appropriate Cramer decision tree to select with regards to the most adequate, safe human exposure level.

1518 Identifying Target Organs and Candidate Contaminants Based on Adverse Outcomes following Subchronic Oral Exposure in Rats to Contaminated Soil Extracts from a Pesticide Manufacturing Site

B. Boamah[1], S. Barnsley[1], L. Finch[1], J. Briens[1], S. Siciliano[1], N. Hogan[1], M. Hecker[1], M. Hanson[2], P. Campbell[3], K. Bradshaw[4], A. Manek[5], and A. N. Al-Dissi[6]. *[1]University of Saskatchewan Toxicology Centre, Saskatoon, SK, Canada; [2]University of Manitoba, Winnipeg, MB, Canada; [3]Wood Environment and Infrastructure Solutions, Winnipeg, MB, Canada; [4]Federated Co-operatives Limited, Saskatoon, SK, Canada; [5]University of Saskatchewan College of Medicine, Saskatoon, SK, Canada; and [6]Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, SK, Canada.*

Soil sample extracts from a legacy contaminated site were examined using an effects-directed approach. The study aimed to identify target organ toxicities after twice-weekly oral gavage of 3 different soil extracts (vehicle control and 0.1% of each extract in polyethylene glycol) in male Sprague Dawley rats (n=10/group). After 28 days, a significant increase in blood markers of inflammation was seen in rats exposed to all 3 extracts compared to control. A significant reduction in cholinesterase activity was observed in plasma, but not brain from rats exposed to extract A compared to control. A significant increase in hepatic ethoxyresorufin-o-deethylase activity was also observed after exposure to extracts A and B compared to control. Oxidative stress was detected in the brain and kidney tissues after exposure to extracts B and C, respectively. Acute tubular necrosis was seen in rats exposed to all 3 extracts. Candidate causative agents include organochlorine, organophosphate/carbamate insecticides or their metabolites. Kidney damage and systemic inflammation are clear targets, but some risk may arise from brain oxidative stress. Actual human risk is unclear and must be assessed in combination with potential exposure levels.

1519 Systematic Evidence Mapping of Inorganic Mercury Salts—Mercuric Chloride, Mercuric Sulfide, and Mercurous Chloride

N. Keshava, S. V. Vulimiri, A. S. Persad, S. Ramasamy, and K. Thayer. *US EPA/CPHEA, Research Triangle Park, NC.*

Systematic evidence mapping (SEM) approaches are increasingly being used to aid in scoping and problem formulation for chemical assessments. In brief, SEMs use systematic review methods to identify the relevant literature and characterize the amount and type of evidence available for an assessment. Through this process, key data gaps and areas of scientific complexity are also identified. The IRIS Program has begun to routinely conduct SEMs as part of its problem formulation activities to promote transparency in the early stages of assessment development. The use of specialized software applications makes production time for SEMs relatively rapid, weeks to several months for most chemicals. This methodology was used to identify relevant literature on the three inorganic mercury salts (mercuric chloride, mercuric sulfide and mercurous chloride) currently under development as IRIS assessments. First, Populations, Exposures, Comparators, and Outcomes (PECO) criteria were developed to outline the evidence considered applicable to address the specific aims of the assessment. Following the literature search from three different databases (PubMed, Toxline, and Web of Science), studies were sorted in SWIFT Review, a text mining work bench tool, using a predetermined list of health outcomes (cancer, cardiovascular, developmental, endocrine, gastrointestinal, etc.) and evidence streams (human, animal, *in vitro*). In addition to screening title and abstract and full-text against the PECO criteria, studies containing supplemental material that may be potentially relevant to the assessment were tracked in DistillerSR. Following full-text review, study designs and results were summarized in a structured format and visualized in Tableau software. The SEM approach identified several oral subchronic and chronic animal studies for both mercuric chloride and mercuric sulfide for further study quality evaluation. No oral studies on mercurous chloride were found. A pool of mechanistic studies, tagged as supplemental, were informative for hazard characterization and linking biomarkers to apical effects. In conclusion, these results will be helpful for consideration of alternative approaches, such as bioavailability and read-across, for use in the derivation of reference values for other data-poor mercury salts.

1520 Determining Mutagenicity of Different Chemicals Using Whole Genome Sequencing of Pooled Clones

A. W. Alund[1], B. Pan[1], H. Du[1], J. Yan[1], T. Robison[2], R. Heflich[1], and T. Chen[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]US FDA, Silver Spring, MD.*

Major advancements have been made over the last decade in next generation sequencing (NGS) technologies and their applications in genotoxicity assessments. An initial disadvantage of NGS is the inability to distinguish somatic mutations from sequencing errors, which can occur every 10^4 bases. To overcome this and accurately identify induced somatic mutations by NGS we utilized a novel approach of performing whole genome sequencing (WGS) of pooled clones. Using WGS of pooled clones for evaluating mutagenicity of a compound subverts the inherent mutation bias of the Ames test toward limited types of mutations and its need for multiple tester strains. The pooled clone approach nullifies the sequencing error-rate disadvantage of NGS and increases number of the targeted base-pairs by simultaneously sequencing of multiple genomes per sample. The Ames test strain, *Salmonella* typhimurium (TA 100), was cultured and treated with different doses of Benzo[a] pyrene (B[a]P), Aristolochic Acid (AA), *N*-ethyl-*N*-nitrosourea (ENU), and 2-Nitrofluorene (2-NF). All these chemicals are mutagenic in the Ames test. ENU, AA, and 2-NF exhibited significant cytotoxicity, resulting in dose-dependent reductions in colony forming efficiency. WGS was performed on pooled samples of five clones for each dose, as well as for vehicle controls, to identify mutations. Treatment with these mutagens resulted in significant mutation induction in a dose dependent manner. The approach also effectively detects mutation signatures specific to each mutagen. Different types of mutations including base-pair substitutions, insertions, deletions, etc. could be visualized and compared using WGS data. We show here that the WGS of pooled clones could be used as a less cumbersome and cost-efficient method for mutation detection.

1521 Significance of Toxicological Interaction Studies

G. B. Guillot. *International Prevention Research Institute, Lyon, France.*
Sponsor: G. Guillot, EUROTOX

Risk assessment for mixtures of chemicals requires to investigate the presence of potential interactions between those chemicals. This is usually done by assessing how experimental toxicological mixture data depart from the model of Loewe additivity (*Effect of combinations: mathematical basis of problem*, Arch. Exp. Pathol. Pharmakol. 114, 1926). Several recent scientific studies propose to perform this task using an *ad hoc* method known as Model Deviation Ratio (MDR) method. More recently, the first official European regulatory document for the study combined exposures recommends the use of the MDR method (EFSA Scientific Committee et al. *Guidance on harmonised methodologies for human health, animal health and ecological risk assessment of combined exposure to multiple chemicals*. EFSA Journal, 2019). We show here that the MDR method is not calibrated, it leads to erroneous decisions and that the results reported lately in studies using the MDR are likely inaccurate. In contrast, we show that a classical statistical technique known as likelihood ratio test provides accurate results, including when sample size are close to the minimum required by OECD guidelines. We show also that the variance of the MDR can be evaluated by simulations and we explain how it allows us to use MDR when no other experimental are available, a situation typical of meta-analyses.

1522 Next-Generation Risk Assessment (NGRA) for Cosmetic Safety Assessment: A Case Study

G. Reynolds, S. Cable, T. Cull, P. Carmichael, M. Dent, M. Delagrange, P. Kukic, M. Lee, H. Li, G. Maxwell, A. Middleton, T. Moxon, A. Nathanail, B. Nicol, J. Reynolds, A. White, and M. Baltazar. *Unilever, Bedford, United Kingdom*.

Next Generation Risk Assessment (NGRA) is an exposure-led, hypothesis-driven approach integrating new approach methodologies (NAMs) to ensure the safety without animal data. We have applied an *ab initio* tiered NGRA framework (Berggren et al., 2017) based upon ICCR principles (Dent *et al*., 2018) to a hypothetical safety assessment of a consumer product - 0.1% coumarin in a face cream. For the purpose of evaluating the use of NAMs, existing animal and human data for coumarin were excluded from the safety assessment. In Tier 0, applied dose exposure estimates for coumarin were determined and an internal C_{max} (0.004 µM) was defined using a physiologically based kinetic (PBK) model. *In silico* chemistry predictions (ToxTree, OECD Toolbox, DEREK) gave alerts for skin sensitisation and genotoxicity. A skin allergy risk assessment was conducted using Tier 1 *in vitro* data for coumarin (DPRA, KeratinoSens, h-CLAT and U-Sens) and a point of departure (PoD) derived using a published Skin Allergy Risk Assessment (SARA) defined approach (Reynolds *et al*., 2019). We conclude a low risk of inducing skin sensitisation in consumers exposed tocoumarin at 0.1% in a face cream. For the systemic toxicity risk assessment, a battery of Tier 1 *in vitro* NAMs were used; genotoxicity (ToxTracker®), receptor-mediated and immunomodulatory effects (Eurofins Safety44 screen and BioSeek® respectively), and non-specific pathways/general bioactivity (ToxCast data, cell stress panel [WC1] and high-throughput transcriptomics (HTTr) in HepG2, HepaRG and MCF7 cells) to which a novel statistical Bayesian approach was applied to the dose-response data. Cell stress and HTTr assays utilising 3D cultures of HepaRG cells were used for Tier 2 refinement. The PoDs from the *in vitro* assays demonstrating a dose response were plotted against the calculated *in vivo* exposure (C_{max} with associated uncertainty) in order to calculate a margin of safety (MoS). The results indicate that coumarin is not genotoxic, does not bind to any of the 44 receptors or show any immunomodulatory effects. The most sensitive PoDs were the inhibition of carbonic anhydrase inhibition assay (Ki= 3-9 µM) and MAO-A and B (AC50= 12-19 µM). The predicted 95th percentile of plasma C_{max} (0.004 µM) was lower than all PoDs. This large MoS indicates that systemic exposure to coumarin following application of 0.1% in a face cream would be of low risk. This case study provides additional data on the value of integrating exposure science with computational modelling and *in vitro* bioactivity data for non-animal, next generation safety assessments.

1523 A Novel Dose-Response Framework with Quantitatively Integrated MOA Information

Q. Chen, and K. Shao. *Indiana University, Bloomington, IN.*

In the framework of chemical risk assessment, dose-response assessment first quantifies the relationship between dose and critical health effects, and then extrapolates the biologically/statistically significant dose (i.e., point of departure) to a reference dose for regulatory use. Typically, the POD for carcinogens is the benchmark dose (BMD) or its statistical lower bound (i.e., BMDL). From a conservative perspective, US EPA suggests that linear extrapolation should be used as a default approach to derive cancer slope factor which may be employed to estimate cancer risk at a given dose. If sufficient evidence of mode of action (MOA) can support a conclusion that the dose-response relationship is nonlinear in the low-dose region (i.e., to confirm that the agent is non-mutagenic), an oral reference dose (RfD) or an inhalation reference concentration (RfC) will be calculated instead. However, RfD/RfC lacks the utility to quantify the risk of adverse effects in support of probabilistic risk assessment. Therefore, this project aims to develop a novel framework of dose-response assessment for carcinogens with sufficient data to characterize its MOA. TCDD is used as an example of Aryl hydrocarbon receptor (AhR) mediated MOA for liver tumor to demonstrate the proposed methodology. There are three major steps in the framework: (1) key events along the pathway of TCDD-induced liver tumors are identified by literature review, and the dose-response data are extracted; (2) the BMD method is applied to derive the critical dose level that activates each key event; (3) a pathway dose-response relationship is quantified to estimate the dose level that can induce the key event considered as critical/irreversible in the MOA. As a result, a series of events are identified along the pathway of TCDD-induced liver tumors, including genomic expression changes, enzyme and protein inductions, cellular homeostasis changes, hepatopathy, hyperplasia and tumors. A critical dose of 55 pg/kg/day is estimated by defining the hypertrophy occurred around 31 weeks as the sentinel event for TCDD-induced hepatocarcinogenesis. By quantitatively integrating human variability, this value can be used to derive a risk-specific reference dose. Rather than using a specific health effect to derive a POD in the current dose-response assessment framework, the new approach not only considers the mechanism of tumor formation, but also probabilistically quantifies the dose level that may induce a defined critical key event. This approach may fundamentally unify the linear and nonlinear methods before extrapolating to a human reference dose.

1524 Proposal for Use of *In Vitro* Bioaccessibility Data When Methods Validated Using Animal Models Are Unavailable

A. Feldpausch, and R. Schoof. *Ramboll US Corp, Seattle, WA.*

Use of relative bioavailability adjustments (RBA) for lead and arsenic in soil is common in site-specific risk assessment since US EPA approved *in vitro* methods for assessing relative bioavailability of these metals in soil based on validation in animal models. When other metals are evaluated at contaminated sites, exposure estimates are unadjusted for relative bioavailability. The resulting risks are likely overestimated because toxicity values used in estimating risk are typically derived using much more soluble chemical forms of the metal compared to their forms in weathered soil. Use of RBA to refine the risk assessment process would reduce uncertainty in exposure estimates and increase confidence in risk management decision-making. For a site in the western US, *in vitro* bioaccessibility (IVBA) data were collected for metals in 24 soil samples (<149 µm size fraction) for which *in vitro* methods have not been validated using animal models to produce RBA regression estimates: Al, Sb, Cd, Cr, Co, Fe, Mn, Ni, Tl, and Va. The mean IVBA results for Sb, Cd, and Mn were 0.33, 0.82, and 0.52, respectively, and mean results for the remaining metals were 0.20 or below. More specifically, IVBA values for four metals were less than 0.10 (Cr, Fe, Ni, Va) and IVBA values for three additional metals were less than 0.20 (Al, Co, Tl). IVBA also was measured for lead and arsenic, and their respective regression analyses developed in validating the *in vitro* models yielded RBA values lower than the IVBA values for all but the lowest arsenic IVBA result (Pb IVBA=0.1-0.5, RBA=0.06-0.41; As IVBA=0.1-0.5, RBA=0.11-0.43). Comparison of these results to data for metals with validated IVBA methods, i.e., lead and arsenic, shows that the IVBA data are comparable to the RBAs and suggests that use of the unmodified IVBA data (i.e., use of IVBA without adjustment in a regression model) may provide a reasonable estimate of RBA values for use in site-specific risk assessment. Due to limitations in the ability of animal studies to provide RBA estimates for poorly absorbed metals in soil, assuming an RBA of 0.25 to provide an upper-bound estimate of RBA for the seven metals with IVBA values equal to or less than 0.20 is recommended. For Sb, Cd, and Mn, the mean site-specific IVBA values are recommended. Other IVBA/RBA comparison studies reported in the literature also provide evidence that IVBA results are good predictors of RBA, and that using animal models to generate reliable RBA estimates for metals with very low bioavailability is challenging.

1525 Systematic Evidence Mapping of Provisionally Peer-Reviewed Toxicity Value Assessments

S. V. Vulimiri[1], A. S. Persad[1], C. Keshava[1], P. G. Reinhart[1], S. Kim[1], R. Mezencev[1], B. Schulz[1], K. Thayer[1], and S. C. Wesselkamper[2]. *[1]US EPA/CPHEA, Research Triangle Park, NC; and [2]US EPA/CPHEA, Cincinnati, OH.*

Provisional Peer-Reviewed Toxicity Value (PPRTV) assessments identify and characterize human health hazards and provide an important source of toxicity values for chemicals of concern to the US Environmental Protection Agency's Superfund Program. PPRTV derivation traditionally relies on *in vivo* toxicity databases; however, new approach methods (NAMs) involving expert-driven read-across are being utilized for data-poor chemicals. In the present study, we examined the use and applicability of a systematic evidence map (SEM) approach to aid with the scoping, prioritization and the development of PPRTV assessments for multiple chemicals of interest. A broad-based literature search was conducted using four databases, i.e. PubMed, Web of Science (WoS), Toxline, and Toxic Substances Control Act Test Submissions (TSCATS), followed by title/abstract and full-text screening based on tailored Populations, Exposures, Comparators, and Outcomes (PECO) criteria. Potentially relevant supplemental studies were tagged as mechanistic (genotoxic and nongenotoxic), exposure, absorption, distribution, metabolism, and excretion/toxicokinetics (ADME/TK), case reports or case series, mixtures, studies with no original or useful data, etc. Based on this SEM approach, three lines of assessment development emerged: (1) candidates for traditional PPRTV assessment, (2) candidates for NAM-based read-across PPRTVs, and (3) candidate chemicals where the databases were too limited for the development of an assessment. Through the use of specialized software applications and well-trained staff, the SEMs generally take several weeks to prepare compared to several months by other methods. Results from this pilot study show that systematic review methods can be applied to PPRTVs in an efficient manner and help inform decision-making early in the scoping and problem formulation process.

1526 Variability of Common Toxicological Endpoints, a Comparative Study

R. C. Siwakoti, and E. Demchuk. *CDC/ATSDR, Atlanta, GA.*

Environmental and occupational public health assessment typically relies on a quantitative framework associated with chemical-specific health guidance values, such as the ATSDR minimal risk levels, and other common toxicity estimators. The latter include the highest-no- and lowest-observed adverse effect levels (NOAELs and LOAELs), benchmark doses, median lethal doses (LD_{50}s), and other. Because each of these endpoints is a measured quantity, they carry a certain level of natural variability. This variability can be of two types: within-study and cross-study variability. The first reflects such factors as the number of subjects, precision of the dose, etc. The second deals with fundamental differences in study design at different labs. Generally, the extent of toxicological endpoint variability is unknown, although a common perception of it does exist. For instance, NOAELs are commonly perceived as less certain quantities than LOAELs. However, such perception often stems from general scientific judgement rather than a rigorous quantitative analysis. In the present work, variability of LOAELs, NOAELs, and LD_{50}s was assessed using information accumulated over years in the toxicological profiles of chemical substances released by the Agency for Toxic Substances and Disease Registry (ATSDR) and other public databases. The variability of each endpoint was estimated using an empirical distribution of sample standard deviations (SDs) of specific endpoint data for each chemical. It was found that the variability of LD_{50}s on the $\log_{10}$ scale was approximately half of that of LOAELs or NOAELs. The median SD of log-transformed LD_{50}s was calculated to 0.26 (95% CI: 0.23 - 0.28), whereas median SDs of log-transformed LOAELs and NOAELs were approximately twice larger: 0.53 (95% CI: 0.50 - 0.58) and 0.57 (95% CI: 0.47 - 0.67), respectively. Note, the calculated SDs of LOAELs and NOAELs were statistically indistinguishable. Indeed, LOAEL and NOAEL represent two adjacent points on the same measured dose-response curve. Therefore, *a priori* expectations of their marked distinctions may be exaggerated. *Disclaimer: The findings and conclusions in this presentation have not been formally disseminated by the Centers for Disease Control and Prevention/the Agency for Toxic Substances and Disease Registry and should not be construed to represent any agency determination or policy.*

1527 Bolstering the Existing Database Supporting the Noncancer Threshold of Toxicological Concern Values with Toxicity Data on Fragrance-Related Materials

A. Patel[1], K. Joshi[1], S. Gadhia[1], J. Rose[2], M. Laufersweiler[2], S. P. Felter[2], and A. Api[1]. *[1]Research Institute for Fragrance Materials, Woodcliff Lake, NJ; and [2]Procter & Gamble, Cincinnati, OH.*

The use of threshold of toxicological concern (TTC) supports the safety assessment of exposure to low levels of chemicals when toxicity data are limited. The Research Institute for Fragrance Materials (RIFM) delivers safety assessments for fragrance materials that result in safe products for consumer use. A major goal for the RIFM safety assessment program is to invest in alternative methods to animal testing for use in assessment of fragrance materials. This includes use of TTC, which provides a pragmatic approach for safety evaluation of fragrance materials in the absence of chemical-specific toxicity data and reduces the need to generate new animal data. To bolster the TTC approach for support of fragrance materials and specifically to strengthen the Cramer class II threshold, the RIFM database was reviewed with a goal of identifying fragrance materials with repeat-dose and developmental and reproductive toxicity data that can be added to the existing TTC databases. The RIFM database identified a total of 476 chemicals that were added to the existing TTC databases. These chemicals from the RIFM database were then individually assigned a Cramer class and 238, 76 and 162 chemicals in Cramer class I, II and III respectively were identified. The RIFM-TTC dataset was then combined with the COSMOS-Federated TTC dataset for a total of 421, 111 and 795 chemicals in Cramer class I, II and III respectively. This further expands the TTC dataset thereby supporting more robust 5th percentile thresholds. This is especially important for Cramer class II: the combined dataset now includes a total of 111 chemicals, which is a significant improvement over the original (Munro) TTC database which only had 28 chemicals in Cramer Class II and the COSMOS Federated dataset which had 40 chemicals. This work confirms the adequacy of the existing TTC values and provides further support for the use of TTC as a tool to conduct safety assessments for fragrance materials. It further opens the future possibility of updating the existing values with more robust TTC values for fragrance and cosmetic materials.

1528 A Method for Comparing the Impact on Carcinogenicity of Tobacco Products: A Case Study on Heated Tobacco versus Cigarettes

W. Slob[1], L. G. Soeteman-Hernández[1], W. Bil[1], Y. C. Staal[1], E. Stephens[2], and R. Talhout[1]. *[1]Rijksinstituut voor Volksgezondheid en Milieu (RIVM), Bilthoven, Netherlands; and [2]University of St Andrews, St Andrews, United Kingdom.* Sponsor: Y. Staal, EUROTOX

Comparing the harmful health effects related to two different tobacco products by applying common risk assessment methods to each individual compound is problematic. We developed a method that circumvents some of these problems by focusing on the change in cumulative exposure (CCE) of the compounds emitted by the two products considered. The method consists of six steps. The first three steps encompass dose-response analysis of cancer data, resulting in relative potency factors (RPFs) with confidence intervals. The fourth step evaluates emission data, resulting in confidence intervals for the expected emission of each compound. The fifth step calculates the change in CCE, probabilistically, resulting in an uncertainty range for the CCE. The sixth step estimates the associated health impact by combining the CCE with relevant dose-response information. Results: As an illustrative case study, we applied the method to eight carcinogens occurring both in the emissions of Heated Tobacco Products (HTPs) and tobacco smoke. The CCE was estimated to be 10- to 25-fold lower when using HTPs instead of cigarettes. Such a change indicates a substantially smaller reduction in expected lifespan, based on available dose-response information in smokers. However, this is a preliminary conclusion, as only eight carcinogens were considered so far. Furthermore, an unfavorable health impact related to HTPs remains as compared to complete abstinence. Our method results in useful information that may help policy makers in better understanding the potential health impact of new tobacco and related products. A similar approach can be used to compare the carcinogenicity of other mixtures.

1529 Transcriptomic Dose-Response Modeling in >21 Year-Old Archival Mouse Liver Tissue for Risk Assessment

L. Wehmas, and S. Hester. *US EPA, Research Triangle Park, NC.*

Gene expression data from short-term *in vivo* studies shows efficacy in quantifying dose-dependent effects that inform and precede toxicity outcomes of regulatory concern. With archival formalin-fixed paraffin-embedded (FFPE) tissue samples, this data can be obtained and related to pathological effects without the need for new animal studies. Advances in technology can help overcome the challenges of isolating and sequencing damaged nucleic acid from old FFPE tissue samples. This study investigated the efficacy of performing transcriptomic benchmark dose modeling (BMD_T, BMDExpress 2.0) on whole genome TempO-sequencing in >21 yr-old paired frozen (FR) and FFPE liver tissue harvested from male mice exposed to 0, 1, 2, and 3.5 g/L dichloroacetic acid via drinking water for 6 d. for which total RNA-sequencing data existed. BMD_Ts calculated from preselected *Cyp4a* targets in FR total RNA sequencing data were 277-284 mg/kg-d, which was ~6.5-fold higher than the IRIS BMD for liver adenoma and carcinoma. BMD_T performed poorly on FFPE total RNA sequencing data due to a 97% loss in gene count signal; however, BMD_T analysis of whole transcriptome TempO-sequencing on the same FFPE tissue only suffered a 40% loss relative to paired FR. Furthermore, DESeq2 analysis of TempO-sequencing data identified 8865 and 16434 differentially expressed genes (DEGs) (FDR<0.05, ±2-fold change) across all doses for FR and FFPE datasets, respectively. Of those DEGs, 5355 were common and 1022 FR and 726 FFPE passed the Williams Trend Test (p-value <0.05) and had BMD_T values ≤ to the highest dose. The median BMD_T value for FFPE TempO-sequencing results was 335 mg/kg-d, 38% higher than paired FR and 16% higher than the FR total RNA sequencing BMD_T results. TempO-sequencing BMD_T for *Cyp4a* target genes in FFPE samples was quite consistent (166-325 mg/kg-d) but not as consistent as the FR (202-225 mg/kg-d). While median TempO-sequencing BMD_T values were still higher than the IRIS BMD, they were within an order of magnitude and calculated from a short *in vivo* exposure (6 d.) unlike cancer endpoints. These BMD_Ts may also be improved with molecular pathway level data, saving time and resources. Our results show very old FFPE tissue samples can be used to obtain quantitative gene expression data and with additional refinement, used to enhance traditional risk assessments. *This abstract does not represent US EPA policy.*

1530 An Interactive Web Application for the Calculation of TD_{50} Values from Carcinogenicity Study Summary Data

J. Hutchinson, C. Blaser, J. Warmka, and R. Roy. *3M, Saint Paul, MN.*

According to ICH M7 guidance, the default approach for calculating compound-specific acceptable intake (AI) values for mutagenic impurities with available carcinogenicity data in pharmaceuticals involves linear extrapolation to a lifetime risk level of 1 in 100,000 from a cancer potency estimate known as the TD_{50}. The TD_{50} is defined as the dose rate which, if administered chronically for a lifetime, halves the probability of remaining tumor-free throughout that period. The Carcinogenic Potency Database (CPDB) serves as a widely-used resource for publicly-available TD_{50} values. The site provides TD_{50} values for 1547 chemical agents calculated from historical cancer bioassays, but it does not include cancer potency estimates from studies published since 2005. Building upon the work achieved by the CPDB project, the non-profit organization, Lhasa Limited, UK has established the Lhasa Carcinogenicity Database (*Toxicol. Res.* 8, 696–703; 2019), which provides TD_{50} values estimated from the same data contained in the original CPDB and, in the future, will include TD_{50} estimates from more recent cancer studies. The statistical methods used by Lhasa Limited to calculate the TD_{50} from summary incidence data were implemented as a script encoded in the statistical package, R. This R-script has been made publicly-available in order to provide a reproducible, documented, and validated method for generation of TD_{50} values. In an effort to give risk assessors a user-friendly way to utilize these statistical methods, we built a publicly available interactive web app (based on the R-script first published by Lhasa Limited) that allows for the calculation of TD_{50} values by fitting the one-hit multistage cancer model to experimental dose-response data. Beyond assessment of mutagenic impurities per ICH M7, calculated TD_{50} values may be useful for the rapid risk assessment of carcinogens in general. An advantage of using the TD_{50} app (as opposed to other more common approaches for estimating cancer potency – i.e. benchmark dose (BMD) modeling, the T25 method, etc.) is ease-of-use. The user is only required to input study summary data; no calculations or BMD modeling expertise are required, thus allowing established cancer potency estimation methods to be utilized by a much wider user base than what was previously possible. Additionally, because the one-hit model is the most conservative of the multistage models, potency estimates generated by the app are often more health-protective than those generated by other methods. Overall, while the app allows users to obtain quick, conservative estimates of cancer potency for use in risk assessments, it is not intended to serve as a replacement for comprehensive dose-response assessment, which includes scientific judgment, fitting experimental data to multiple models, careful evaluation of model fit (especially in the low-dose region), and selection of a "best-fitting" model or model averaging to obtain a point of departure (PoD).

1531 Rodent Short-Term MoA Studies Predict Rodent Tumor Outcome and Point of Departure

A. Sarma, E. Bianchi, K. Johnson, L. Murphy, and Z. Yan. *Corteva Agriscience, Indianapolis, IN.*

For human health assessment of agrochemicals, carcinogenicity studies in both rats and mice have been used for decades to assess tumorigenic potential of the substances to humans. However, particular concern has been raised about the relevance of the rodent cancer bioassay to assess the human health risk of non-genotoxic carcinogens. Furthermore, when a positive carcinogenicity effect has been identified, human risk assessment may rely on identification of a plausible mode of action (MoA) in animals and establishing if the MoA is relevant to humans. A retrospective analysis of short-term rodent tumor MoA studies and rodent oncogenicity studies on Leydig cell, thyroid and liver tumors was conducted for three agrochemicals (sulfoxaflor, pronamide, nitrapyrin) to examine (1) if tumor NOAELs can be estimated based on the MoA key events NOAELs, (2) if NOAEL from MoA studies, including key events and associated events, are more sensitive than tumor NOAELs. MoA key and associated event endpoints include, but are not limited to, gene expression biomarkers of nuclear receptor activation, cell proliferation, hormonal level, as well organ weight/histopathology. For sulfoxaflor-induced rodent liver, data showed that the MoA key events NOAELs (100 ppm) were concordant with tumor NOAELs (100 ppm). Similar results were observed for pronamide-induced rodent Leydig cell and thyroid tumors NOAELs (200 ppm) and MoA key event NOAELs (200 ppm). Furthermore, pronamide or nitrapyrin-induced liver MoA key events NOAELs (nuclear receptor activation NOAELs = 20 mkd, 75 mkd, increased liver weight/hypertrophy NOAELs = 15mkd, 75 mkd and hepatocellular proliferation NOAELs = 20 mkd, 75 mkd) were protective of liver tumors NOAELs (50 mkd, 125 mkd). In addition to qualitatively predicting potential tumor outcomes and human relevance, these data suggest that a human health-protective point of departure may be established from a short-term MoA study.

1532 Risk Comparison of 1-bromopropane in Production Enterprises and Use Enterprises with Two Toxicological Health Risk Assessment Methods

Y. Zhang, J. Xiao, Z. Li, X. Chen, J. Song, W. Cai, H. Fu, and B. Li. *National Institute for Occupational Health and Poison Control, Chinese Center for Disease Control and Prevention, Beijing, China.*

The objective was to compare and analyze the risk of 1-bromopropane (1-BP) hazards in production enterprises and use enterprises through two risk assessment methods and to evaluate the occupational health risk. Occupational health investigation and 1-BP detection for workplaces were carried out in three production enterprises in northern of China and in three use enterprises in southern of China. The risk ratings of different posts were assessed by US Environmental Protection Agency (EPA) inhalation risk (EPA assessment model) and Singapore Semi-quantitative Assessment Model (MOM assessment model). The risk classification results of the 2 risk assessment methods were compared and analyzed, based on occupational exposure limits for hazardous agents in the workplace (GBZ2.1-2019) and classification for hazards of occupational exposure to toxicant (GBZ230-2010). The concentration of 1-BP on the positions of reaction, rectification, lavation and packaging were 0.1, 0.9, 1.6 and 0.5mg /m^3 respectively in production enterprises, while on the positions of clamping, cleaning 1 line, cleaning 2 line, and checking were 56.4,29.7,63.4 and 33 mg /m^3 respectively in use enterprises. By the EPA assessment model, all of the positions were evaluated as negligible risk in production enterprises, while the positions of cleaning 1 line and checking were low risk as well as the positions of clamping and cleaning 2 line were medium risk in use enterprises. Through the MOM assessment model, the four positions were negligible risk in production enterprises and all of the positions were medium risk in use enterprises. Current results suggested that 1-BP exposure levels were higher in use enterprises than production enterprises. The EPA assessment model could quantitatively and qualitatively assess the non-carcinogenic effects of chemicals, but the assessment results were low risk and relatively conservative for two positions where the exposure concentration were above the limit. Based on the comprehensive consideration of

both hazard level and exposure level, the MOM model was assessed as more suitable for risk warning than the EPA model for 1-BP occupational health hazard risk assessment in China.

1533 A Systematic Approach to Organize 182 Toxic Air Contaminants by Target Organ: A Risk Assessment Tool

D. G. Farrer[1], S. Wegner[1], T. Hudson[1], H. M. Dixon[1], and S. MacMillan[2]. *[1]Oregon Health Authority, Portland, OR; and [2]Oregon Department of Environmental Quality, Portland, OR.*

The Oregon Department of Environmental Quality (DEQ) recently adopted health-risk based regulations for industrial point source emissions of toxic air contaminants. The new regulations require industrial point sources to assess health risks that their emissions may pose to neighbors. The risk assessment process for noncancer effects includes summing hazard quotients for toxic air contaminants that affect the same target organ or organ system. The Oregon Health Authority (OHA) and DEQ developed a spreadsheet that lists target organs and organ systems for all 182 toxic air contaminants regulated under the new regulations. The spreadsheet lists chronic and acute noncancer targets separately. OHA and DEQ created criteria for including a target organ or organ system for each chemical and sought feedback from an external technical advisory committee. The committee had expertise in toxicology, risk assessment, and development of chemical-specific toxicity reference values. OHA and DEQ used summarized information from the US Environmental Protection Agency, Agency for Toxic Substances and Disease Registry, and the California Environmental Protection Agency's Office of Health Hazard Assessment to populate the spreadsheet according to the *a priori* established criteria. For each chemical, the spreadsheet includes the source of information for each target organ and notation about the quality and certainty of information linking the toxic air contaminant to each target organ. The spreadsheet displays a breakdown of uncertainty factors, species tested, and duration of exposure for the critical studies used to derive toxicity reference values for each toxic air contaminant. OHA and DEQ anticipate that this publicly available spreadsheet will be a useful tool for assessing noncancer risks for emissions sources in Oregon and may be useful for risk assessors outside of Oregon as well.

1534 Application of 3R Principles to Dog Studies for Agrochemicals: Building the Case for Eliminating the Dog as a Required Species?

L. Murphy, K. Stebbins, R. Rasoulpour, and C. Terry. *Corteva Agriscience, Indianapolis, IN.*

A core requirement for global pesticide registration is a 90-day toxicity study in a non-rodent species, for which the dog is usually chosen (USEPA 1998, EU 2010/63, OECD 1998, JMAFF 2000). To establish toxicologically relevant dose levels for the 90-day dog study, palatability and 28-day toxicity studies are conducted first. There are no published guidelines for conduct of these preliminary studies, so there is significant opportunity to refine the design and minimize animal use. A combined palatability/28-day study design, using the same animals, is now our standard. The preferred route of exposure is via diet as it is the least invasive route of administration and is more relevant for human health risk assessments. Significant differences in palatability can exist for herbicides and insecticides, and this combined study design considers options and alternatives for each active ingredient. For the herbicide florpyrauxifen benzyl, with no palatability or toxicity issues, the combined study evaluated 500 mg/kg/day in 2 female dogs for 7 days. On day 8, 2 males were offered 500 mg/kg/day for 21 days and 2 dogs/sex/dose were offered 1000 mg/kg/day until day 28. This approach reduces animal use as only two dose levels are tested, and control animals are not needed. Any potential treatment-related effects are compared to pre-exposure measurements of food consumption, body weight and clinical observations on the study animals. The insecticide, sulfoxaflor, presented challenges due to reduced palatability and tolerability with food consumption and body weight effects. Palatability was evaluated using alternatives, such as addition of bacon or peanut butter flavoring, pelletizing the diet, and gelatin capsule administration with the option of supplemental canned diet to encourage food consumption. The combined palatability/28-day study has reduced the use of dogs up to 83% compared to traditional toxicity testing designs and eliminated animal stress indicative of maximum tolerated dose exposures. Further refinements could include consideration of re-homing animals, if termination at study conclusion is not necessary. In addition, animal enrichment opportunities are of critical importance and include consideration of provided toys, minimum daily exercise, and expanded housing space to accommodate regular companionship of group animals. These refinements represent initial, but key steps towards an animal-free toxicity testing future.

1535 Evaluation Framework to Qualitatively Assess the Health Effects of New Tobacco and Related Products

Y. C. Staal, A. Havermans, L. Van Nierop, W. Visser, S. Wijnhoven, W. Bil, and R. Talhout. *Rijksinstituut voor Volksgezondheid en Milieu (RIVM), Bilthoven, Netherlands.* Sponsor: Y. Staal, EUROTOX

Many new tobacco and related products (TRP) have emerged on the market, with unknown health risks. Here, we present an evaluation framework containing all factors and relations between them that contribute to the TRP's health effects. As an example, we evaluated the JUUL, a very popular e-cigarette. Factors that determine attractiveness, addictiveness and toxicity of TRP were defined based on previous assessments, literature, and expert discussions, resulting in an evaluation framework. Relations between factors were evaluated, which was supported by literature. Relevant publications on JUUL were used to evaluate all factors. Results: Our framework can be used to identify aspects of TRP that require specific attention for public information or product regulation. In addition, it can gauge attractiveness for specific user groups, while considering exposure. Aspects of concern for JUUL are its attractive and discrete shape, user-friendly prefilled pods, high aerosol nicotine levels, and liquids containing nicotine salts instead of free-based nicotine. Our framework will aid in identifying the key risk factors contributing to increased risk of adverse health effects for a product in a qualitative manner. In case of JUUL, the addictiveness and especially attractiveness are sufficiently high to have a large potential impact on population health due to its contribution to use and hence exposure, even if the amounts of toxicants in the emissions should be lower than for other e-cigarettes. As results can change over time due to changes in use and product modification, market research and monitoring is crucial. Our framework and the tests we recommend can be used for risk assessment of TRP. Since all factors presented contribute (in)directly to the, attractiveness, and addictiveness and toxicity of TRP, policy makers are advised to consider these factors as a possible target for future product regulation. In addition to the identified aspects of concern for the JUUL, we advise to consider regulation of the many JUUL compatible pods, JUUL knock off devices, and e-liquid brands selling high-nicotine products.

1536 Evolving the Use of Respiratory Irritation as a Health Endpoint in Occupational Risk Assessments

E. Frank, T. Niemeier, and C. Whittaker. *NIOSH, Cincinnati, OH.*

The effects of occupational irritant exposures are of major importance to public health. Approximately 40% of the exposure limit values for agents listed in the current NIOSH Pocket Guide are estimated based on exposure thresholds for respiratory irritation. Respiratory irritation signs and symptoms include rhinorrhea (runny nose), coughing, and airway obstruction and accompanying exposure levels can coincide with sensory irritation responses in other tissues such as stinging and burning in the eyes and skin. Inhalation and dermal exposure to irritants is highly relevant to the use of solvents, catalysts, cleaners, fragrances, and many other agents extensively utilized in workplaces and industrial processes. Despite this, existing guidelines to assess and characterize irritation hazards are limited by inadequate testing methods, poor mode-of-action knowledge, and outdated risk characterizations. NIOSH is responding to these gaps with coordinated efforts across the agency and collaborating partners to meet scientific needs in the following specific areas: 1) Assessing the relationship between sensory irritation responses and traditional respiratory toxicity endpoints in animals (i.e., respiratory depression, airway histopathology, corrosion, inflammatory activation); 2) Investigating the utility of *in vitro* tests for generating irritation toxicity data using primary tissue and cultured cell lines: 3) Developing updated protocols for evaluating irritation toxicity data and integrating existing hazard information to derive exposure limit values, including recommended exposure limits, short-term exposure limits, and ceiling/immediately-dangerous-to-life-and-health (IDLH) values; and 4) Investigating the toxicological mechanisms targeted by irritants and working towards a consistent understanding of the adverse outcome pathways involved. These efforts will address occupational health needs by increasing the prevalence, quality, and utility of irritation toxicity data and improving the efficiency and accuracy of risk assessments for irritation hazards. In addition, these outcomes will be of scientific benefit to consumer product safety, environmental health in industry-adjacent communities, and numerous other public health needs arising from exposure to chemical irritants.

1537 Performance Comparison of BMDL Calculation by the Model Averaging Methods for Quantal Dataset

A. Hirose[1], K. Yoshii[2], K. Inoue[1], Y. Shigeta[1], M. Matsumoto[1], T. Kawamura[1], T. Yamaguchi[3,4], and H. Nishiura[2]. *[1]National Institute of Health Sciences, Kawasaki, Japan; [2]Hokkaido University, Sapporo, Japan; [3]CREST, Kawaguchi, Japan; and [4]Shiga University, Hikone, Japan.*

At the step of dose-response analysis on the chemical risk assessment, benchmark dose lower bound (BMDL) is increasingly used as an alternative to the NOAEL in order to estimate more appropriate POD for establishing TDI or ADI. Although several statistical models for estimating BMDL are well known, the selection criteria of a model to guide an appropriate BMDL are controversial and there is no international consensus. Recently, as a new concept for BMDL derivation, the model averaging was introduced by the EFSA (PROAST) and the USEPA (BMDS). We have also developed a new averaging method (MA-3) by using frequentist approach like PROAST, and Shao and Shapiro (2018) developed an online model averaging system (BBMD) used Bayesian method like BMDS. Model averaging techniques are said to lead to the most appropriate BMDL, but the consistency of performance on these various systems is unclear. About a hundred dichotomous dose response data sets (mainly from the OECD TG 407 and TG422 studies, and several long-term studies) were used for BMDL calculation. As for calculation software, the BMDS v3.1.1, the PROAST v67, the BBMD and MA-3 were used. Each calculated BMDL was compared to the corresponding NOAEL derived from the actual studies. The BMDL calculated by the BMDS averaged approximately 1.5 times higher than the NOAEL, whereas that calculated by the BBMD was approximately 4.5 times higher. The BMDLs calculated by the PROAST and the MA -3 were approximately 2 and 3 times higher than the corresponding NOAEL, respectively. In case of studies with large numbers of animals per group, differences in BMDL values calculated in these four softwares tended to be smaller. Even though the model averaging methods (especially when using the Bayesian methods) were used, it was clarified that the values of BMDL varied several folds depending on the software used. *Acknowledgment: This study is supported by Research Program for Risk Assessment Study on Food Safety (No. 1801), Food Safety Commissions of Japan.*

1538 Semiautomated Data Extraction Workbench for Environmental Health

B. Howard[1], A. Maharana[1], A. Tandon[1], S. Patel[1], T. Albert[1], J. Phillips[1], M. Taylor[2], K. Thayer[2], and R. Shah[1]. *[1]Sciome LLC, Research Triangle Park, NC; and [2]US EPA, Research Triangle Park, NC.*

Systematic review, already a cornerstone of evidence-based medicine, gained significant popularity in several related disciplines including environmental health and evidence-based toxicology. A critical, time-consuming process that occurs during systematic review is the extraction of relevant qualitative and quantitative raw data from the text of scientific documents. The specific data extracted differs among disciplines, but within a given domain, certain data points are extracted repeatedly for each review that is conducted. We have recently developed a semi-automated data extraction workbench for use in this context. Our research has focused on three specific goals. First, we are using deep learning to build novel data extraction components for items of interest within the domain of environmental health. Second, we have created web-based software specifically designed for extraction in the context of systematic review. Finally, we have introduced new protocols to standardize the inputs and outputs for data extraction software components. A beta version, currently under evaluation at EPA, includes more than 30 novel data extraction components relevant to environmental toxicology. Performance varies among data types with some tasks inherently more difficult than others. For certain simple data items, like sex of the experimental animal, we achieve F-scores in excess of 95%. For more difficult entities, we were still able to achieve an F-score of 65% or more, when sufficient training data was available. Importantly, the design of our workbench makes it easy to include extraction components developed by other research groups. The workbench currently includes several such components, with new ones added regularly. Because accurate data extraction is a challenging problem, and given that current methods rarely achieve 100% accuracy, we are integrating our methods into a "human-in-the-loop" system that combines machine and human intelligence in a manner that is superior to using either in isolation. The resulting system makes systematic reviews both more efficient to produce and less expensive to maintain, greatly accelerating the process by which scientific consensus is obtained in a variety of health-related disciplines.

1539 Applications of Physiologically Based Pharmacokinetic (PBPK) Modeling in Regulatory Risk Assessment for Pesticides

C. Tan[1], A. Lowit[2], and M. Embry[3]. *[1]US EPA, Research Triangle Park, NC; [2]US EPA, Arlington, VA; and [3]HESI, Washington, DC.*

Physiologically based pharmacokinetic (PBPK) modeling is widely recognized as a scientifically sound, robust approach for evaluating and characterizing uncertainty in chemical risk assessment by accounting for pharmacokinetic differences across and within species. While the development and application of PBPK models for environmental chemicals, including pesticides, have grown steadily since the 1970s, only a handful of models have been accepted to support regulatory risk assessment due to challenges, such as the difficulty to recruit reviewers with both modeling expertise and risk assessment experience, or the lack of transferability across modeling platforms. Despite these challenges, the number of PBPK models for pesticides submitted to regulatory agencies has risen in recent years. These models have been applied to estimate data-derived extrapolation factors (DDEFs) in lieu of default uncertainty factors when conducting inter-species and/or intra-species extrapolations. In other cases, PBPK models have been used to estimate human points of departure that are specific to exposure routes, durations and frequencies, and life-stages; assess mechanisms of biological responses based on their relationship with dose metrics by linking to a pharmacodynamic model; or investigate the major determinants of pharmacokinetic behaviors for pesticides within the same class. Case studies on triazines, pyrethroids, and carbaryl will be presented to demonstrate these various applications of PBPK modeling analysis that have been accepted by regulatory agencies to support human health risk assessment. In addition to using these examples to highlight how regulatory agencies incorporate kinetic information with computational approaches, lessons learned from reviewing PBPK model submission will also be shared to encourage more frequent use of PBPK modeling as a quantitative tool to characterize the impact of pharmacokinetics on dose-response assessment, and to reduce uncertainty in regulatory risk assessment for pesticides. *Disclaimer: The views expressed in this abstract are those of the authors and do not necessarily represent the views or policies of the US EPA.*

1540 The Threshold of Toxicological Concern (TTC) Is a Pragmatic Risk Assessment Tool for the Safety Assessment of Cosmetic Ingredients with Low Consumer Exposure

D. Bury[1], M. Klaric[2], D. Keller[3], and J. L. Rose[4]. *[1]L'Oréal Safety R&I, Clichy, France; [2]Cosmetics Europe, Brussels, Belgium; [3]Henkel AG, Düsseldorf, Germany; and [4]Procter & Gamble, Cincinnati, OH.* Sponsor: A. Schepky

The Threshold of Toxicological Concern (TTC) is a pragmatic and conservative tool for risk assessment of substances. The TTC is based on the principle of establishing a human exposure threshold value for all chemicals, below which there is a very low probability of a possible risk to human health. Such threshold values may be identified for many substances on the basis of their chemical structures and the known toxicity of chemicals sharing similar structural characteristics. The TTC concept has been internationally accepted and used in a wide range of regulatory contexts, such as food contact materials, food flavorings, genotoxic impurities in pharmaceuticals and pesticide metabolites in ground water. The TTC approach utilizes human exposure threshold values (TTC values) that have been originally derived from oral toxicity data on cancer and non-cancer toxicity endpoints (Munro et al., 1996). This database has been substantially enlarged by the COSMOS database, an enhanced oral non-cancer TTC dataset on a larger chemical domain, thereby resulting in a new, transparent and public TTC database which also includes 552 cosmetics-related chemicals (Yang et al., 2017). The 5th percentile point of departure (POD) value for each Cramer Class was determined, from which human exposure TTC values have been derived. The COSMOS-plus-Munro federated dataset provided TTC values of 46, 6.2 and 2.3 µg/kg bw/day for Cramer Class I, Cramer Class II and Cramer Class III, respectively. Overall, the TTC is accepted by regulatory authorities and most scientific committees, and there is broad application potential for use in safety assessments of cosmetic ingredients. In order to demonstrate the successful application of the TTC concept not only to cosmetic impurities but also to cosmetic ingredients including hair dyes, fragrances and plant-derived ingredients, Cosmetics Europe has prepared several case studies. Particularly for hair dyes, the comparison with available risk assessments on the basis of *in vivo* data illustrates that the TTC approach is sufficiently conservative and safeguards the safety of the consumer. Overall, we have shown that the TTC concept is not only useful to avoid animal testing but is also successfully used for the safety evaluation of cosmetic ingredients for which human exposures are low or negligible.

1541 *In Vitro-In Vivo* Assay Validation for Vaginal Irritation of Chemicals

A. Armento, T. Landry, M. Klausner, Y. Kaluzhny, and S. Ayehunie. *MatTek, Ashland, MA.*

The goal of the study is to validate the utility of the 3D human *in vitro* vaginal tissue model as an alternate for rabbit vaginal irritation using a set of coded test articles (TAs). A double-blinded study was conducted in which the investigator and the animal testing facility were provided with N=14 coded test articles and assayed *in vitro* and *in vivo* following topical application at 2% dose of each TA and 5 repeat exposures over 6 days. Dose volumes were proportionally adjusted based on the surface area and N=5 rabbits and N=3 EpiVaginal tissues were used per TA. While the RVI score was used to monitor *in vivo* irritation; MTT, TEER, and histological analysis were used as endpoints for the *in vitro* assays. The results showed that four TA including two known irritants, benzalkonium chloride (BZK) and nonoxynol 9 (N9) were predicted as irritants by MTT viability and TEER (<50% reduction). While BZK was identified as a mild/severe irritant in the RVI assay, the effect of N9 in rabbits was highly variable - in three independent animal RVI studies, irritation was detected only in 25-30% of the animals. Furthermore, the other two TAs, copper sulfate and sodium dodecyl sulfate (SDS), that were determined as vaginal irritant *in vitro* were not identified as irritant in the RVI test. Additionally, cytokine analysis from culture supernatants showed that N9, SDS and BZK induces a significant increase (>2 fold) in IL-1α/IL-1β release by Epivaginal tissues. In contrast, only BZK showed a significant increase in IL-1α/IL-1β from rabbit vaginal lavages. Based on the *in vitro in vivo* data, we expanded the study to include N=55 test articles and the *in vitro* reproducibility of the results for the 55 test articles were monitored using reconstructed tissues from cells obtained from N=4 donors. In short, a combination of MTT, TEER, and IL-1α/IL-1β were found to be valuable makers of *in vitro* vaginal irritation. In conclusion, the *in vitro* assay method performs equally well or better compared to the standard RVI assay and could be a useful tool to assess vaginal toxicity of formulations, drugs, and medical devices.

1542 Maternal Gestation Engineered Nanomaterial Exposure Reduces Fertility in F1 Females

E. Bowdridge, K. Garner, J. Griffith, T. Batchelor, W. Goldsmith, K. Engels, S. Hussain, and T. Nurkiewicz. *West Virginia University, Morgantown, WV.*

We have reported that maternal inhalation exposure to nano-titanium dioxide (nano-TiO_2) during gestation severely reduces circulating estrogen levels and compromises placental efficiency at gestational day (GD) 20 in Sprague Dawley (SD) rats. Alterations to normal gestational milieu neonates are subjected to during development has been extensively shown to significantly contribute to the developmental origins of health and disease. The objective of this study was to determine the effects of gestational exposure on puberty onset, cyclicity, fertility, and pregnancy outcomes. Female, SD rats were housed in the West Virginia University Inhalation Facility under a regulated temperature and 12:12 hour light-dark cycle. Dams of F1 offspring were randomly assigned to either the sham-control or nano-TiO_2 exposure groups and acclimated for 48-72-hours before mating. Inhalation exposures lasted for 6 days after GD 10 to decrease animal stress. The pregnant rats were exposed to an average target concentration of 12 mg/m^3. This exposure paradigm (12 mg/m^3, 6h/exposure, 6 days) produced a calculated lung burden of 525±16 µg. Twenty-four hours after the last exposure dams were sacrificed on GD 20. F1 females (n=3) that were exposed to nano-TiO_2 during development had reduced litter size (3±0.57 pups) when they conceived to the first mating after reaching cyclicity. Additionally, rats born to exposed dams experienced increased time to conception, requiring at least two matings prior to successful conception. Rats that became pregnant to second matings (n=4) had litter sizes (12.5±1.26 pups) comparable to sham-control dams. Dams exposed to nano-TiO_2 also had significantly reduced liter sizes (10.0±0.73) with decreased number of males (4.4±0.38), but not females (6.2±0.88) compared to sham-controls (12.7±0.71, 7.3±1.1, and 5.8±1.1, respectively). Maternal nano-TiO_2 exposure during gestation reduces both liter size and males born compared to sham-control. Furthermore, F1 females born to dams exposed during gestation experienced increased time to conception as well as decreased liter size ultimately leading to decreased fertility. *Support: ES015022 (TRN) U54GM104942 (SH).*

1543 Cytoskeletal and Ultrastructural Alterations Induced by TiO_2 and ZnO Nanoparticles into Antral Follicular Cells

R. Santacruz-Márquez, S. González-Pozos, S. P. García-Zepeda, A. Solorio-Rodríguez, A. De Vizcaya-Ruiz, and I. Hernández-Ochoa. *Cinvestav, Ciudad de México, Mexico.*

Titanium dioxide nanoparticles (TiO_2-NP) and zinc oxide nanoparticles (ZnO-NP) are metallic NP widely used in several personal care products, cosmetics, textiles and food. TiO_2-NP have been detected in ovaries from exposed mice, and studies have found that exposure to TiO_2-NP and ZnO-NP alters hormone levels, mating and pregnancy rates. However, no studies have evaluated a direct interaction of NP with ovarian cells. Antral follicles are the functional units of the ovary. They possess steroidogenic activity and are responsible for growing, housing, and promoting competence to the oocyte for fertilization. Previously, we characterized both NP in culture media, and we found impaired antral follicle growth and morphological alterations. This work aimed to evaluate ovarian follicle alterations in the cytoskeleton arrangement and ultrastructure after TiO_2-NP and ZnO-NP exposure. Antral follicles from C57BL6/J mice were cultured with TiO_2-NP (0, 5, 25 and 50 µg/mL) or ZnO-NP (0, 5, 15 and 25 µg/mL) for four days. After culture, immunofluorescence and transmission electron microscopy were performed to determine cytoskeletal and ultrastructural alterations, respectively. Our results show alterations in the cytoskeletal organization in cells from exposed antral follicles, as evidenced by the loss of microtubule boundless irradiating to the periphery and by the appearance of hole-like structures in microtubule such as disorganization in microfilaments. TiO_2-NP were mainly internalized into antral follicles using endocytosis and macropinocytosis transport systems. TiO_2-NP were localized at every follicular cell type but the oocyte. ZnO-NP were not observed in follicular cells because they may dissolve in the culture media. Finally, both NP affected mitochondrial ultrastructure and the trans-zonal projections located from surrounding cumulus cells through the oocyte. Our results suggest that NP elicit toxicity in ovarian follicles via different mechanisms of toxicity, possibly due to their differentiated fate in the culture. *Supported by Fondo de Investigación Científica y Desarrollo Tecnológico del Cinvestav (grant No. 189).*

1544 Subchronic Exposure to DEHP Alters the Expression of Genes Encoding for Proteins Involved in the Extrusion of First Polar Body

L. Y. Parra-Forero, A. Lopez-Luna, E. Lopez-Bayghen, M. F. Hernandez-Avila, A. Salazar-Aguilar, and I. Hernandez-Ochoa. *Cinvestav, Mexico City, Mexico.*

Di (2-ethylhexyl) phthalate (DEHP) is an endocrine disrupting chemical used as a plasticizer that has been related to numerous pathologies including syndromes such as infertility. Previous studies have shown that subchronic exposure to DEHP to environmentally relevant doses impairs the oocyte maturation, evidenced by an increased number of ovulated oocytes that do not reach metaphase II (MII) and do not extrude the first polar body. This study was aimed to evaluate mRNA levels of genes encoding for proteins involved in the extrusion of polar body, including anillin, myosin-9, septin-2 and septin-7. Female CD1 mice were administered orally with 0, 20, 200, or 2000 µg DEHP/kg body weight (bw)/day for 30 days. After the dosing period, females were induced to superovulate by injecting ip 5 IU pregnant mare serum gonadotropin (PMSG), followed by 5 IU human chorionic gonadotropin (hCG) at 48 h later. At 20 h post-hCG injection, oocytes were obtained by washing the oviducts, and then they were classified according to their stage of maturation in germinal vesicular (GV), metaphase I (MI) and MII. Oocytes were subjected to RNA extraction and two-step real time PCR from at least three independent experiments. We found significantly lower mRNA levels of Anillina, myosin-9 and septin-2 at the GV, MI and MII stages of maturation in oocytes from mice treated with 200 and 2000 µg DEHP/kg bw/day compared to controls. Further, we found significantly lower mRNA levels of septin-7 from the MI stage in oocytes from either dose of DEHP compared to controls. These results suggest that DEHP may interfere with genes involved with the extrusion of the first polar body at transcriptional levels for contributing to impair oocyte meiosis.

1545 Levels of Mono-n-butyl Phthalate in the Tissues of Adult CD-1 Female Mice after Repeated Oral Administration of Di-n-butyl Phthalate

E. J. Jauregui, J. Lock, L. Rasmussen, and Z. R. Craig. *University of Arizona, Tucson, AZ.*

Di-n-butyl phthalate (DBP) is an endocrine disruptor commonly used worldwide as a plasticizer or solvent in many consumer products such as infant care, personal, and cosmetic products. Exposure to phthalates is postulated to cause developmental and reproductive toxicity. While various studies utilizing mice have shown that DBP causes health problems, no quantitative evidence of the accumulation of the active metabolite of DBP, mono-n-butyl phthalate (MBP), in the tissues of exposed female mice currently exists. Previously, we detected MBP in serum (15.74±2.46 µg/ml), liver (2.78±0.43µg/g), and ovary (2.03±0.53 µg/g) of mice treated with a single dose of DBP (1000 mg/kg) after 2 h with the highest concentration of MBP detected 6 h after the DBP dose in serum (19.45 ±5.79 µg/ml), liver (5.22±1.65 µg/g), and ovary (2.77±0.1 µg/g). To investigate the accumulation of MBP after repeated dosing with DBP, we utilized a highly sensitive liquid chromatography/tandem mass spectroscopy assay to determine MBP levels in the liver, serum, and ovary of adult CD-1 female mice after 10 daily oral doses of DBP. We pipet-fed adult mice (n=5 per treatment/time point) with tocopherol-stripped corn oil (vehicle) or ten doses of DBP (1000 mg/kg/day) and collected liver, ovary, and serum at 2, 6, 12, and 24 h after treatment. In mice treated with vehicle, background MBP levels were detected in serum (0.001±0.0002 µg/ml) and liver (0.005±0.012 µg/g), but not in ovaries. Interestingly, there was significant MBP accumulation observed in serum (75.6±10.7 µg/ml, p=0.0014), liver (1255.9±215.3 µg/g, p=0.0013), and ovary (1186.8±201.3 µg/g, p=0.0013) of mice treated with 10 oral dosages of DBP (1000 mg/kg/day) in comparison to the levels detected in mice treated with a single dose of DBP (1000 mg/kg) in our previous study. In the serum, liver, and ovary of mice treated with 10 dosages of DBP the highest concentration of MBP was detected at 2 h after the treatment and decreased with time to undetectable levels at the 24 h time point. In conclusion, we have measured, for the first time, MBP in the tissues of mice after repeated oral exposure to DBP. This study provides evidence that MBP is accumulating in the ovary after oral exposure, thus, it supports a role for direct exposure of this phthalate in the ovary of mice. *This work was supported by NIEHS grant R01026998-01A1 (ZRC).*

1546 The Effects of Oral Dibutyl Phthalate (DBP) Exposure on Transcription Factor Activation in the Mouse Ovary

F. M. Nunez, and Z. Craig. *University of Arizona, Tucson, AZ.*

Phthalates are a family of endocrine disruptors found ubiquitously in the environment, making the human population susceptible to exposure. Previous research has shown changes in ovarian gene expression following exposures to dibutyl phthalate (DBP). To elucidate the mechanistic effects of DBP, we sought to determine whether oral exposure to DBP alters the activation rate of transcription factors in the ovary. To do so, female CD-1 mice (60 days old, n=14-16 per treatment) were orally administered daily doses of tocopherol-stripped corn oil (vehicle), environmentally relevant doses of DBP (10 and 100 µg/kg/day), or a classical high dose (1000 mg/kg/day) for 10 days. Following dosing, whole ovaries were collected and nuclear protein extracted. Transcription factor activation profiling plate arrays were used to measure the activation of 95 transcription factors in the ovary. A total of 35 transcription factors showed increased activation after DBP exposure, 20 showed decreased activation after DBP exposure, and 40 transcription factors showed differing patterns of increased and decreased activation among the different DBP doses. Our results showed a decrease in NF-E2 activation in the 10 µg/kg/day (p=0.015), 100 µg/kg/day (p=0.05), and 1000 mg/kg/day (p=0.007) groups. Additionally, HOX4C showed increased activation in both the 100 µg/kg/day (p=0.001) and 1000 mg/kg/day (p=0.03) groups. The 1000 mg/kg/day dose also induced an increase in activation for HIF (p=0.05). Lastly, exposure to 100 µg/kg/day induced significant increases in the activation of E2F-1 (p=0.031), COUP-TF (p=0.022), GFI1 (p=0.001), MZF (p=0.007), PAX3 (p=0.011), PAX8 (p=0.018), ROR (p=<0.001), and RXR (p=0.005). These results provide evidence supporting altered transcription factor activation in the ovary following oral exposure to DBP. Interestingly, several of these transcription factors are involved in cell and tissue differentiation and histone modifications. Further studies are necessary to determine the impact of these DBP-induced alterations on these processes. *Supported by NIH R01ES026998 and T32 ES007091-36A1.*

1547 An Environmentally Relevant Phthalate Mixture inhibits Ovulation by Decreasing Prostaglandin Production in Mouse Antral Follicles *In Vitro*

M. E. Lane, K. L. Land, and P. R. Hannon. *University of Kentucky, Lexington, KY.*

Phthalates are endocrine-disrupting chemicals that humans are ubiquitously exposed to as a result of their widespread use as plasticizers and solvents in personal care products, building materials, food and beverage containers, and medical supplies. Exposure to these endocrine-disrupting chemicals may impact female reproduction by disrupting the production and metabolism of ovarian prostaglandins, which are integral molecules of the inflammatory response during ovulation. Prostaglandin synthesis is stimulated by the mid-cycle luteinizing hormone (LH) surge that triggers ovulation and formation of the corpus luteum (CL) from the preovulatory antral follicle. This study investigates the hypothesis that phthalates are able to inhibit ovulation by downregulating genes involved in prostaglandin production (*Pla2g4a*, *Ptgs2*, *Ptges*) and transport (*Abcc4*, *Slco2a1*) while increasing prostaglandin metabolic enzymes (*Hpgd*). Isolated antral follicles from CD-1 mice were cultured for 96hr in supplemented media containing follicle-stimulating hormone to induce pre-ovulatory development, and were treated with vehicle control (dimethylsulfoxide, DMSO) or phthalate mixture (PHTmix; 1-500µg/ml). Media were then replaced with maturation media ± hCG (an LH analog) to induce ovulation and treated with DMSO or PHTmix for 0, 4, 11, and 18hr. Next, oocyte release was observed, media were collected for prostaglandin measurements via ELISA, and the follicle/CL was collected for gene expression analysis (n=3-9, p≤0.05). Treatment with PHTmix resulted in a dose-dependent decrease in ovulation at 18hr, with the 500µg/ml dose being statistically equal to the DMSO group that had zero ovulations. Compared to hCG controls, PHTmix decreased *Hpgd* expression and increased *Slco2a1* expression. Further, treatment with PHTmix resulted in dose-dependent decreases in expression of *Ptgs2* with corresponding reductions in the ovulatory mediator prostaglandin E2 when compared to hCG controls. These changes support the hypothesis that PHTmix inhibits ovulation by disrupting prostaglandin production, which may in turn lead to infertility and have negative effects on reproductive health. *Supported by K99/R00ES028748.*

1548 The Effects of a Phthalate Metabolite Mixture on Antral Follicle Growth and Sex Steroid Synthesis in Mice

D. D. Meling, G. R. Warner, J. R. Szumski, L. Gao, A. V. Gonsiorski, S. Rattan, and J. A. Flaws. *University of Illinois at Urbana-Champaign, Urbana, IL.*

Phthalates are used as solvents and plasticizers in a wide variety of consumer products. Most people are exposed to phthalates as parent compounds through ingestion, inhalation, and dermal contact. However, these parent compounds are quickly metabolized to more active compounds in several tissues. Although studies indicate that the phthalate metabolites reach the ovary, little is known about whether they are ovarian toxicants. Thus, this study tested the hypothesis that phthalate metabolites influence the expression of genes involved in sex steroid synthesis, cell cycle regulation, cell death, oxidative stress, and key receptors, as well as production of sex steroid hormones by mouse antral follicles. The selected metabolite mixture consisted of 36.7% monoethyl phthalate, 15.3% monobutyl phthalate, 10.2% monoisobutyl phthalate, 8.2% monobenzyl phthalate, 19.4% mono(2-ethylhexyl) phthalate, and 10.2% monoisononyl phthalate. Antral follicles from adult CD-1 mice were cultured for 96 hours with vehicle control (DMSO) or metabolite mixture (0.065-325 µg/ml). Growth of follicles in culture was monitored every 24 hours. Total RNA was isolated after 24 and 96 hours and used for gene expression analysis. Media were collected and subjected to hormone analysis. Exposure to the phthalate mixture inhibited follicle growth, decreased expression of steroidogenic enzymes, and altered the levels of sex steroids relative to control. The mixture also altered expression of cell cycle regulators, apoptotic factors, and oxidative stress genes, reduced expression of receptors such as *Esr1*, *Esr2*, *Fshr*, *Lhcgr*, and *AhR*, and increased expression of the receptor *Pparg*. Collectively, these data suggest that mixtures of phthalate metabolites can directly impact follicle health.

1549 Phthalate and Phthalate Metabolite Mixtures Alter Gene Expression in Mouse Neonatal Ovaries

G. R. Warner, J. S. Yue, and J. A. Flaws. *University of Illinois at Urbana-Champaign, Champaign, IL.*

Phthalates are a group of chemicals often used as additives in various consumer products, medical equipment, and personal care products. Although phthalates have short biological half-lives, phthalates and their metabolites are consistently detected in humans, indicating widespread and continuous phthalate exposure. Because a wide range of phthalate structures are used in consumer products, mixtures of phthalates and phthalate metabolites are present in the body. Thus, environmentally relevant mixtures of phthalates and phthalate metabolites were investigated to determine the effects of phthalates on the function of the ovary during the sensitive neonatal period of development. Neonatal ovaries from CD-1 mice were cultured with either DMSO (vehicle control) or phthalate mixture (0.1-100 µg/mL) composed of 35% diethyl phthalate (DEP), 21% di(2-ethylhexyl) phthalate (DEHP), 15% dibutyl phthalate (DBP), 15% diisononyl phthalate (DiNP), 8% diisobutyl phthalate (DiBP), and 5% benzylbutyl phthalate (BBzP). In a second experiment, neonatal ovaries were cultured with either DMSO (vehicle control) or a mixture of the major metabolites of the phthalate mixture (0.1-100 µg/mL) composed of 15% monoethyl phthalate (MEP), 8% mono-(2-ethylhexyl) phthalate (MEHP), 6% monobutyl phthalate (MBP), 4% monoisobutyl phthalate (MiBP), 4% mono-isononyl phthalate (MNP), and 3% mono-benzyl phthalate (MBzP). After 96 hours of culture, ovaries were harvested for gene expression analysis for cell-cycle regulators, apoptosis regulators, and metabolizing enzymes. Phthalate mixture exposure significantly decreased levels of anti-apoptotic factor *Bcl2l10* (1 µg/mL) and cell-cycle regulator *Ccne1* (1 µg/mL), while exposure to the metabolite mixture borderline increased expression of cell proliferation marker *Ki67* (0.1, 1 µg/mL) and pro-apoptotic factor *Casp3* (1 µg/mL). These data suggest that phthalates alter ovarian gene expression and that phthalates and their metabolites differentially impact the developing ovary. *Supported by NIH R01ES028661 and NIH T32ES007326.*

1550 Short-Term Exposure to Di(2-ethylhexyl) Phthalate and Diisononyl Phthalate Disrupts Ovarian Folliculogenesis for as Long as 18 Months following Cessation of Exposure

C. Chiang[1], L. R. Lewis[2], G. Borkowski[2], and J. A. Flaws[2]. *[1]US EPA, Durham, NC; and [2]University of Illinois at Urbana-Champaign, Urbana, IL.*

Di(2-ethylhexyl) phthalate (DEHP) is a chemical used as a plasticizer in products such as flooring tiles, car upholstery, food containers, and medical equipment. DEHP has become a ubiquitous environmental contaminant because it is used in a variety of products. Studies have shown that DEHP has endocrine disrupting capabilities and can disrupt ovarian folliculogenesis in mice. Diisononyl phthalate (DiNP) is a common DEHP replacement that is rapidly increasing in use and, subsequently, human exposure. Concerningly, some studies have shown that DiNP has negative effects similar to DEHP, but few studies have been done to assess whether DiNP has negative effects on female reproduction. Further, little is known about the consequences of exposure during adulthood to DEHP or DiNP and any persistent effects that may occur after exposure has stopped. Thus, this study tested the hypothesis that adult exposure to DEHP or DiNP negatively affects ovarian folliculogenesis during late-life in female mice. Female CD-1 mice aged 39-40 days were orally dosed with either vehicle control (corn oil), DEHP (20 µg/kg/day-200 mg/kg/day), or DiNP (20 µg/kg/day-200 mg/kg/day) for 10 days. Mice were aged with no additional phthalate exposure and ovaries were collected at 12, 15, and 18 months post-dosing for analysis of ovarian follicle populations. At 12 months post-dosing, DEHP decreased the number of primary and preantral follicles and reduced the total number of follicles in the ovary when compared to control. DiNP decreased primordial follicles and increased preantral and antral follicles when compared to control. At 15 months post-dosing, DEHP and DiNP increased preantral follicles and decreased antral follicles when compared to control. At 18 months post-dosing, DiNP increased primordial follicles and decreased antral follicles when compared to control. Taken together, these data show that short-term exposure to DEHP or DiNP during adulthood affects folliculogenesis more than a year following completion of dosing. *Supported by R56 ES 025147 (JAF), R01 ES 028661 (JAF), Billie A. Field Fellowship (CC), and T32 ES 007326 (CC).*

1551 Prenatal Exposure to Di(2-ethylhexyl) Phthalate and High-Fat Diet Synergistically Disrupts Fetal Oogenesis and Folliculogenesis in Mice

P. Karumanchi[1], S. Mirihagalle[1], T. You[2], L. Suh[1], C. Patel[1], and J. Qiao[1]. *[1]University of Illinois at Urbana-Champaign, Urbana, IL; and [2]University of Illinois at Urbana Champaign, Urbana, IL.*

Di-(2-ethylhexyl) phthalate (DEHP) is a chemical that is widely used as a plasticizer. Exposure to DEHP has been shown to alter ovarian function in humans. Additionally, foods high in fat content, regularly found in the western diet, have been shown to be another potential disruptor of fetal ovarian function. Due to DEHP's lipophilicity, high-fat foods can be easily contaminated. Therefore, exposure to DEHP and high fat diet are both health concerns, especially in pregnant women and the effects of these exposures on fetal oocyte quality and quantity should be elucidated. In this study, our goal was to determine if there are synergistic effects of DEHP exposure at an oogenesis and folliculogenesis. Dams were fed with high fat diet (45 kcal% fat) or a control diet (10 kcal % fat) one week before mating and during pregnancy and lactation. The pregnant mice were dosed with DEHP (20 µg/kg body weight/day) or vehicle control from E 10.5 to litter birth. We discovered that treatment with an environmentally relevant dosage of DEHP and consumption of high-fat diet significantly increases synapsis defects in meiosis and affects folliculogenesis in the F1 generation, indicating DEHP + high-fat consumption can exert adverse effects to several generations.

1552 Investigating Additive Impact of Obesity on Zearalenone-Induced Ovotoxicity

M. González Alvarez, B. McGuire, and A. F. Keating. *Iowa State University, Ames, IA.*

Zearalenone (ZEA) is a non-steroidal estrogenic mycotoxin produced by *Fusarium graminarium* and other *Fusarium* species. Zearalenone and ZEA metabolites bind to estrogen receptors imparting estrogenicity. Additionally, ZEA has negative reproductive female effects, including decreased fertility, changes to external genitalia, reduced litter size, pseudopregnancy, and changes in the estrous cycle. Obesity affects 40% of women and 20% of girls, with higher rates in minority populations in the United States. Obesity impedes female reproduction, causing infertility, poor oocyte quality, miscarriage, and offspring defects. We hypothesized that obesity would enhance ovarian sensitivity to ZEA-induced ovarian toxicity. Female wild type non-agouti KK.Cg-a/a mice (lean) and agouti lethal yellow KK.Cg-Ay/J mice (obese) were fed and given water *ad libitum*. At 6 weeks of age, mice received saline (CT) or ZEA (40 µg/Kg) *per os* for 15 days. Mice were weighed and food intake was quantified twice per week. Daily vaginal cytology was performed every morning to assess the estrous cycle stage. After euthanasia, tissues were collected and weighed. Progesterone and 17ß-Estradiol were measured by ELISA. The abundance of ovarian proteins involved in chemical metabolism (glutathione S-transferase Pi (GSTP1) and microsomal epoxide hydrolase 1 (EPHX1)), DNA damage sensing and repair (ataxia telangiectasia mutated (ATM) and histones H4K16 (acetylated) and H3K9 (trimethylated) and epigenetic modification (histone deacetylase (HDAC) and DNA (cytosine-5)-methyltransferase 3A (DNMT 3A)) were quantified via western blotting. There were no observable effects of ZEA in lean on any of the endpoints examined. In the obese mice, there was no impact ($P > 0.05$) of ZEA on the abundance of ovarian proteins examined, nor did ZEA affect food intake, final body weight, steroid hormone level, or organ weights outside of the reproductive tract. Exposure of obese mice to ZEA decreased ovarian weight ($P < 0.05$), increased uterine weight ($P = 0.08$), increased time spent in estrus ($P < 0.05$) but decreased time spent in the metestrus/diestrus stage of the estrous cycle ($P < 0.05$). Taken together, these data support that obesity is additive to ZEA-induced ovotoxicity and raises concern about the influence of altered physiological status on ovarian xenobiotic exposure effects. *Supported by funding from the Iowa State University Bailey Career Development Award to AFK, the Iowa State University Nutritional Sciences Council Martin Fund to AFK, and the Fulbright Foreign Student Program to EGA.*

1553 Determining Impacts of Glyphosate Exposure on Ovarian Function in Lean and Obese Mice

B. C. McGuire, M. E. Gonzalez-Alvarez, and A. F. Keating. *Iowa State University, Ames, IA.*

Obesity affects approximately 39% of the female population and is associated with increased incidence of reproductive dysfunction and ovarian cancer. Glyphosate (GLY) is a herbicide with high usage in both rural and urban

environments and recent reports have detected both GLY and a major GLY metabolite in human urine. Our previous work discovered an additive impact of obesity on ovotoxicity, thus, we tested the hypothesis that GLY exposure would alter ovarian endpoints and that hyperphagia-induced obesity would be additive to these effects. Female non-agouti KK.Cg-a/a mice (designated lean) and agouti lethal yellow KK.Cg-Ay/J mice (designated obese) were exposed to GLY (2 mg/kg daily *per os*) for 70 days (from 6 to 16 weeks of age). Food intake and body weight were monitored twice weekly, tissues and blood were collected at euthanasia and weighed. Ovarian protein was isolated for the purposes of protein quantification by western blotting. There was no effect of GLY exposure on most endpoints measured in the lean mice, however, GLY exposure reduced ($P < 0.05$) time spent in the metestrus/diestrus stage of the estrous cycle. In the obese mice, GLY exposure increased ($P < 0.05$) feed intake though final body weight was lower ($P < 0.05$). There was a tendency ($P = 0.1$) for decreased time spent in the estrus stage of the estrous cycle in the obese mice exposed to GLY, though no other cyclicity changes were observed. There was no effect of GLY in either the lean or obese mice on estradiol or progesterone levels, organ weights, or on the protein abundance of histone H3 [trimethyl Lys 9] (H3K9me3), ataxia telangiectasia mutated (ATM), or DNA (cytosine-5)-methyltransferase 1 (DNMT1), histone deacetylase 1 (HDAC). Taken together, these data support an effect of GLY exposure on estrous cyclicity in lean mice, but an effect on feed intake, body weight and estrous cyclicity in the obese mice supporting an additive impact of obesity on ovarian effects of GLY exposure. *This work was supported by R21ES026282 and R21ES026282-S1 from the NIEHS.*

1554 Imidacloprid Interferes with Ovarian Antral Follicle Growth, Gene Expression, and Steroidogenesis

V. Mourikes, L. Gao, and J. Flaws. *University of Illinois at Urbana-Champaign, Urbana, IL.*

Neonicotinoid pesticides became some of the most popular chemicals in the world following the removal of organophosphorus pesticides from the agricultural market. They are systemic neurotoxicants used to exterminate sucking insects, termites, and fleas. Imidacloprid, the most commonly used member of the neonicotinoid family, is water-soluble and breaks down slowly in the environment, resulting in large-scale environmental accumulation, and chronic exposure of non-target species including humans, birds, fish, and pollinators. Little research has been done to determine whether imidacloprid is an endocrine disrupting chemical (EDC). This study tested the hypothesis that environmentally relevant levels of imidacloprid interfere with antral follicle growth and steroidogenesis. Antral follicles were dissected from ovaries from CD-1 mice (31-41 days old). They were cultured in media treated with dimethyl sulfoxide (DMSO) or imidacloprid (0.2µg/ml, 2µg/ml, 20µg/ml, and 200µg/ml). Follicle growth was measured after 48 hours in culture, and follicles and media were collected separately. The media were used to quantify estradiol, progesterone, and testosterone production via enzyme-linked immunosorbent assays. RNA was extracted from antral follicles and used in qPCR reactions to quantify gene expression of steroidogenic genes. Imidacloprid (0.2µg/ml) inhibited follicle growth, whereas imidacloprid (200µg/ml) increased follicle growth compared to control. Despite having the greatest percent growth, the media collected from the follicles exposed to 200 µg/ml imidacloprid contained the least amount of estradiol compared to control. Imidacloprid at various concentrations altered expression of the aryl hydrocarbon receptor (*AhR*), both estrogen receptors (*Esr1* & *Esr2*), pro-apoptotic and anti-apoptotic factors, cell cycle regulators and steroidogenic enzymes. These data suggest that imidacloprid might follow a nonmonotonic dose response curve, as do many EDCs. Imidacloprid also interferes with cell proliferation, apoptosis, and steroidogenesis. Finally, imidacloprid affects ovarian antral follicles in such a way that growth and estradiol release are not changed in the same direction, and these affects might be mediated via the *Ahr*, *Esr1*, or *Esr2*.

1555 Effect of Nicotine in Diabetic Rat Ovary: A Double-Edged Sword

S. Kushwaha[1], and G. Jena[2]. *[1]Babasaheb Bhimrao Ambedkar University, Lucknow, India; and [2]National Institute of Pharmaceutical Education and Research, Chandigarh, India.*

Among the components of cigarette smoke, nicotine is known to exert ovarian damage. However, the underlying mechanisms responsible for the toxic effects of nicotine in the diabetic ovary are still to be delineated. Present study was undertaken to evaluate the effect of nicotine in diabetic rat ovary. Female Sprague Dawley rats were randomized into four groups: Group I received citrate buffer and normal saline and served as control, group II received nicotine treatment (100 µg/ml) and served as nicotine control, group III received single dose of streptozotocin (STZ) at the dose of 55 mg/kg and served as diabetic control. Group IV received STZ (55 mg/kg) and nicotine (100 µg/ml) treatment and served as Diabetic + Nicotine. The present results indicated that diabetic animals exhibited more cotinine level as compared to normal nicotine treated animals due to more water intake by diabetic rat. However, nicotine exposure in diabetic rat did not alter the blood glucose level. Results indicated that nicotine *per se* significantly reduced the ovarian weight, further the decrease was observed with Diabetic + Nicotine treated animals, but not statistically significant when compared to *per se* diabetic animals. Results showed that nicotine not only exacerbated the ovarian DNA damage, but also increased the frequency of DNA damage in diabetic ovary. Histological analysis revealed that nicotine further reduced the number of primary follicles in diabetic rat. Furthermore, TUNEL assay results showed that most of the cell death was confined to the ovarian follicles in *per se* diabetic and Diabetic + Nicotine groups. Moreover, to confirm the regulation of ovarian follicular development and steroidogenic capacity of ovarian follicles, 3β-hydroxysteroid dehydrogenase (HSD) immunostaining was performed. Results showed that nicotine treatment led to decrease in the expression of 3β-HSD in the ovary of normal as well as diabetic rat. Further, western blot analysis results showed that nicotine significantly increased the levels of caspase-3, NF-κB and COX-2 expressions in diabetic ovary. Present results showed that nicotine not only exacerbated the DNA damage, but also increased the apoptotic cell death and inflammation in diabetic rat ovary. These findings provide the evidence that nicotine leads to an increase in the inflammatory markers through different signaling pathways and worsens the ovarian reserve in diabetic milieu.

1556 Impact of Heat Stress on Ovarian Chemical Biotransformation Enzyme Abundance

J. Rishi, C. M. Roach, L. Baumgard, J. Ross, and A. F. Keating. *Iowa State University, Ames, IA.*

Heat stress (HS) induces infertility in many production animal species, including swine. During HS, blood is redistributed to the periphery, the intestine becomes "leaky", feed intake is dramatically reduced but paradoxically, animals become hyperinsulinemic. Seasonal infertility occurs due to HS and includes alterations to reproductive endpoints including anovulation and early pregnancy loss. Insulin regulates hepatic and ovarian chemical biotransformation enzymes including microsomal epoxide hydrolase (EPHX1), glutathione S-transferase pi (GSTP1) and cytochrome P450 2E1 (CYP2E1) and our previous work discovered that in another physiological state in which hyperinsulinemia features, obesity, ovarian chemical biotransformation enzymes are altered in abundance and respond differently to ovotoxicants than those of lean females. Thus, the hypothesis for this study is that HS alters abundance of the ovarian enzymes EPHX1, GSTP1 and CYP2E1. Twelve post-pubertal gilts (126.02 ± 21.6 kg) were synchronized for 14 d by orally administering Matrix® to ensure that gilts were heat-stressed during the follicular phase of the estrous cycle. Immediately after Matrix® withdrawal, gilts were split in two groups (n = 6) and were exposed to HS or thermal neutral (TN) conditions for 5 d. TN gilts experienced an average ambient temperature of 20.3°C ± 0.5°C, while the HS gilts was housed in an environment with an average ambient temperature of 31.1°C ± 1.4°C due to cyclical heating to imitate the diurnal pattern. Ovarian protein was isolated and western blotting performed to measure abundance of EPHX1, GSTP1 and CYP2E1. Relative to ovaries from TN gilts, ovarian abundance of EPHX1 was decreased ($P = 0.03$), GSTP1 was unaltered ($P > 0.05$) and CYP2E1 was increased ($P = 0.01$). We have previously noted this opposing abundance pattern between EPHX1 and CYP2E1 during ovotoxicant exposures. These data support that HS affects the capacity of the ovary to metabolize ovotoxicants, potentially contributing to observed infertility. *This work was supported by the Iowa Pork Producers Association (AFK, JWR, LHB).*

1557 Bisphenol S Enhances Gap Junction Intercellular Communication in Human Ovarian Theca Cells

J. Gingrich[1], Y. Pu[1], B. L. Upham[1], S. Pearl[2], M. Hulse[1], D. Martin[2], A. Avery[1,2], and A. Veiga-Lopez[1]. *[1]Michigan State University, East Lansing, MI; and [2]Sparrow Hospital, Lansing, MI.*

Gap junctions are intercellular channels composed of two hexameric connexon complexes, allowing the diffusion of molecules <1 kDa between cells. Gap junction intercellular communication (GJIC) occurs through phosphorylation of these connexons. Temporospatial regulation of GJIC is tightly controlled during ovarian follicular development and ovulation. Ovarian steroidogenic theca cells support the structure and vascularity of the developing follicle and need GJIC for steroid hormone trafficking. GJIC can be altered by hormone signaling and exposure to endocrine disrupting chemicals (EDCs), such as bisphenols, EDCs used in the production of polycarbonate plastics. We have previously demonstrated that bisphenol S (BPS), the second most

abundant bisphenol, enhances GJIC in ovine theca cells. Whether this effect is conserved in human theca cells remains unknown. Here, we have investigated if BPS exposure enhances GJIC in human theca cells. To test this hypothesis, ovaries of healthy women (31-48 years old, n=3) without prior history of cancer or hyperandrogenism were collected (IRB: 17-1066M), and theca cells from antral follicles isolated and purified. Cell viability, cytotoxicity, and purity were assessed by trypan blue, MTT assay, and fibulin-5 immunostain, respectively. Cells were grown to ~80% confluency and exposed to control conditions (0.1% DMSO), BPS (200 ng/ml), or a combination of BPS and a panMAPK inhibitor (SB202190) for 24 h. GJIC was assessed using a scrape loading/dye transfer assay. Following BPS exposure in pre-luteinized human theca cells, GJIC was enhanced by >40% compared to the control group. Additionally, we demonstrate that this effect can be blocked by a MAPK inhibitor. This is the first report of BPS-induced GJIC modulation in human ovarian theca cells. Upregulation of GJIC could result in hyperplasia of the theca cell layer, a pathology seen in polycystic ovarian syndrome and hyperandrogenism, or lead to premature ovulation via disrupted steroid signaling. Further studies are necessary to understand 1) if BPS-induced GJIC upregulation is restricted to theca cells and 2) if the BPS-induced GJIC effect seen in theca cells results in altered follicular development and/or poor fertility outcomes. *JG was supported by NICHD T32HD087166. 1558 Vitrification Enables a Long-Term-Storage and Ready-to-Use Murine Ovarian Follicle Bank for High-Throughput Ovotoxicity Screening

S. Xiao[1], Y. Wang[1], M. Xu[1], J. Xu[1], J. Stanley[2], G. Scott[1], S. Chatterjee[1], and M. B. Zelinski[2]. *[1]University of South Carolina, Columbia, SC; and [2]Oregon Health and Science University, Beaverton, OR.*

The ovary is the primary female reproductive organ and contains various developmental stages of follicles as the functional unit. The primary functions of follicles are to secrete hormones and to mature germ cell-oocytes for maturation, ovulation, and fertilization. Increasing evidence reveals that a broad spectrum of environmental chemicals and pharmaceutical compounds cause ovarian toxicity (ovotoxicity) and increase women's risks of premature ovarian failure, hormonal imbalance, and infertility. Unfortunately, the lack of optimal *in vitro* models makes the current gold standard for testing the ovotoxicity of chemicals rely on whole laboratory animals. However, *in vivo* models are time consuming, costly, and harmful to animals. In this study, we aimed to use vitrification method to cryopreserve and bank individual mouse ovarian follicles and further integrate our 3D encapsulated *in vitro* follicle growth (eIVFG) model to develop a high-throughput ovotoxicity screening platform. Preantral follicles were isolated from 16-day old CD-1 female mice for vitrification. The vitrified follicles were then warmed and recovered for eIVFG. Results indicated that follicles after vitrification had comparable follicle and oocyte reproductive outcomes with freshly harvested follicles, including follicle survival, follicle development from preantral to antral stage, ovarian steroidogenesis, and oocyte maturation and ovulation. We further used vitrified follicles to screen for the ovotoxicity of doxorubicin (DOX, positive control) and 6 analogs of microcystins (MCs), an emerging category of environmental contaminants from harmful algal blooms (HABs). Our results demonstrated that DOX showed consistent dose-dependent ovotoxicities on vitrified follicles as we previously discovered on freshly harvested follicles, and MCs exhibited endocrine disrupting effects on the ovary. In summary, our study demonstrate that vitrification and eVIFG allow us to establish a long-term-storage and ready-to-use ovarian follicle bank and a high-throughput female reproductive toxicity screening.

1559 Parabens and Phthalates Inhibit the Proliferation of Murine Oviductal Epithelial (MOE) Cells *In Vitro*

M. Dean, and A. Ziv-Gal. *University of Illinois at Urbana-Champaign, Urbana, IL.*

The mammalian oviduct is a central organ for female reproduction as it is the site of fertilization and actively transports the embryo to the uterus. Recent studies, suggest that phthalates and parabens, prevalently found in daily-used products, can impact female reproductive health. Yet, their effects on the oviduct are unknown. Here, we hypothesized that *in vitro* paraben and phthalate exposure of spontaneously immortalized murine oviductal secretory epithelial (MOE) cells would inhibit cell proliferation. To test this hypothesis, MOE cells (400 cells/well) were cultured for 7 days in media containing a wide range of concentrations (0.001-100 µg/mL) of propylparaben, methylparaben, propylparaben + methylparaben, di-2-ethylhexyl phthalate (DEHP), diethyl phthalate (DEP), or DEHP + DEP, or dimethylsulfoxide (DMSO) as vehicle control. Cell proliferation was examined by the sulforhodamine B colorimetric assay, and the optical densitometry readings were used to determine the percent of observed cytotoxicity relative to control. Additionally, we performed a colony formation assay by culturing MOE cells (500 cells/100 mm dish) for 7 days in media containing either DMSO, methylparaben 100 µg/mL, or propylparaben 10 and 100 µg/mL, followed by 4.5 days of culture with only media. Then, the number of colonies was determined with ImageJ. Differences between treatments and DMSO were analyzed by ANOVA and Dunnett post-hoc test (n = 3-5). The results indicate that cell proliferation was reduced compared to DMSO (set as 100%). Specifically, statistically significantly reduction in proliferation ($p \leq 0.05$) were observed at propylparaben 10, 25, 50, and 100 µg/mL (% proliferation ± SD; 33% ± 22, 8% ± 2, 5% ± 3, and 6% ± 4, respectively), methylparaben 25, 50, and 100 µg/mL (70% ± 19, 29% ± 12, and 12% ± 6), propylparaben + methylparaben 5, 12.5, 25, and 50 µg/mL (48% ± 18, 17% ± 9, 6% ± 2, and 3% ± 1), DEHP 10 µg/mL (79% ± 6), DEP 100 µg/mL (74% ± 8), and DEHP + DEP 5, and 50 µg/mL (74% ± 6, and 71% ± 6). Colony formation assays showed statistically significantly decreases in colony numbers ($p \leq 0.05$) between DMSO (mean ± SD; 309 ± 44), methylparaben (223 ± 13), and propylparaben 100 µg/mL (0.3 ± 0.6); whereas propylparaben 10 µg/mL (251 ± 53) was not different from DMSO. Overall, these findings suggest that parabens and phthalates can selectively affect mouse oviductal secretory epithelial cells proliferation and survival, under the examined conditions.

1560 Effect of Bisphenol A on Oxidative Stress, Proliferation, and Differentiation of Human Placental Trophoblast Cells

T. Hamad, B. Bediako, A. Ishaque, and A. Elnabawi. *University of Maryland Eastern Shore, Princess Anne, MD.*

Bisphenol A (BPA) is ubiquitous endocrine disruptive chemical suspected to cause adverse effects on human health. BPA has been detected in amniotic fluid, cord blood, placental tissue, and fetal plasma. The presence of BPA in maternal reproductive tissues and fluids is concerning because it suggests that exposure to BPA can occur at all developmental stages and it has potential to affect the reproductive processes in males and females as well as fetal development. Oxidative stress plays a central role in the pathophysiology of miscarriage, pre-eclampsia and fetal growth restriction. Hormones, such as 17β-estradiol (E2), play key roles in the implanting blastocyst and in the process of placentation. In addition, the beta subunit of human chorionic gonadotropin (β-hCG) is secreted by the trophoblast and syncytiotrophoblast and plays a key role in implantation and in the maintenance of pregnancy. Differentiation of cytotrophoblasts (CTBs) into the syncytiotrophoblasts (STBs) is a process required for the development of a functional placenta. This study was aimed to examine the effect of BPA on forskolin-induced cell differentiation and fusion, reactive oxygen species (ROS) production and the release of β-hCG in the human placental trophoblast (BeWo) cells. To induce BeWo cell differentiation, cells were treated with various concentrations of forskolin (FK). Cells were treated with BPA or E2 at various concentrations alone or in combination. Cell proliferation, viability, cell death, ROS production and level of β-hCG were assessed. BPA significantly reduced cell viability in a concentration-dependent manner after 24h of exposure. Low concentrations of BPA significantly potentiates E2-induced cell proliferation. The estrogen antagonist, ICI 182,780, blocked this effect. Treatment of BeWo cells with E2 significantly increased β-hCG. A significant decrease in β-hCG secretion was observed at 0.01nM-10nM BPA. The decreased β-hCG release indicates loss of cell function. Exposure to BPA increased the production of ROS in BeWo cells. Our data suggest that BPA-mediated ROS production can cause oxidative damage and cell death, and any unbalance in β-hCG secretion and steroid hormones action could have serious consequences for pregnancy and fetal development. *Supported by Title III.*

1561 Exploring the Use of Placental Tissue Explants and Trophoblast Cell Lines to Study Toxicity of Anticancer Drugs

G. Eliesen, H. van Hove, M. H. Meijer, P. van den Broek, F. G. Russel, and R. Greupink. *Radboudumc, Nijmegen, Netherlands.*

Studying interference with placental function is a useful approach to investigate the safety of drugs during pregnancy, as the placenta is essential in maintaining a healthy pregnancy. Here, we studied the application of placental tissue explants and trophoblast cell lines with respect to assessing the toxic potential of various anticancer drugs. Third trimester placental villous tissue explants (~ 5mg) were cultured for 7 days and exposed for 72h (day 4-7) to a concentration range of doxorubicin, paclitaxel, crizotinib, imatinib or sunitinib. Cell lines representing extravillous trophoblasts (JEG-3), villous trophoblasts (BeWo), and syncytiotrophoblasts (BeWo cells induced with forskolin to syncytialise) were exposed for 48h to the same drugs. Tissue and

cell viability were assessed via a MTT assay and progesterone levels in culture medium were quantified via LCMS/MS. Data are presented as mean ± SEM. We found that placental explants remained viable for 7 days, and all cell lines for 48h. In placental explants, progesterone release ranged from 0.01 to 3.3 ng·mg^{-1} wet weight ·24h^{-1} under control conditions. In syncytialised BeWo cells, progesterone production was on average 174 ± 11 ng·mg^{-1} protein ·48h^{-1} under control conditions and 2.12 ± 0.12 fold higher than in BeWo cells. Paclitaxel did not affect explant viability, whereas it reduced cell viability to 50% or less in all cell lines at 3 - 10 nM. Furthermore, it was consistently less cytotoxic in syncytialised BeWo cells compared to BeWo and JEG-3 cells. Doxorubicin (1 µM) reduced viability in explants to 83 ± 7%, whereas it fully inhibited viability in all cell types. For crizotinib, sunitinib and imatinib differences between cells and explants were less profound. Interference with progesterone release in explants could not be studied due to a large variability in measurements, but syncytialised BeWo cells proved suitable for this purpose. We found that 1 µM sunitinib significantly reduced progesterone release to 76 ± 6%, without affecting cell viability. For the other compounds no major effects on endocrine function were seen. In conclusion, placental explants are a suitable model for testing effects of drugs on tissue viability. The additional use of cell models may provide information on the type of trophoblast that is most prone to cytotoxicity. Furthermore, syncytialised BeWo cells proved suitable for studying interference with steroidogenesis.

PS 1562 17-Alpha Hydroxyprogesterone Caproate (17p) Alters the Nitric Oxide Signaling Pathway in an *In Vitro* Placental Cell Culture System

A. M. Keshava[1], J. Szilagyi[1], T. Manuck[2], and R. C. Fry[1]. *[1]UNC Gillings School of Global Public Health, Chapel Hill, NC; and [2]University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, NC.*

Preterm birth (PTB) impacts 1 in 10 pregnancies annually in the United States. A current therapy for recurrent spontaneous PTB prevention is 17-alpha hydroxyprogesterone caproate (17P), a synthetic progestogen. While the precise mechanism of action is not well established, the therapeutic effects of 17P may be driven by an inhibition of nitric oxide (NO) signaling. To understand the mechanism of 17P, gene and protein expression experiments were conducted. Initially, a cytotoxicity assay was performed to determine the appropriate doses of 17P. JEG-3 trophoblasts were treated with 17P for 24h at doses ranging from 0.1 to 100ug/mL. RT-PCR was conducted to detect changes in mRNA expression of seven inflammation-related genes such as endothelial Nitric Oxide Synthase (*eNOS*), Vascular Endothelial Growth Factor (*VEGF*), interleukin-8 (*IL8*), Chemokine Ligand 2 (*CCL2*), matrix metalloprotein-1 (*MMP1*), and other target genes of the NO signaling pathway. In addition, protein expression was assessed using Western Blot. Cytotoxicity was observed at or above doses 30ug/mL. Based on these results, doses of 0.3-10ug/mL were selected for gene and protein expression studies. Cells treated with 17P showed a significant dose-dependent increase in *VEGF* and *eNOS*. A slight increase in IL6 and MMP1 gene expression and dose-dependent decreases in IL4 and CCL2 gene expression were noted after exposure to 17P. Dose-dependent decreases were observed in IL4 and *CCL2*. Under the same treatment conditions, JEG-3 cells were also assessed for intra- and extra-cellular NO content using a modified Griess reagent assay. These data provide evidence of a NO-dependent mechanism of action of 17P.

PS 1563 Development of Fibrosis in Endometriotic Cells Is NR4A1 Dependent and Can Be Inhibited by NR4A1 Antagonists

K. Mohankumar[1], S. Han[2], and S. Safe[1]. *[1]Texas A&M University, College Station, TX; and [2]Baylor College of Medicine, Houston, TX.*

Endometriosis is an inflammatory and highly painful disease that is treated by hormonal therapies and this can be problematic for women of reproductive age. Thus there is urgent need for development of alternative therapies. We recently reported that NR4A1 promoted growth and activated mTOR signaling in Ishikawa endometrial cancer cells (a model for epithelial-derived endometriosis) (1) and found similar results in stromal-derived endometriotic cells from patients. Some of the currently used therapies are toxic, whereas the NR4A1 ligands (C-DIMs) are relatively non-toxic. In this study, we showed that knockdown of NR4A1 by RNA interference in epithelial or stromal-derived endometriotic cells thus inhibited fibrosis and this was accompanied by decrease α-smooth muscle actin (α-SMA) and related fibrotic genes including collagen Type I alpha1 (COL1A1), connective tissue growth factor (CTGF) and Fibronectin (FN). These results demonstrate the pro-fibrotic activity of NR4A1 in endometriosis and this was in contrast to a report from another laboratory which suggested the NR4A1 repressed fibrosis. We also treated endometriotic cells with two different bis-indole derived compounds which act as NR4A1 antagonists, namely, 1,1-bis (3′-indolyl)-1-(p-hydroxyphenyl)methane (CDIM8, DIM-C-pPhOH) and a second generation buttressed analog of CDIM8, 1,1-bis (3′-indolyl)-1-(3-chloro-4-hydroxy -5-methoxy)methane (DIM-C-pPhOH-3-Cl-5-OCH_3) which act as NR4A1 antagonists. Treatment of endometriotic cells with DIM-C-pPhOH or DIM-C-pPhOH-3-Cl-5-OCH_3 gave results comparable to those observed after NR4A1 knockdown, namely there was a decrease in expression of α-SMA, COL1A1, CTGF and FN. Moreover, the buttressed DIM-C-pPhOH-3-Cl-5-OCH_3 analog was more potent than the parent compound. In summary, our results confirm that NR4A1 represents a druggable target for treating endometriosis with bis-indole derived NR4A1 antagonists. *References: 1. K Mohankumar, X Li, S Sridharan, K Karki, S Safe. Nuclear receptor 4A1 (NR4A1) antagonists induce ROS-dependent inhibition of mTOR signaling in endometrial cancer. Gynecol Oncol. 2019; 154(1):218-227.*

PS 1564 Maternal Health and Placental Outcomes after Pulmonary Nanoplastic Exposure

J. N. D'Errico, and P. A. Stapleton. *Rutgers University, New Brunswick, NJ.*

Accumulating plastic waste in the environment has recently led to increasing concerns pertaining to human health. Microplastic concentrations have been measured in the environment, bottled water, food, and human feces. Studies have also demonstrated the ability of plastic to fragment into smaller particles, producing nanoplastics. Though methods of nanoplastic detection and quantification are still in development, the breakdown of micro- to nano-sized particles has been identified. Our lab has shown nanoparticles produced from metallic bulk material can cause adverse pregnancy outcomes after maternal inhalation, including fetal growth restriction. However, maternal-fetal outcomes and placental toxicity after nanoplastic exposure remain unexplored. Here we sought to begin the evaluation of gestational health after pulmonary nanopolystyrene exposure. Sprague-Dawley rats were administered 300 µL of either 20 nm rhodamine-labeled polystyrene (PS) beads (8.8 x 10^{14} particles/mL) or saline on gestational day 19. Animals were sacrificed 24 hours later and tissues were collected for assessment. Dams who were administered PS had significantly more circulating 17β- estradiol (1104.5 ± 68.1 pg/mL vs 972.0 ± 18.4 pg/mL) and hCGβ (53.4 ± 12.0 pg/mL vs. 6.3 ± 7.5 pg/mL) compared to saline controls. Placental weights in the exposed group were also significantly increased (0.522 ± 0.06 g vs 0.472 ± 0.08 g), with no compensatory increase in fetal weight (2.6 ± 0.7 vs 2.6 ± 0.1). Therefore assessment of placental efficiency, identified as the ratio of placental to fetal mass, was decreased (4.8 ± 0.53 vs 5.5 ± 0.74) in the exposed group. Overall, these studies demonstrate a disruption to maternal endocrine homeostasis during late-stage pregnancy after PS pulmonary exposure. Further, placental mass is elevated within 24 hours of a single maternal pulmonary exposure, which may be due to PS translocation and/or placental inflammation. Increases in hCG production and placental weight without increase in fetal weight indicate placental adaptation to nanoplastic exposure, but with negative effect on placental efficiency. If sustained, these findings suggest maternal compensation to maintain fetal growth and development after PS exposure. *Supported by: NIH-R00-ES024783 (PAS); T32-ES007148 (JND); P30-ES005022.*

PS 1565 Cigarette Smoke Condensate Exposure Activates Aryl Hydrocarbon Receptor Signaling in Human Trophoblast Stem Cells and Alters Markers of Growth and Differentiation

A. Alsousi[1], R. Biswell[1], J. Johnston[1], E. Grundberg[1], M. J. Soares[2], and C. A. Vyhlidal[1]. *[1]Children's Mercy Kansas City, Kansas City, MO; and [2]University of Kansas Medical Center, Kansas City, KS.*

Although the association of cigarette smoke with increased risk of poor birth outcomes such as low birth weight and neonatal mortality is well-established, we do not understand the exact mechanism of these outcomes. Cigarette smoke contains thousands of chemicals known or suspected to cause disease. The placenta is an essential organ for fetal development. Hemochorial placentation is characterized by the differentiation of trophoblast cells specialized to interact with uterine and fetal vascular beds. Human trophoblast stem (TS) cells provide an *in vitro* model for testing the effects of environmental toxins such as cigarette smoke condensate (CSC) on differentiation and function. In this study, we utilized RNA-Seq analysis to examine changes in gene expression in human TS cells following exposure to CSC. About 900 transcripts were significantly (padj < 0.05) altered. *CYP1A1* and *CYP1B1* were among the top induced transcripts. The top affected associated network includes genes mapping to cellular assembly and organization, DNA replication, repair, and cellular development. Transcripts that were significantly downregulated by CSC include *TAGLN*, a marker of smooth muscle differentiation; *ACTA1* which plays a role in cell motility, structure and integrity; *HAND1*, a key transcription factor for trophoblast cell differentiation; and *ASCL2* which is crucial for the

differentiation of progenitor cell populations into specialized trophoblast cell types. Significant increases were observed for transcripts such as *AMER2*, a negative regulator of canonical Wnt signaling; *ID2*, which antagonizes the activities of basic helix-loop-helix transcription factors; and *GCM1*, involved in the control of placenta-specific gene expression. These data suggest that gene expression in human TS cells is significantly altered by cigarette smoke exposure including via the AhR pathway and genes encoding proteins implicated in the regulation of trophoblast cell differentiation and function. These alterations may impair proper development and function of the placenta and pregnancy outcomes. Ongoing studies are assessing the specific role of AhR signaling in trophoblast differentiation and function. *Supported by the Cross Family Foundation CPGM Pilot Award and NIH R01ES029280.*

1566 Regulation of Mouse Uterine Aquaporin Expression in the Preimplantation Period and the Impact of Ovarian Superovulation

J. Schaefer[1], V. de Oliveira[1], B. Abu-Rafea[2], G. A. Vilos[2], A. G. Vilos[2], M. Battacharya[1], S. Radovick[1], and A. Babwah[1]. *[1]Rutgers, The State University of New Jersey, New Brunswick, NJ; and [2]University of Western Ontario, London, ON, Canada.*

Uterine fluid level in early pregnancy is a critical determinant of fertility and aquaporins (AQPs), selective bidirectional transporters that move water along a concentration gradient, are major regulators of water homeostasis. The expression of mouse uterine AQP genes and proteins in early pregnancy has been studied but these studies yielded inconsistent results. To better understand their roles in regulating luminal fluid levels in the preimplantation period, we conducted a multi-pronged analysis of uterine *Aqp*/AQP expression on the morning of D1 and D4 of pregnancy in ovarian superovulated and non-superovulated WT C57 Bl/6 mice. Expression was also determined in ovariectomized mice that received E2, P4 or E2 + P4 and in D4 pregnant RU486-treated mice. Our analyses revealed that in the non-superovulated females, *Aqp3*, *Aqp4*, *Aqp5* and *Aqp8* exhibit greater expression on D1 and are induced by E2 while *Aqp1* and *Aqp11* exhibit greater expression on D4 and are induced by P4. Interestingly, *Aqp9* is constitutively expressed. We also observed that P4 inhibits the E2-induced expression of *Aqp3* and *Aqp4* (with the negative effect on *Aqp3* being transient) while *Aqp1* and *Aqp11* are negatively regulated by E2. Superovulation increased *Aqp1*, *Aqp3*, *Aqp5* and *Aqp8* expression on D4 and triggered dramatic spatial changes in AQP expression in both D1 and D4 uteri. These aberrant changes in expression following superovulation likely reduce implantation success and might be managed by targeting E2 or P4 levels and actions in the uterus during *in vitro* fertilization and embryo transfer (IVF/ET).

1567 Glyphosate's Role in the Male Fertility Epidemic and Its Effect on Spermatogenesis

E. R. Lawson[1,2], K. M. Symosko[1,2], K. W. Greeson[1,2], C. M. Cary[1], and C. A. Easley IV[1,2]. *[1]University of Georgia, Athens, GA; and [2]Regenerative Bioscience Center, Athens, GA.*

Since being introduced in 1974, 1.8 million tons of Glyphosate have been sprayed on crops in the US, thus representing the #1 herbicide used in the United States. Recently, studies have shown that glyphosate is capable of acting as an endocrine disruptor and thus may impact male fertility. In the last 40 years, semen parameters in Western men have declined by as much as 50%. Exposure to ubiquitous environmental toxicants could explain this sharp decline in semen parameters. To investigate whether glyphosate directly impacts the male germline, we utilized our novel *in vitro* spermatogenesis model to determine if glyphosate affects differentiation, proliferation, and viability of spermatogenic cells. This study shows that at residential and occupational use levels, glyphosate exposure increased the percentage of apoptosis in male germline cells. We hypothesize that glyphosate may induce cell death in *in vitro* spermatogenic cells through receptor mediated apoptosis pathways such as TRAIL, TNFa, FasL, NADD, and FADD.

1568 Establishment of a Historical Database for Normal Cynomolgus Macaque Spermatozoa Evaluation in Male Reproductive Toxicology Studies

A. Celori, L. Baydak, P. Ampo, S. Kaur, J. Hynek, S. McGrath, N. Reed, L. Lawrence, and E. Leung. *Altasciences, Everett, WA.* Sponsor: T. Rogers

ICH guidance S5(R2) recommends the assessment of sperm count, motility, and morphology to help confirm or characterize effects of pharmaceuticals on male reproduction, with the cynomolgus macaque commonly used as a test system. However, S5(R2) highlights that non-human primates lack historical background data and may differ kinetically from humans and that animal numbers used are too low for detection of risk. Additionally, studies using cynomolgus macaques are typically analyzed via the WHO Laboratory Manual for the Examination and Processing of Human Semen (currently Fifth Ed., 2010), as few publications exist specifically describing the normal cynomolgus macaque sperm. To assist and improve the assessment of cynomolgus macaque sperm for toxicology studies, historical sperm counts/concentration, motility, and morphology assessments were collated from over 400 non-human primates between 2007 and 2019. All animals were either facility stock or had been dosed with a control/sham article. Sperm was collected via direct penile electrostimulation, with ejaculate volume recorded and motility and sperm count assessed using the TOX IVOS or TOX IVOS II computerized assisted sperm analysis (CASA) systems. Morphology was evaluated using light microscopy. Potential differences due to age and origin were also evaluated.

1569 Estrogen-Related Receptor Is Critical Player in Di-butyl Phthalate-Mediated Male Reproductive Toxicity

S. Gupta[1,2], and R. Kristipati[1,2]. *[1]CSIR-Indian Institute of Toxicology Research, Lucknow, India; and [2]AcSIR, Ghaziabad, India.* Sponsor: H. Gupta

Growing incidences of male infertility in the past few years in part due to exposure to environmental chemicals is a global concern. These xenobiotics disrupt endocrine function and/or cause oxidative stress adversely affecting male fertility. However, knowledge of the molecular mechanisms and the associated candidates underlying chemical mediated male sub-fertility is limited. Di-butyl phthalate (DBP), commonly used as plasticizer in food and water containers, is known to affect male fertility. Therefore, an attempt was made to identify the mechanisms/candidates underlying DBP mediated reduction in male fertility using *Drosophila melanogaster*, an already established model for male reproductive toxicity studies. We observed that DBP exposed males had reduced fertility like in mammals. These males had mislocalized as well as reduced mitochondria with altered membrane potential in testes. Further, ultrastructural analysis involving the apical region of testes in DBP exposed males revealed round swollen mitochondria with deformed cristae. Also, transcripts/proteins associated with mitochondrial biogenesis (cdk4, NRF1, NRF2, cyclin D), mitochondrial dynamics (drp1, mitofusin) as well as mitophagy (dpink and parkin) were misregulated in testes/sperm from DBP exposed males. Besides, ATP-5α Synthase (marker of ATP synthesis) levels were significantly reduced in testes/sperm suggesting functional alterations also in mitochondria from DBP exposed males. Mutational/genetic analyses revealed that these phenotypes parallel those observed in the *Drosophila* testes lacking Estrogen-Related Receptor (dERR), a steroid hormone receptor known to act in carbohydrate metabolism and mitochondrial homeostasis. Interestingly, the transcript and activity levels of dERR were altered by DBP exposure Consistent with this, DBP exposed males had metabolic hallmarks typical of ERR knockdown and testes specific depletion of dERR attenuated DBP mediated reduction in male fertility. Therefore, estrogen related receptor is critical for DBP mediated male reproductive toxicity. To conclude, DBP mediated modulation of ERR might generate non-functional defective mitochondria thereby affecting the testicular/sperm energetics leading to reduced male fertility.

1570 Evidence of Oxidative Damage and Reproductive Dysfunction Accompanying Di-n-butyl Phthalate Exposure in Male Wistar Rats

J. O. Olugbodi[1], R. Bello[1], D. David[2], and G. Adebayo-Gege[1]. [1]*Bingham University, Karu, Nigeria; and* [2]*University of the Western Cape, Bellview, South Africa.*

Di-n-butyl phthalate (DnBP) is a widely reported chemical used in manufacturing household products, rocket fuel and paints, has been noted to pose lot of danger to the body due to its toxicity, causing a great health challenge and concern. This study aimed at providing evidence regarding the DBP-induced reproductive dysfunction in male Wistar rats. Twenty-eight Male Wistar was randomly divided into four groups (n=7). The rats were orally administered with vehicle, DBP (100, 250 and 500 mg/kg) for twenty-eight days. Thereafter, sperm kinematics, sperm motility, selected biomarkers of oxidative damage, endocrine disruption, inflammation, and DNA damage was evaluated. DnBP-treated rats showed decrease in the body weight gain, testis and epididymis weights. The cauda epididymal sperm total motility, progressive motility and epididymal sperm concentration, curvilinear velocity, straight line velocity, average path velocity, linearity, straightness, beat/cross-frequency were significantly decreased ($p<0.05$) in all treated groups. Increased levels of sperm abnormality, non-progressive motility, wobble and immotility was observed in all treated groups. DnBP increased testicular and epididymal malondialdehyde (MDA) level and hydrogen peroxide generation, but significantly decreases ($p<0.05$) Catalase (CAT), Superoxide dismutase (SOD), Glutathione (GSH), Glutathione peroxidase (GPx) and Glutathione S-transferase (GST) activities in the testes and epididymis. Also, DnBP induced hormonal imbalance, markedly increase expressions of testicular cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (iNOS), and 8-hydroxy2-deoxyguanosine (8-OHdG). Histological study revealed moderate congestion of interstitial vessels, oedema in the testes, fibrotic connective tissues and lack spermatozoa storage in the epididymis of DnBP treated rats. Overall, DnBP induced reproductive dysfunctions as well as inflammation and DNA damage in male rats.

1571 Phthalate-Induced Testicular Injury Results in an Increase of Peritubular Macrophages and Consequent Increase in Differentiating Spermatogonia

R. Tiwary, and J. Richburg. *University of Texas at Austin, Austin, TX.*

Peripubertal exposure to the phthalate metabolite mono-(2-ethylhexyl) phthalate (MEHP) in rodents causes testicular inflammation, spermatocyte apoptosis, and disruption of the blood-testis barrier. The MEHP-induced inflammation response includes an infiltration of macrophages and neutrophils to the testes, although the cause and purpose of this response is unknown. Recently, a population of testicular macrophages phenotypically distinct from those which are resident in the interstitium was described in mice. Testicular peritubular macrophages aggregate near the spermatogonial stem cell niche and are believed to stimulate their differentiation. We hypothesize that if testicular peritubular macrophages do indeed stimulate spermatogonial differentiation, MEHP exposure would result in an increase of peritubular macrophages to stimulate the replacement of lost spermatocytes. Male rats were exposed to 700 mg/kg MEHP or corn oil (vehicle control) via oral gavage at PND 28 and euthanized at 48 hours, 1 week, or 2 weeks later. Tubules were stained with immunofluorescent markers for macrophages and undifferentiated spermatogonia. Peritubular macrophages were observed in rat testis similar to those previously described in mice: MHC-II+ cells on the surface of seminiferous tubules with heterogeneous morphology. Quantification of MHC-II+ cells revealed that, unlike in the mouse, their numbers did not increase through puberty. MEHP increased macrophage presence by six-fold 48-hours after exposure and remained elevated by two-fold two weeks after exposure. An increase of differentiating spermatogonia occurred two weeks after MEHP exposure. Taken together, our results suggest that peritubular macrophages play a crucial role in the testis response to acute injury and the subsequent recovery of spermatogenesis.

1572 Dipentyl Phthalate Induces Multinucleated Germ Cells and Reduces Testosterone in the Rat Fetal Testis with a Similar Dose-Response

D. J. Spade[1], J. M. Conley[2], C. Lambright[2], S. Bell[1], A. Zsom[1], and L. E. Gray[2]. [1]*Brown University, Providence, RI; and* [2]*US EPA, Research Triangle Park, NC.*

Phthalic acid esters (phthalates) are male reproductive toxicants that exert their most potent toxicity during a window of sensitivity in fetal development. In the fetal rat, exposure to phthalates reduces testosterone biosynthesis, alters the development of seminiferous cords, and induces the formation of abnormal multinucleated germ cells (MNGs). While human and mouse fetal testes may be less sensitive to the anti-androgenic effects of phthalates than the rat, our previous work demonstrated that phthalates with medium-length side chains cause both induction of MNGs and reduction of testosterone in the rat fetal testis. In this experiment, we sought to compare the relative sensitivity of testosterone reduction and MNG induction as markers of phthalate toxicity, using dipentyl phthalate (DPeP), a known toxic phthalate, and mono-(2-ethylhexyl) tetrabromophthalate (TBPH), a suspected toxic phthalate. We also sought to develop an improved image analysis method for identification of MNGs in histological sections using a neural network approach. Timed pregnant Sprague Dawley rats were exposed to 1-100 mg/kg/d DPeP, 62.5-500 mg/kg/d TBPH, or corn oil vehicle, by daily oral gavage from gestation day (GD) 16-20. Fetal testes were isolated on GD 20 for analysis of testosterone production and quantification of MNGs in histological sections. We found that DPeP induced MNGs and decreased testosterone production with similar dose response. TBPH, conversely, did not exert any toxic effect at any dose up to 500 mg/kg/d. For image analysis, we trained a convolutional neural network with a U-Net architecture using hand-labeled images with human-identified MNGs, to identify MNGs on unlabeled images. With hand-labeled images not used in model training, we assessed the performance of the model, finding it comparable to a human. We conclude that induction of MNGs is a dose-dependent marker of DPeP exposure, with sensitivity similar to testosterone production, which may be generalizable to other phthalates. The use of automated image analysis will allow data on this histopathological endpoint to be more readily collected for analysis of phthalate toxicity. *Abstract does not necessarily reflect US EPA policy.*

1573 Mono-(2-ethylhexyl) Phthalate Enhances All-Trans Retinoic Acid Toxicity in *Ex Vivo* Cultured Fetal Mouse Testis

M. A. Alhasnani, S. Loeb, Z. Caruolo, R. Ephrem, S. J. Hall, and D. J. Spade. *Brown University, Providence, RI.*

Phthalates are a class of chemicals that cause developmental and reproductive toxicity. Phthalates are used primarily as plasticizers in polyvinyl chloride plastics and are found in medical devices, industrial, and commercial products. Human exposure to phthalates is pervasive because they are not covalently bound to plastic polymers. Despite their known adverse effects on male reproductive development, there are significant gaps in the current understanding of the mechanisms of phthalate toxicity. Retinoic acid signaling is involved in both spermatogenesis and fetal gonad development. There is evidence that phthalates disrupt retinoic acid signaling, which could contribute to phthalate toxicity. However, the contribution of this interaction to phthalate toxicity is unclear. In this study, we hypothesized that mono-(2-ethylhexyl) phthalate (MEHP) would enhance the toxicity of all-trans retinoic acid (ATRA) during mouse fetal testis development. To test this hypothesis, gestation day 14 C57BL/6 mouse testes were isolated and cultured on media containing MEHP (10^{-4}, 10^{-5}, or 10^{-6} M), ATRA (10^{-6}, 10^{-7}, or 10^{-8} M), a co-exposure consisting of 10^{-6} M ATRA with the full concentration range of MEHP, or vehicle control (1:4000 DMSO). After 3-day culture, tissues were fixed for histological analysis including quantification of germ cells and seminiferous cords per testis section. Immunofluorescence was performed to assess the number of germ cells, labeled with GCNA, induction of meiosis, indicated by STRA8, SOX9-positive Sertoli cell number, and abnormal FOXL2-positive somatic cells. Exposure to ATRA disrupted seminiferous cord morphogenesis, stimulated the expression of the ovarian protein, FOXL2, and enhanced germ cell meiotic entry. However, the number of SOX9-positive cells was not altered in a dose-dependent fashion. Germ cell count was slightly reduced in the ATRA and co-exposure treatments, but this was not significant. Co-exposure to MEHP and ATRA increased the number of FOXL2-positive cells and reduced seminiferous cord number, relative to ATRA alone. However, the co-exposure did not modify the impact of ATRA on STRA8 expression. We conclude that MEHP enhances some adverse effects of ATRA in the fetal mouse testis, suggesting an interaction between MEHP and the retinoic acid signaling pathway.

1574 Flusilazole Affects Retinoic Acid Signaling in Fetal Rodent Testes

M. K. Draskau[1], C. M. Spiller[2], J. Boberg[1], J. Bowles[2], and T. Svingen[1].
[1]Danmarks Tekniske Universitet, Kgs. Lyngby, Denmark; and [2]University of Queensland School of Biomedical Sciences, Brisbane, Australia.

Azoles are widely used anti-fungal agents used for both medicine and crop protection. In fungi they typically work by damaging the cell membrane by inhibition of cytochrome P450 enzymes, primarily CYP51. However, azoles can have endocrine disrupting effects in mammals and fetal exposure to certain azoles can disrupt reproductive development. We recently showed that the agricultural fungicide flusilazole has potent anti-androgenic effects *in vitro*, but less so *in vivo*. Rats exposed *in utero* did not display classic anti-androgenic effects such as shorter anogenital distance. However, the sex hormone profile was disrupted in male fetuses, with higher androstenedione and lower estrogen levels. This suggests reduced CYP19 (aromatase) activity. Since the *in vitro* effects did not predict the *in vivo* effects, however, we aimed to characterize additional mechanisms for which azoles potentially can disrupt reproductive development. Using *ex vivo* rat gonad cultures we found that flusilazole also affects retinoic acid signalling in mammals, for instance disrupted *Dax1* expression; a key gene for mammalian gonad differentiation. In this project, we are exploring further, using explanted gonads from transgenic mouse strains, how flusilazole - and environmental chemicals more broadly - can disrupt gonadal sex differentiation, which can have severe consequences for reproductive development and function.

1575 Comprehensive Protein Expression Analysis in Rat Testis at Repeated Administration of Testicular Toxicants

T. Tsuchiya, Y. Hidoh, N. Takahashi, Y. Iwata, and K. Abe. *Nonclinical Research Center, Tokushima Research Institute, Otsuka Pharmaceutical Co. Ltd., Tokushima, Japan.*

Some chemicals have testicular toxicity to animals and humans: ethylene glycol monomethyl ether (EGME) and 1,3-dinitrobenzene (1,3-DNB), etc. However, their primary toxic targets are different each other: spermatocytes and Sertoli cells, etc, and their detailed mechanisms of toxicity are unclear. In addition, comprehensive protein expression analysis (proteomics) using liquid chromatography-tandem mass spectrometry (LC-MS/MS) is useful for understanding biological reactions in the tissue, and its use has been increasing in recent years. Therefore, in this study, we analyzed the changes in protein expression during repeated administration of testicular toxicants with different toxic targets, and estimated their respective toxic mechanisms and related biological responses. Test substances were administrated once a day to 8-week-old male SD rats for up to 14 days, and the testes collected from rats were subjected to organ weight measurement, histopathological examination, and proteomics by LC-MS/MS. Pathway analysis were performed for these expression data by Ingenuity Pathway Analysis (IPA) (QIAGEN Bioinformatics). Histopathological examination observed the morphological changes characteristic of each test substance: degeneration of spermatocytes by EGME, and vacuolation in seminiferous tubules by 1,3-DNB, etc. As a result of comprehensive protein expression analysis, changes were observed in various pathways: enzyme induction, redox reaction, energy production, etc. Some pathways showed common changes to test substances, and the other showed different patterns for each test substance. In this presentation, based on these results, we will discuss and report the relationship between toxic target differences and patterns of pathway changing.

1576 Characterization of Rat Testicular Organoids Exposed to Ionizing Radiation

Y. Chen, J. M. Shemansky, L. Muskhelishvili, and D. Petibone. *US FDA/NCTR, Jefferson, AR.* Sponsor: D. Petibone, Environmental Mutagenesis and Genomics Society

Exposure of male germ cells or somatic testicular cells to certain chemical or physical agents can result in testicular toxicities that adversely affect fertility or offspring. However, suitable *in vitro* models for investigating toxic events in testicular cells are lacking. Therefore, we developed an *in vitro* testicular organoid model using cells from postnatal day 20 (PND20) rat testes. Immunolabelling (IL) was used to characterize the cell types and cellular architecture within the testicular organoids. The testicular organoids were exposed to 0, 2, and 5 Gray (Gy) ionizing radiation (IR) and the media was collected at 0, 2, and 4 hours post-IR. Lactate and lactate dehydrogenase (LDH) levels were measured using the media to assess metabolic function and cytotoxicity, respectively. At 4 hours post-irradiation, mRNA was isolated from the organoids and used to quantify IR-induced gene expression levels. IL analysis revealed that the organoids contain seminiferous tubule-like structures (STSs) with a Sertoli cell barrier (SCB). Spermatogonial stem cells (SSCs) and undifferentiated spermatogonia were also associated with the STSs. IR exposure decreased lactate and increased LDH release in a dose-dependent manner. A ≥ 2-fold change in expression was observed in several genes involved in toxicity and male fertility. These data reveal that the testicular organoids possess cell types and cellular architecture resembling the *in vivo* testes and are capable of producing detectable changes in metabolic function, cytotoxicity, and gene expression following IR treatment. These preliminary results suggest that rat testicular organoids could be a suitable *in vitro* model for evaluating testicular toxicity.

1577 Small RNAs in Rat Sperm as Biomarker of Exposure to Testicular Toxicant Methotrexate

H. Li, A. Stermer, S. Hall, E. Bianchi, T. Nolan, C. Hopkins, S. Madnick, and K. Boekelheide. *Brown University, Providence, RI.*

Methotrexate (MTX), a widely prescribed drug to treat neoplastic, autoimmune and inflammatory diseases, can lead to the inhibition of DNA and RNA synthesis, causing cytotoxicity and genotoxicity. In particular, testicular injury has been observed with MTX in both preclinical models and clinically. The present study established a low-dose subchronic MTX exposure model in the rat with the ultimate goal of identifying distinct sperm RNA expression patterns associated with testicular injury and creating novel biomarker panels for testicular toxicity assessment. MTX was administrated intraperitoneally (IP) at the dose of 2, 5 and 10mg/kg to adult male Fisher rats (n=10) weekly for 13 weeks. The animals were sacrificed one week after the last MTX injection. To characterize the testicular injuries, testes/epididymal weights, sperm count, sperm motility and testes/epididymal histology were assessed. Moreover, total RNA was isolated from epididymal sperms and small RNA was profiled using next generation RNA-sequencing. Sperm count and motility were similar among the control and treated groups. MTX treatment at 10mg/kg significantly decreased testes weight. There was a clear dose-related effect of MTX exposure on testicular histopathology, including a loss of spermatocytes in late stages of the seminiferous epithelial cycle and a loss of round spermatids in early stages of the cycle, resulting in seminiferous epithelial thinning and decreased seminiferous tubule diameter. Neither retained spermatid heads (RSH) nor Sertoli cell vacuoles were a prominent feature, only being observed in a minority of the high dose rats. Significant dose-dependent changes in piRNA length and piRNA length-distributions were identified from sequencing analysis. These data showed that sub-chronical low-dose MTX cause testicular histopathological abnormalities, and sperm piRNAs can be developed as useful biomarkers of MTX-induced testicular injury.

1578 An mTOR-Dependent Regulation of the Blood-Testis Barrier: A Potential Novel Mechanism of Male Reproductive Toxicity

S. Amir[1], S. T. Shah[1], V. Salemme[2], J. McGaunn[2], and A. Suvorov[2].
[1]COMSATS University Islamabad, Islamabad, Pakistan; and [2]University of Massachusetts Amherst, Amherst, MA.

Alarming decline in sperm quality in terms of number and motility observed in recent years is a clear indication of malfunctioning of male reproductive system. Environmental toxicants such as PBDEs demonstrate strong relationship with defected spermatogenesis. PBDEs have been also shown to modulate mTOR pathway. It was demonstrated recently that activity of mTORC1 promotes opening of the Blood Testes Barrier (BTB) and activity of mTORC2 promotes its integrity. Thus, we hypothesize that one possible pathway through which environmental toxicants, e.g. PBDE, may exert reproductive toxicity consists in the mTOR-dependent modulation of the BTB permeability. Sertoli cell specific knockout mice for Raptor (mTORC1) & Rictor (mTORC2) were generated by breeding animals with floxed target genes and transgenic animals with Cre controlled by Amh promoter. Six animals from each group were sacrificed at postnatal weeks 8, 12, 22 and one year of age to analyze changes in testes weight, sperm count & morphology followed by biotin tracer assay to assess the BTB integrity. Sperm DNA was used to measure mitochondrial copy number and telomere length. Significant reduction in testes weight and sperm count were observed in both knockout types as compared to wild type. The mTORC2 knockouts showed an age-related increase in abnormal spermatozoa, mitochondrial copy and telomere length as compared to the mTORC1 knockout and WT. Biotin tracer assay reveled intact BTB in mTORC1 knockouts and wild type animals while the mTORC2 knockouts showed compromised BTB. Moreover, the histology of testes showed a degradation of seminiferous epithelium in mTORC2 knockouts. Together these data suggest that chemical compounds that affect balance of mTOR complexes may exert reproductive toxicity via altered permeability of the BTB.

1579 Amino Acid/Lipid Profiling in Plasma of Rats with Chronic Inflammation Induced by Endocrine-Disrupting Chemicals and Sex Hormone

R. D. Beger, L. Pence, and N. Nakamura. *US FDA/NCTR, Jefferson, AR.*

Estrogen and testosterone regulate prostate growth, and endocrine disrupting chemicals (EDCs) can lead to prostate disease development. Elevated estrogen levels can occur during aging and/or reduced testosterone levels. Thus, cases of prostatitis in young men are most likely to have unknown causes. Blood levels of lipids and amino acids have been investigated as potential biomarkers for many diseases, including prostate cancer, yet there are few studies to examine lipid and amino acids from plasma samples from prostatitis patients. Our previous study found that chronic inflammation in the prostates of Sprague-Dawley (Hsd:SD) rats was induced by estradiol benzoate (EB; EDC), and testosterone (T)/estradiol (E). Pups on postnatal days (PNDs) 1, 3, and 5 were injected with EB, and then additional E and T exposure were performed via silastic tube implants in the subcutaneous region from PND 90 through PND 200. To determine whether chronic inflammation induced by postnatal EB, T and E exposure affects amino acid and lipid profiling, we performed Xevo TQ-S triple-quadrupole mass spectrometer with Biocrates p180 kit using the rat plasma. Acylcarnitines, glycerophospholipids, and sphingomyelines were significantly increased in the rats dosed with EB, T and E, and were associated with chronic inflammation. In addition, glycine, citrulline and tryptophan levels were altered during chronic inflammation. The metabolomics findings suggest that these metabolic changes may be associated with activated pro-inflammatory signaling, altered beta oxidation and may be potential biomarkers of prostatitis. As this study used a rat model, further experiments using human plasma samples will be necessary to confirm these findings.

1580 Surgical Implantation of Vascular Access Buttons Has No Impact on Male or Female Reproduction in Crl:CD1(ICR) Mice

L. Wang[1], J. Huang[1], D. Harrison[1], A. Gaitan[1], M. Stamen[1], S. Lane[1], J. Bultman[1], M. Herberth[1], A. Cohen[2], A. Shirvan[2], and P. Coder[1]. *[1]Charles River, Ashland, OH; and [2]Atox Bio, Ness Ziona, Israel.*

Reproductive toxicology studies in mice typically entail daily dosing for approximately 5 weeks for females and up to 8 weeks for males. As opposed to conventional routes of administration, such as oral gavage, daily tail vein intravenous administration is extremely difficult in the mouse and therefore, requires the use of surgically catheterized animals. The use of Vascular Access Buttons (VABs) presents significant advantages as the access button is fitted with a light weight magnetic cap that allows untethered access and permits social housing throughout the study. We present control group data from two independent definitive reproductive toxicity studies conducted per guideline ICH 4.1.1 in male and/or female Crl:CD1(ICR) mice implanted with VABs. Twenty two male or female mice were surgically implanted with jugular vein catheters using VABs. Animals were dosed daily with Phosphate Buffered Saline (PBS), pH 7.4, via bolus intravenous injection and later mated with naïve animals of the opposite sex for up to 15 days. Males were dosed for 28 days prior to mating and continuing through 1 day prior to euthanasia (at least 56 doses). Females were dosed for 14 days prior to mating and continuing through Gestation Day 7 (24-30 doses). Evaluated endpoints included: clinical signs, body weights, body weight gains, food consumption, gross necropsy and reproductive organ weights. In the VAB-females (mated with native males) or naïve female (mated with the VAB-males), the mean numbers of corpora lutea and implantation sites and intrauterine embryonic survival were evaluated. Parameters of reproductive performance included precoital intervals, mating, fertility, and copulation/conception indices. In addition, sperm parameters in males (motility, concentration, sperm production rate, and morphology) and estrous cyclicity in females were evaluated. The data demonstrated that the surgical implantation of VABs had no impact on male or female reproduction versus non-VAB animals, as compared to the Charles River Ashland historical control data. Therefore, the use of surgical implanted VABs is an acceptable approach for mouse reproduction studies.

1581 GSK2245035, a TLR7 Agonist, Does Not Increase Pregnancy Loss in Cynomolgus Monkeys

A. E. Hillegas[1], L. Posobiec[1], M. A. Price[2], A. Baker[3], A. Phadnis-Moghe[3], C. C. Maier[1], and D. J. Stanislaus[1]. *[1]GlaxoSmithKline plc, Collegeville, PA; [2]GlaxoSmithKline plc, Ware, United Kingdom; and [3]Covance Inc., Madison, WI.*

GSK2245035 is a novel small molecule Toll-like Receptor 7 (TLR7) agonist that was in development as an immunomodulatory, intranasal treatment for allergic airways disease aiming to reduce Th2 and enhance Th1/Treg responses to aeroallergens *via* the local induction of type I interferons (IFNs). GSK2245035 demonstrated selectivity for potent release of type I IFNs compared to TNFα and IL-6 with dose dependent increases in the interferon inducible chemokine, IP-10 in the nasal compartment. Pregnancy is a highly complex condition requiring several phases of immune regulation. Implantation requires some pro-inflammatory processes including IFNs, ISGs (Interferon Stimulated Genes), TNFα, and IP-10. As intravenous administration of type I IFNs to pregnant monkeys have resulted in abortions, a pregnant monkey study was conducted with GSK2245035 to assess the risk for pregnancy. Pregnant monkeys were given 0, 3 or 30 ng/kg/week GSK2245035 intranasally at 50 µL/nostril once weekly, beginning on Gestation Day 20 (GD20) through delivery and from Day 7 postpartum (pp) through Day 63 pp. There was no GSK2245035-related effect on pregnancy or infant loss. Non-adverse GSK2245035related effects included an increased incidence of nasal discharge and increased mean body temperature at 30 ng/kg/week in maternal animals compared to controls, dose-dependent increases in IP-10 and IFNα at ≥3 ng/kg/week in maternal animals, and decreased IgM and IgG titers following KLH immunization in infants from maternal animals given ≥3 ng/kg/week. Even though there were systemic increases in cytokines as well as increased maternal body temperatures which together confirmed pharmacologic activity, systemic IFNα levels did not reach equivalent levels of recombinant type I IFNs that were abortifacient in monkey. These lower IFNα levels as well as the once weekly dosing and local intranasal administration vs daily subcutaneous or intramuscular dosing with recombinant type I IFNs, may be the reasons for the lack of effects on pregnancy; however, it should be noted that there was an undesired impact on immune function in the offspring.

1582 Toxicity and Microbiome Assessments of Triclosan as Determined in a Dose Range-Finding Study in Harlan Sprague Dawley Rats

V. Sutherland[1], B. McIntyre[1], H. Cunny[1], L. Miller[2], C. Hebert[2], M. Lahiani[3], G. Kuppan[3], C. Cerniglia[3], and S. Khare[3]. *[1]NIEHS/NTP, Research Triangle Park, NC; [2]Southern Research, Birmingham, AL; and [3]US FDA/NCTR, Jefferson, AR.*

A dose range-finding study of Triclosan (TCS) was performed in rats to evaluate general toxicity and potential disruption of the gastrointestinal microbiome. TCS was examined due to its previous use as an antibacterial chemical in health and skincare products and concerns for continued exposure due to potential levels in surface and sewage waters. Ten dams per dose group were orally gavaged with 100, 250, 500, or 1000 mg/kg from Gestation Day (GD) 6-21 and through lactation until postnatal day (PND) 28. Pups were exposed *in utero* and dosed postnatally from PND 12-28, at the same level as their respective dams. Additional cohorts were included to collect biological samples for internal exposure levels and for microbiome assessments on the ileum, colon, and feces. Two corn oil control groups (2 mL/kg and 5 mL/kg) were also assessed for potential differences in microbial populations. Moribundity was observed at ≥ 500 mg/kg. Additionally, reductions in maternal body weight gain and food consumption were observed at ≥ 500 mg/kg. Reductions in pup body weight gain were observed at ≥ 250 mg/kg, but no treatment-related toxicity was observed at 100 mg/kg. Selected animals were also assessed for effect of TCS on taxonomic diversity and composition of the microbiota in feces. When examining the microbial population, the bacterial genus and species abundance in both dams and pups showed a significant change in the phyla level at 1000 mg/kg in the dams. Alterations at the genus level were noted in PND28 pup samples at the lowest dose (100 mg/kg) and TCS exposure differences in bacterial species were seen between dams and pups. These data suggest that TCS, at the exposure levels examined, is associated with both general maternal and pup toxicity at doses of ≥ 250 mg/kg and had impacts on the maternal and pup gastrointestinal microbiome at doses of 100 mg/kg and higher.

1583 Trichloroethylene Decreases Fetal Weight in Timed-Pregnant Wistar Rats: Differential Effects of N-acetyl-L-cysteine and Aminooxyacetic Acid on Modulating Trichloroethylene Toxicity

A. L. Su[1], I. L. Bergin[1], L. H. Lash[2], and R. Loch-Caruso[1]. [1]*University of Michigan, Ann Arbor, MI; and* [2]*Wayne State University, Detroit, MI.*

Trichloroethylene (TCE) is an industrial solvent used as a metal degreaser and in synthesis of various chemicals. Although epidemiological studies associate TCE exposure with adverse pregnancy outcomes, mechanistic explanations for these associations are incomplete. We hypothesize that toxicity of TCE is due to its glutathione conjugation metabolism, which has been scarcely studied in pregnancy. In the present study, we exposed timed-pregnant Wistar rats to 480 mg TCE/kg/day from gestational day (GD) 6 to GD 16. Rats were exposed to vehicle alone, TCE alone, or TCE in combination with the glutathione metabolic pathway modulators aminooxyacetic acid (AOAA) at 20 mg/kg/day or N-acetyl-L-cysteine (NAC) at 200 mg/kg/day administered from GD 5 to GD 16. AOAA is an inhibitor of cysteine conjugate β-lyase (CCBL), which is important for metabolic activation of TCE to 1,2-dichlorovinylthiol (DCVT), a highly reactive and toxic metabolite. NAC is a precursor of reduced glutathione and can augment intracellular glutathione concentration and scavenge free radicals. TCE decreased fetal weight in the rats, an effect that was rescued by AOAA but not NAC pre/co-treatment, suggesting that TCE confers its toxicity to fetuses via CCBL activity and DCVT formation. However, enzyme activity assays indicated that AOAA was effective as a CCBL inhibitor in maternal kidney but not in maternal liver nor the placenta, suggesting that the reduction in fetal weight was independent of AOAA-sensitive CCBL metabolic activation of TCE in placenta and maternal liver, but may be mediated by kidney and possibly other organs. Whereas placental morphometric measurements did not differ between the control and TCE-only treatment group, the TCE + NAC group had larger basal zone area and width along with smaller labyrinth zone area and width compared to the TCE-only treatment group when normalized to total placenta dimensions. This morphology of the TCE + NAC group is similar to a developmentally delayed placenta. We propose that the effect of NAC could be due to its ability to augment synthesis of glutathione, a substrate for glutathione *S*-transferases that is upstream of DCVT in the TCE glutathione metabolic pathway. Efforts are underway to more fully understand the role of glutathione metabolism in TCE fetal toxicity.

1584 Dioxin Induced Adaptations at the Maternal-Fetal Interface

K. Iqbal[1], P. Dhakal[1], K. Roby[1], S. Pierce[1], R. Scott[1], C. Vyhlidal[2], and M. Soares[1]. [1]*University of Kansas Medical Center, Kansas City, KS; and* [2]*Children's Research Institute, Children's Mercy Kansas City, Kansas City, MO.*

The actions of dioxins, such as 2,3,7,8-tetrachlorodibenzodioxin (TCDD), are mediated by the aryl hydrocarbon receptor (AHR), a ligand-dependent transcription factor. Dioxin-AHR interaction results in the transcriptional activation of target genes such as *Cyp1a1*. TCDD has been reported to affect pregnancy and possibly development of the hemochorial placenta. The purpose of this study was to investigate TCDD actions on pregnancy and placentation using the rat as a model. High TCDD exposures resulted in pregnancy failure; however, lower TCDD exposures resulted in prominent adaptations at the maternal-fetal interface. Gestation day (gd) 13.5 placentation sites from TCDD-treated pregnant rats exhibited deep intrauterine endovascular trophoblast invasion and uterine spiral artery remodeling, which was not observed in oil treated controls. Immunostaining for CYP1A1 in gd 13.5 placentation sites revealed specific activation of AHR signaling in endothelial cells lining small diameter blood vessels at the uterine-placental boundary (metrial gland) and in endothelial cells within the extraembryonic mesenchymal cores of the labyrinth zone but not in the junctional zone of the placenta. Single cell RNA-Seq analysis of the metrial gland of pregnant rats revealed a high level of expression of *Ahr* in endothelial cells; however, minimal expression in intrauterine invasive trophoblast cells. The importance of AHR and CYP1A1 in the placentation site adaptive responses to TCDD were investigated in *Ahr* and *Cyp1a1* null rat models. We found that TCDD-induced intrauterine trophoblast invasion and uterine spiral artery remodeling was AHR-dependent but not affected by CYP1A1. We next evaluated the importance of AHR signaling in maternal versus embryonic/extraembryonic tissues following TCDD treatment. The presence of AHR in maternal tissues was essential for TCDD-induced adaptations at the placentation site. Placentation site adaptations were not affected by embryonic/extraembryonic AHR expression. RNA-Seq, RT-qPCR, and immunostaining of the metrial gland revealed that TCDD dysregulated uterine natural killer (NK) cell specific transcript expression without affecting overall NK cell numbers, indicating that TCDD treatment affected the uterine NK cell phenotype. Uterine NK cells have a prominent restraining effect on intrauterine trophoblast invasion, which may be modified by TCDD. In summary, exposure to dioxin during pregnancy induces robust AHR-dependent structural changes within the uterine-placental interface. Most interestingly, our findings indicate that at least some of the TCDD effects on placentation are mediated through its actions on the mother and not directly on trophoblast cells. *Supported by NIH grants ES028957, ES029280; Sosland Foundation.*

1585 Sex Differences in Benzo[a]pyrene Metabolites and Gonadal Transcriptomal Changes in Mouse Embryos after Oral Dosing to Pregnant Dams

J. Lim[1], A. Ramesh[2], T. Shioda[3,4], and U. Luderer[1]. [1]*University of California Irvine, Irvine, CA;* [2]*Meharry Medical College, Nashville, TN;* [3]*Massachusetts General Hospital Center for Cancer Research, Charlestown, MA; and* [4]*Harvard University, Cambridge, MA.*

Polycyclic aromatic hydrocarbons (PAHs) like benzo[a]pyrene (BaP) are ubiquitous pollutants formed during incomplete combustion of organic materials. We previously reported that maternal oral dosing with BaP from embryonic day (E) 6.5 to E15.5 dose-dependently decreased ovarian follicle numbers in F1 female mice and testicular spermatid counts in F1 males, with the developing ovaries being more sensitive than the developing testes. We also previously showed that exposure to BaP destroys germ cells in cultured E13.5 mouse ovaries, but not in cultured E13.5 testes. The goals of the present study were 1) to measure BaP metabolites in embryos and placentas after oral dosing to pregnant dams and 2) to measure the impact on the gonadal transcriptomes. We hypothesized that greater effects would be found in the developing ovary than the testis. Pregnant C57BL/6J female mice were orally dosed via pipet with 0 (sesame oil), 0.2, or 2 mg/kg/d BaP from E6.5-E11.5. E13.5 gonads from the 0 and 2 mg/kg/d BaP groups were processed for RNA sequencing. Whole embryo (minus gonads) and placentas were harvested from all 3 dose groups for the measurement of BaP metabolites by HPLC. The sum of BaP metabolite concentrations increased with dose in the embryos and placentas ($P=0.006$), and concentrations were higher in female than male embryos ($P=0.034$). The major BaP metabolites detected in both male and female placentas were 3(OH)BaP and 9(OH)BaP, while in both female and male embryos, BaP-7,8-diol and 3(OH)BaP were the major metabolites. Whole gonad RNA sequencing identified 33 differentially expressed genes (DEGs; FDR <0.05) in BaP compared to control ovaries, and 5 DEGs in testes. Seven Kyoto Encyclopedia of Genes and Genome (KEGG) pathways were statistically significant in ovaries (ribosome, oxidative phosphorylation, Huntington's, Alzheimer's, Parkinson's, phagosome, non-alcoholic fatty liver disease), while none were in testes. The results show that BaP metabolites are present in mouse embryos after oral dosing to the mother, that the concentrations are higher in female than male embryos and that gene expression is altered to a greater extent by transplacental BaP in the embryonic ovary than testis, supporting our hypothesis. *Supported by NIH R01ES020454.*

1586 Direct Comparison of Acute Toxicity and Endocrine-Disrupting Effects of Seven Bisphenols in *Danio rerio*

A. Martini, and M. Mukai. *Cornell University, Ithaca, NY.*

Due to endocrine disrupting potential concerns, bisphenol A (BPA) has been replaced with structurally similar compounds. Recent studies have shown some of these alternatives have similar/greater toxicological concerns; however, there are only limited reports of concurrent testing of BPA and alternatives to determine their relative safety *in vivo*. Zebrafish (*Danio rerio*) is an ideal model for use in studies when high-throughput capability is needed. Therefore, we compared acute toxicity and endocrine disrupting effects of BPA and 6 other bisphenols (BPB, BPF, BPS, BPZ, BPAF, and BPAP) in early developmental zebrafish. Embryos were dechorionated and exposed to 7 concentrations (ranging 0.05-500 ppm; n=6, 25/replicate) from 4 to 120 hours-post-fertilization (hpf) and full spectrum lethality curve was generated. In order to compare the endocrine disrupting potential of different bisphenols, three concentrations (LC10, LC10/10, and LC10/1000) was subsequently used in an 8-days exposure protocol (4-hpf to 8-dpf) to investigate potential effects on the hypothalamic-pituitary-gonadal axis. Bisphenols resulted in varying degrees of general toxicity with LC50 values ranging from 1.83 to 209 ppm in the following order: BPAF<BPZ<BPAP<BPB<BPA<BPF<BPS. Malformations caused by BPF exposure was most prominent. Gonadotropin-releasing hormone 3 (*Gnrh3*) mRNA expression was significantly downregulated with BPS at the lowest concentration tested (113 ppb) only vs. controls, showing low-dose effect. Trend towards decrease in *Gnrh3* expression was also observed in all BPA concentrations (4.4 ppb-4.4 ppm) vs. controls although not statistically significant. BPF caused significant increase of gly-

coprotein hormone α subunit (*Cga*) mRNA expression in groups treated with medium concentration (1.3 ppm) vs. controls. Luteinizing-hormone β subunit (*Lhb*) mRNA expression was increased with BPB, BPS, and BPZ at the highest and with BPF at the medium concentration vs. controls. Follicular-stimulating hormone β subunit (*Fshb*) mRNA expression was upregulated only with two lower concentrations of BPAP, showing low dose effect. Our findings present added evidence that BPA alternatives are not necessarily safer than BPA. Low-dose effects were observed with BPS and BPAP on key regulatory genes of the reproductive-axis, warranting further investigation. Moreover, *in vivo* models such as zebrafish could be used to implement comprehensive high-throughput testing in future selection of safer alternatives.

PS 1587 Microcystin-Induced Transgenerational Reproductive Toxicity and the Role of Epigenetic Modifications

C. E. Moore[1], M. Blumenkrantz[2], L. Truong[2], and P. Allard[2]. *[1]San Diego Zoo Global, San Diego, CA; and [2]University of California Los Angeles, Los Angeles, CA.*

Persistent ecosystem damage perpetuates the human and animal health risk of microcystin-producing harmful algal blooms. Well-established acute hepatotoxins, microcystins (MCs) are known serine/threonine protein phosphatase inhibitors and can alter cell signaling, causing a wide variety of clinical signs including death. Studies highlight the reproductive system as an additional target organ and of the over 100 MC congeners, MCLR is the most commonly detected and studied. Multigenerational studies in mammals and aquatic species identify offspring of exposed parents have altered neurodevelopment and growth. In the alternative model *Caenorhabditis elegans* (*C. elegans*) MCs induce germline apoptosis at P0, making it an ideal model to study the generational epigenetic impact of MCs. In our studies L4s are exposed to a range of environmentally relevant concentrations MCLR (0.1-100 µg/L) for 48 hours with food in liquid. The *C. elegans* strains N2 (wildtype), TY2441(yls34 (Pxol-1::GFP+rol-6 (pRF4))) and WH371(ojIs50 [pie-1p::GFP::air-2 + unc-119(+)]) are used. Exposed P0 worms are recovered and each adult generation is evaluated for multi- (F1) and trans- (F3) generational toxicity without further MC exposure. In a general toxicity screen, N2 worm size (length, width, area), eggs laid and brood size of F1 and F3 were not significantly altered after MCLR exposure. Ancestral 0.1 and 100 µg/L MCLR exposure significantly increased germline apoptosis in N2 F1 (18% increase, $p<0.05$) and F3 (40% increase, $p<0.01$) generations and embryonic lethality in the F3 generation (fold change of 2, $p<0.05$). Epigenetic changes evaluated to explain the multi- and transgenerational MCLR-induced reproductive toxicity include chromosomal remodeling, where N2 F3 worms ancestrally exposed to 0.1 and 100 µg/L MCLR have a significant increase in chromosomal clumping (50% increase, $p<0.01$), but do not have an increase in missegregation based on a screen using the GFP::xol-1 strain which identifies GFP positive male embryos. Initial studies using immunohistochemistry identify histone marks H3S10p and H3K9me3 as reduced in N2 F1 late diakinesis oocytes, and using the GFP::air-2 strain, the kinase responsible for H3S10 phosphorylation was also reduced in F1 and F3 maturing oocytes. Together these preliminary results suggest MCLR may cause transgenerational reproductive toxicity through altered histone modifications.

PS 1588 Multigenerational Reproductive Effects of Perfluorooctane Sulfonic Acid in *Daphnia magna*

A. Bline, and P. Allard. *University of California Los Angeles, Los Angeles, CA.*

Perfluorooctane sulfonic acid (PFOS) is a widespread environmental contaminant routinely detected in drinking water and human serum samples across the US. Since PFOS has also been detected in human follicular and amniotic fluids, female germ cells and developing embryos are subject to direct PFOS exposure. To test the hypothesis that germ cell and early developmental exposure to PFOS produce negative reproductive effects across multiple generations, age-matched, sexually mature *Daphnia magna* were individually exposed to 10µg/L PFOS, 100µg/L PFOS, or standard culture medium for 10 days. These exposure concentrations were designed to produce internal PFOS concentrations relevant to human levels. The exposure period was long enough for internal concentrations to stabilize and for at least one cycle of oocyte maturation to be completed. After this time, F_1 neonate (<24 hours) offspring were pooled within treatments and twelve offspring per treatment randomly selected and maintained individually in standard culture conditions for 21 days. The third broods of the F_1 generation were used to establish the F_2 generation, which was maintained similarly to the F_1 generation. Each generation was monitored daily with counting and removal of live and dead offspring, as well as aborted embryos. PFOS exposure to the P_0 generation caused an insignificant decrease in total live offspring produced at 100µg/L. However, using a generalized linear model, the total number of nonviable (i.e. sum of dead neonates and aborted embryos per adult) was significantly increased at 100µg/L PFOS. In the F_1 generation, prenatal/neonatal PFOS exposure resulted in a significant increase in nonviable offspring produced at both 10µg/L and 100µg/L. In the F_2 generation, the rate of survival to adulthood was decreased in both PFOS treatment groups. These preliminary results suggest that early life exposure to PFOS may negatively impact adult reproductive health.

PS 1589 The Pesticide Temefos Decreases Sperm Quality and is Metabolized in Reproductive Tissues at the Recommended Safe Concentrations in Rats

I. Camacho-Hernández[1], A. Sierra-Santoyo[1], M. Solís-Heredia[1], F. Verdín-Betancourt[1], A. Ramos-Flores[1], A. Duana-Moreno[1], A. Rojas-García[2], and B. Quintanilla-Vega[1]. *[1]Cinvestav, Mexico City, Mexico; and [2]Universidad Autónoma de Nayarit, Tepic, Nayarit, Mexico.*

The organophosphorus (OP) pesticide temefos (Tem) is used in the control of vectors that transmit diseases in Mexico. The LOAEL of Tem in male rats according to the WHO is 100 mg/kg/day/44 days (Category III) and 0.9 mg/kg/day/7-90 days for EPA (Category II). *In vivo* studies demonstrated the acetylcholinesterase (AChE) inhibition and DNA damage, and studies in HepG2 cells, which are metabolically active have reported the formation of micronuclei. Tem is unstable and previous studies have suggested that Tem is metabolized by mixed-function oxidases; some oxidized metabolites have been detected in rats, such as Tem-sulfoxide, Tem dioxon sulfoxide, Tem dioxon sulfone, and hydrolyzed products including thiodiphenol (TDP), TDP-sulfoxide, and TDP-sulfone (known as bisphenol S-BPS, considered as an endocrine disruptor). Due to the limited information of the toxic effects of Tem on the reproductive system, our interest was to evaluate the effects of Tem exposure (1 or 100 mg/kg/d/7 d, gavage) on AChE activity, sperm quality, peroxidative damage (MDA concentration), and DNA integrity (by SCSA) in spermatozoa collected from the epididymis-vas deferens, as well as the presence of Tem and its metabolites in different tissues (by HPLC-DAD-MSD) of male Wistar rats euthanized 1-hour post treatment. At 1 mg/kg/d, AChE activity decreased (22-29%) from the 3rd day, and no adverse effects on sperm cells were observed. At 100 mg/kg/d, AChE was inhibited (70-79%) from the 3rd day; 41% of the animals died after the 5th dose, and a decrease (11.5%) in the liver relative weight was observed. Sperm motility and viability decreased (30 and 8%, respectively), lipid oxidation increased (25%), and a poor sperm chromatin condensation was observed. Tem was widely distributed in a tissue-dependent fashion and it was 17-fold higher in the epididymis than in testis. The order of Tem metabolic activity was: liver> testis > epididymis. These results suggest that the liver and male reproductive system are targets of Tem that can cause fertility problems. Very importantly, the proposed safe concentrations (LOAEL) of Tem should be reevaluated in toxicological studies in different tissues.

PS 1590 Bisphenol S Impairs Human Cytotrophoblast Syncytialization through Competitive Epidermal Growth Factor Receptor Binding

E. Ticiani, J. Gingrich, Y. Pu, and A. Veiga-Lopez. *Michigan State University, East Lansing, MI.*

Bisphenol S (BPS) is an endocrine disrupting chemical and the second most abundant bisphenol detected in humans. Recently, we have demonstrated that *in utero* exposure to BPS reduces the endocrine capacity of the ovine placenta by reducing binucleate cell number. During placentation, ovine trophoblast cells undergo homokaryotic fusion to form binucleate trophoblast cells, a process similar to that of human syncytiotrophoblast formation. Syncytiotrophoblasts are essential for hormone production and nutrient exchange. Given that BPS reduces binucleate cell number in the ovine epitheliochorial placenta, we hypothesized that BPS will also impair trophoblast syncytialization in the human hemochorial placenta. To test this hypothesis, we used human cytotrophoblast cells (hCTBs) that were isolated from healthy placentas (n=6; IRB#15-484) derived from elective C-section pregnancies at term. hCTBs were cultured for 96 h with: 1) Vehicle (0.1% DMSO), 2) BPS (200 ng/ml), 3) human epidermal growth factor (hEGF, 10ng/ml), or 4) BPS+hEGF. hEGF was used as a syncytialization-induction signal and served as a positive control. Exposure to BPS reduced hEGF-mediated syncytialization rate (Vehicle: 11.58±1.17%, BPS: 11.23±1.17%, EGF: 21.71±1.17%, BPS+EGF: 11.97±1.17%; $P<0.001$). We additionally tested whether BPS could inhibit the EGF response by blocking EGFR phosphorylation in MDA-MD-231 breast cancer cells due to their high expression of EGFR. Cells were exposed to the same aforementioned treatments and phosphorylation of EGFR (pEGFR) and AKT (pAKT), a downstream signal to EGFR, were assessed by western blotting. As expected, hEGF upregulated pEGFR and pAKT (15.2 and 10.1-fold, respec-

tively, compared to the vehicle), but hEGF+BPS reduced pEGFR and pAKT (5.1 and 1.2-fold, respectively,compared to the hEGF group). To test if BPS directly competes with hEGF for the EGFR binding site we used an EGF/EGFR AlphaLISA assay, and demonstrated that BPS blocked EGF binding in a dose dependent fashion, with a reduction of up to 58%. This is the first study to demonstrate that BPS can 1) prevent EGF-mediated trophoblast syncytialization, 2) block EGFR phosphorylation, and 3) compete with EGF for receptor binding. Given the role of EGFR in placental development, including trophoblast proliferation and differentiation, BPS interference may result in placenta dysfunction. *Supported by NIEHS R01 ES027863 to A.V-L.*

1591 Effects of Pyrethroid Insecticides on Fetal Growth, Neurodevelopment, and Placental Function

B. A. Elser[1], K. Kayali[1], R. Dhakal[1], K. Wang[1], L. Schulz[2], H. Lehmler[1], and H. Stevens[1]. *[1]University of Iowa, Iowa City, IA; and [2]University of Missouri, Columbia, MO.*

Prenatal exposure to pyrethroid insecticides has been associated with increased risk for neurodevelopmental delay and low birth weight in children. Despite widespread exposure, there is a significant gap in knowledge about the mechanisms by which pyrethroids alter fetal growth and neurodevelopment. To address this question, CD1 mouse dams were treated with 10mg/kg alpha-cypermethrin or corn oil vehicle via oral gavage from embryonic days 11 to 14 (E11-E14) or E5-E18. Shorter-term exposure reduced fetal body weight and delayed tangential migration of GABAergic progenitors into the cortical plate of E14 offspring embryonic brain. Longer-term exposure also delayed GABAergic progenitor migration, as shown by a higher density of GABAergic interneurons in E18 cortical white matter. To investigate the mechanisms responsible for impaired neuronal migration, migrating GABAergic progenitors were isolated via laser capture from E14 brain tissue and analyzed via RNAseq. Differential gene expression in response to cypermethrin exposure was assessed using Ingenuity Pathway Analysis, which implicated alterations in several critical biosynthetic and metabolic pathways as major contributors to cypermethrin's effects. To investigate whether these effects are due to direct exposure to the embryonic brain, levels of cypermethrin were measured via GC-MS in maternal serum and amniotic fluid. Levels of cypermethrin in amniotic fluid were found to be below the limit of detection, implicating an indirect mechanism by which cypermethrin alters fetal growth and neurodevelopment. Analysis of placental tissue revealed that cypermethrin exposure altered multiple functional domains; in particular, expression of genes responsive to oxidative stress, including Hif-1alpha, Sod1, and Txrnd1. Despite this, cypermethrin exposure did not significantly affect placental weight. In conclusion, these studies suggest that maternal cypermethrin exposure impairs fetal growth and development of the GABAergic system in the embryonic brain. Furthermore, indirect placental mechanisms may play a significant role in the effects of maternal cypermethrin exposure on offspring development.

1592 Pre- and Postnatal Subchronic Toxicity Studies of Boric Acid in the Harlan Sprague Dawley Rat

A. Watson[1], R. Herbert[1], V. Sutherland[1], C. Willson[2], C. Picut[3], H. Cunny[1], L. Miller-Pinsler[4], J. Furr[4], C. Hebert[4], B. Collins[1], S. Waidyanatha[1], K. Aillon[5], L. Smith[5], T. Vinke[5], and B. McIntyre[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; [2]Integrated Laboratory Systems Inc., Research Triangle Park, NC; [3]Charles River, Durham, NC; [4]Southern Research, Birmingham, AL; and [5]MRIGlobal, Kansas City, MO.*

Boron (B), administered as boric acid, has previously been shown to induce developmental and reproductive toxicity, and the USEPA oral reference dose (RfD) is based on reduced fetal weight in the rat ($BMDL_{05}$=10.3 mg B/kg/day). Recent epidemiological studies on boron suggest that infants may be a potentially sensitive subpopulation; however, there is no data from animal studies to assess toxicity concerns for this age group. We evaluated the effects of pre- and postnatal boric acid exposure on development and select male reproductive endpoints in the Harlan Sprague Dawley rat. In the range-finding study, time-mated females were dosed with vehicle (deionized water), 5, 10, or 20 mg B/kg/day (administered as 0, 28.6, 57.1 or 114 mg boric acid/kg/day) via gavage from gestation day (GD) 6 to 21; pups were dosed via gavage from postnatal day (PND) 1 to 28. In 20 mg/kg pups, umbilical hernias were observed, and pup weights were 18% less than control offspring on PND 28. Based on these findings, doses of 0, 4, 8, 12, or 16 mg B/kg/day (administered as 0, 22.9. 48.8, 68.6, 91.5 mg boric acid/kg/day) were selected for the main study, which included subchronic exposure in males from PND 28-118. During lactation, there was increased pup mortality at 16 mg/kg, a dose-dependent increase in umbilical hernias (resolved by PND 28), and lower PND 28 pup weights than the controls (4%, 6%, 12%, and 25% lower at 4, 8, 12, and 16 mg/kg, respectively). Terminal body weights partially rebounded but remained 12% lower than controls at 16 mg/kg on PND 118. Organ weight changes were limited to lower pituitary, adrenal gland, and ventral prostate weights (absolute and relative), which occurred in a dose-dependent manner. No treatment-related effects were present in sperm parameters on PND 118. Plasma boron concentrations on PND 4, 28, and 118 males revealed a dose-proportional increase with the concentration in the controls less than or equal to 3.4% of the concentration of the lowest dose at any timepoint. Overall, the findings of reduced body weight suggest that exposure to boron during early postnatal developmental may result in developmental delay and highlight the importance of evaluating toxicity during the early postnatal period.

1593 Early Exposure to the Hypolipidemic Agent Rosuvastatin and Its Effects on the Development and Fertility of Female Wistar Rats

J. W. Barros[1], C. S. Borges[1], P. V. Silva[1], A. Muller[1], A. Q. Lozano[1], T. L. Pacheco[1], L. Valencise[1], J. A. Anselmo-Franci[2], A. S. Pupo[1], and W. G. Kempinas[1]. *[1]Universidade Estadual Paulista, Botucatu, Brazil; and [2]Universidade de São Paulo, Ribeirão Preto, Brazil.*

Statins are drugs used to reduce cholesterol. The use of statins by young people is increasing due to poor eating habits and sedentary lifestyle. Studies conducted in our Laboratory reported that exposure to rosuvastatin impaired reproductive function of male rats. The effects on the female reproduction remains unknown. This study aimed to evaluate the effects of rosuvastatin in reproductive development and function of female rats exposed to this drug since pre-puberty. Female Wistar rats were allocated into three experimental groups: control, treated with saline (vehicle); and R3 and R10 groups, which were treated with rosuvastatin at doses of 3 or 10 mg/Kg/Day. Treatments were performed daily, gavage, starting on postnatal day / PND 22 and ended at two different ages: at puberty (around PND 42) and at adulthood (PND 75), when the rats were euthanized in estrus and evaluated for body and organ weights, and steroid hormone levels. At adulthood part of the rats from each group was tested for sexual behavior and mated for fertility assessment. Pregnant females were euthanized on gestational day 20. The following parameters were also evaluated: age of puberty onset; estrous cyclicity starting on PND 60; uterine motility, both on gravidic and non-gravidic rats. Additionally, the uterotrophic assay was performed. For this, female Wistar rats were allocated into the same experimental groups and the treatments were associated with estradiol benzoate (0.4mg/Kg/day) or corn oil (vehicle). Treatments were performed from PND 21 until PND 23, and rats were euthanized on PND 24 for measurement of uterus weight. Statistics: ANOVA and Kruskall-Walis, $p < 0.05$. Puberty onset was not altered by juvenile rosuvastatin exposure. However, R10 group showed shorter reproductive cycles than control group. Body and organ weights were not affected by the treatment, except for liver and hypophysis of animals at PND 42, which were reduced in R10 group. Hormone levels were similar among groups at all ages. On the other hand, uterine motility, either in non-gravid and gravid uterus showed alterations in R3 and R10 animals. Rosuvastatin was also associated with altered reproductive performance, once R10 animals were less receptive during sexual behavior and placental weight was decreased compared with control group. Rosuvastatin exposure in the uterotrophic assay did not present signs of estrogenic or anti-estrogenic effects. Our results showed that pre-pubertal exposure to rosuvastatin altered female rat reproductive development and function, raising concern for women reproductive health after using this statin since young ages. *Funding: CNPq.*

1594 Differential Sensitivity to Novel Stimuli and *d*-Amphetamine following Adolescent Methylmercury Exposure

D. Kendricks, and M. C. Newland. *Auburn University, Auburn, AL.*

Methylmercury (MeHg) is an environmental neurotoxicant known to alter dopamine-mediated behaviors. The appropriate development of dopamine systems is essential to behaviors related to attention-deficit/hyperactivity disorder, including sustained attention and short-term memory. The current study modeled sustained attention and memory following exposure to MeHg throughout adolescence, the period of final dopaminergic development, using a mouse model. Mice were exposed to 0, 0.3, or 3ppm MeHg throughout adolescence and trained in a visual signal detection task in adulthood. Sustained attention and memory were probed with novel tactile and visual stimuli. Behavior of all animals, across MeHg exposure groups, was impaired significantly by the tactile stimulus. However, animals exposed to 3ppm were

unaffected by the visual stimulus while 0 and 0.3ppm animals were disrupted. In order to examine this further, animals were administered 0.3mg/kg *d*-amphetamine and probed with the visual stimulus. Animals exposed to 3ppm MeHg were differentially sensitive to *d*-amphetamine under the visual stimulus. This differential sensitivity supports hypotheses that adolescent MeHg exposure alters dopamine neurotransmission and is in line with observations of behavioral inflexibility following adolescent MeHg exposure.

1595 Dietary Route of Exposure for Rabbit Provides a Reliable, Relevant, and Conservative Characterization of Developmental Toxicity

B. R. Hannas[1], P. S. Coder[2], D. Harrison[2], K. Mikles[1], S. Papineni[1], L. Murphy[1], J. Domoradzki[1], R. J. Rasoulpour[1], and C. Terry[1]. *[1]Corteva Agriscience, Newark, DE; and [2]Charles River, Ashland, OH.*

Rabbit prenatal developmental toxicity studies via the dietary route of exposure have been conducted by Corteva Agriscience heritage companies since 2008. Although rabbits can be sensitive to feed palatability and typically display variability in gestation feed consumption, this route of exposure has been optimized using a palatability rangefinder, a daily feed allotment instead of *ad libitum* access, and the use of a flavor additive to improve palatability of test diets. Dietary exposure is most relevant for modeling human pesticide residue exposures and provides a more continuous exposure based on toxicokinetically measured blood concentrations throughout the developmental period. Achieved doses and resulting NOAELs via dietary exposure in the rabbit for four recently registered pesticides (Rinskor, Sulfoxaflor, Inatreq, and Arylex) were in line with the overall toxicology data package. Furthermore, toxicokinetic data from these dietary rabbit studies demonstrated fetal exposure in all cases. Despite the numerous advantages, logistical challenges associated with this route of exposure have prevented most laboratories from attempting to perform dietary developmental toxicity studies in rabbits. Charles River Laboratories, Ashland recently generated historical control data (HCD) with the feed allotment model used by Corteva. Groups of 50 time-mated Hra:(NZW)SPF female rabbits were provided 125 or 150g flavored feed/day during gestation. Mean maternal body weights, gravid uterine weights and net body weights were comparable to historical data for both groups of rabbits given the different allotments. Intrauterine growth, survival and fetal morphology (fetal body weights, sex ratios, pre/postimplantation loss, and incidence of fetal visceral, external, and skeletal anomalies) were also comparable to HCD for *ad libitum* fed females. These data support the use of the laboratory's existing HCD for the interpretation of data obtained on rabbit dietary studies using a set daily feed allotment. Together, these data demonstrate that dietary exposure in rabbits provides reliable and human-relevant exposures that can be used to characterize the potential for an agrochemical to cause developmental toxicity.

1596 Proposal for Study Designs Based on Results of Juvenile Toxicity Studies in Rats

A. Inoue, S. Kawabata, A. Arima, and H. Tsusaki. *Shin Nippon Biomedical Laboratories Ltd., Kagoshima, Japan.*

The ICH S11 guideline Step 2b (2018) clarifies the endpoints that should be implemented when juvenile animal studies (JAS) are conducted. While Step 2b provides details on study methods, appropriate approaches and endpoints must be set on a case-by-case basis. In this presentation, we compare JAS in SD rats conducted at our facility since 2011 with the study design in Step 2b and propose designs we find most appropriate, focusing on 3 main points. Allocation: We used 4 allocation methods in the past JAS. Each method had both advantages and disadvantages, but the most important factor was body weight. In 11 of the 24 studies, a statistically significant difference was noted in body weight among groups at pre-dosing. Of the 11 studies, 8 were definitive JAS, and past results showed that an increase in the number of pups per group was not related to a decrease in bias (e.g. dose-range finding study: 6 to 8 pups/group, definitive study: 10 to 20 pups/group). Preweaning body weight is an important factor as it affects viability and subsequent growth, and nonuniformity in body weight among the groups at pre-dosing affects evaluation of development, one of the purposes of JAS. Accordingly, although it is a more complicated method, we propose allocation based on body weight of pups at allocation. First dosing age: Step 2b states that the first dosing age of pups should be equivalent to the youngest intended target human age. In 54% of 24 JAS conducted at our facility, dosing started from postnatal days (PND) 4 or 7. The current trend of the first dosing age is PND 7 since 80% of JAS conducted at SNBL started on PND 7 in the last 2 years. Neonates for humans is defined as 0-27 days old, and the corresponding time for humans is PND 0-9 for rats. We therefore propose PND 7 as an appropriate first dosing age when the clinical target is neonates in humans. Blood sampling: Although conventional preweaning blood sample collection is often conducted at terminal, we have established a sampling method from the submandibular vein that reduces the number of pups needed for toxicokinetics by approximately 45%. When we sampled 0.2 mL of blood once from PND 10 pups, returned them to their dam, and allowed them to nurse until weaning, no abnormalities were noted in clinical signs or body weight gain in comparison with historical control data. We therefore propose blood sampling from the submandibular vein in JAS in rats. Thus, if the design is set in consideration of the points above, more appropriate toxicity assessment becomes possible.

1597 Developmental Toxicity Studies of an AcetylCoA Carboxylase Inhibitor in Sprague Dawley Rats and New Zealand White Rabbits

N. R. Catlin[1], S. M. Engel[1], E. M. Lewis[2], and G. D. Cappon[1]. *[1]Pfizer Inc., Groton, CT; and [2]Charles River, Horsham, PA.*

Acetyl-CoA carboxylase (ACC) catalyzes the first step of *de novo* lipogenesis (DNL). Pharmacologic inhibition of ACC has been of interest for therapeutic intervention in a wide range of diseases. Developmental toxicity studies were conducted with a systemically acting dual ACC1/2 inhibitor (PF-05175157) in rats and rabbits with doses up to 30 and 50 mg/kg/day administered from GD6-17 and GD7-19, respectively. In rats, there were no effects on maternal body weight and no effects on embryo-fetal survival. Lower gravid uterine weights corresponding to lower fetal body weights were observed in rats at 30 mg/kg/day. Malformations and variations were observed in rat fetuses at 15 mg/kg/day (bifid thoracic centrum) and 30 mg/kg/day (gastroschisis; digit malformations; meningocele with irregularly shaped brain; malformed limbs, digits, or ribs; variations in the development of the skull bones, vertebrae, ribs, and sternebrae; ossification delays of the hyoid, caudal vertebrae and hindlimb phalanges). In the rabbit, maternal effects included lower body weight gain and food consumption at 50 mg/kg/day. Lower rabbit gravid uterine weights corresponding to increased postimplantation loss and reduced fetal body weights were observed at 50 mg/kg/day. Rabbit fetal findings observed at 50 mg/kg/day included short tail, malformed vertebrae or ribs, variations in the development of the skull bones, vertebrae, ribs, and sternebrae. Based on the data from these studies, inhibition of ACC results in developmental toxicity in both the rat and rabbit.

1598 *In Vitro* Evaluation of Acetyl-CoA Carboxylase Inhibitor-Mediated Developmental Toxicity

S. N. Campion, C. Stethem, and G. D. Cappon. *Pfizer Inc., Groton, CT.*

Acetyl-CoA carboxylase (ACC) catalyzes the first step of *de novo* lipogenesis (DNL). Pharmacologic inhibition of ACC has been of interest for therapeutic intervention in a wide range of diseases. PF-05175157, a systemically acting dual ACC1/2 inhibitor, caused developmental toxicity (fetal malformations and/or post-implantation loss) in embryo-fetal development studies in both the rat and rabbit. Additional studies in rat whole embryo culture [WEC], mouse embryonic stem cells [mESC], and zebrafish developmental toxicity assay were conducted to evaluate the utility of these *in vitro* assays in detecting ACCi-induced developmental toxicity. These are relevant models because ACC is expressed in rats and in mESC, and a zebrafish ortholog is present. Evaluation of PF-05175157 in the rat WEC assay revealed a concentration-dependent decrease in morphological scores for the majority of developmental structures, indicating the potential for a direct effect of PF-05175157 on the fetus. In the mESC assay, PF-05175157 showed high risk for teratogenesis. In contrast to the WEC and mESC assays, the zebrafish developmental toxicity assay did not predict the potential for ACCi-mediated developmental toxicity. This was not due to lack of zebrafish exposure, as PF-05175157 was detected in zebrafish in a dose-dependent manner. This work demonstrates that a battery of *in vitro* assays to screen compounds for developmental toxicity is more informative than any single assay.

1599 Gestational and Developmental Toxicity of Polychlorinated Biphenyls (PCBs)

N. Eti, V. E. Klenov, A. J. Rosa, K. N. Gibson-Corley, G. Ludewig, and L. W. Robertson. *University of Iowa, Iowa City, IA.*

Polychlorinated Biphenyls (PCBs) are persistent environmental pollutants with endocrine disrupting properties. Among 209 different congeners, PCB126 is the most potent dioxin-like toxicant which displays numerous adverse effects on human health, including female reproductive health. Our hypothesis is that prenatal exposure of PCB126 causes reproductive and de-

velopmental toxicity in rats. To test this, 12 timed pregnant Sprague Dawley rats (dams) were used. Dams received a single IP dose of corn oil (5mL/kg) or different doses of PCB126 (0.2, 1, 5µmol/kg) on gestation day (GD) 12 and were necropsied after 6 days on GD 18. PCB126 exposed dams showed significant weight loss compared to control dams. PCB126 significantly increased relative liver weight ($p<0.05$) and decreased relative thymus weight ($p<0.05$) compared to controls. It also caused mild to moderate macrovesicular vacuolation in the portal zone area of the liver (H&E stain). PCB126 exposed dams had low glycogen (PAS stain) in the liver. While control rats had no significant liver pathology. PCB126 significantly increased the expression of xenobiotic enzyme of CYP1A1 in livers compared to controls. In addition, serum cholesterol level was significantly increased and non-esterified fatty acids (NEFAs) was significantly decreased in PCB126 exposed dams. Significantly increased serum estradiol levels and significantly reduced plasma leptin level were measured in PCB126 exposed dams. PCB126 not only affected the pregnant dams but also the placentas and fetuses. It significantly decreased placental weight and caused necrosis in the placenta. It increased the thickness of the labyrinth zone in the placenta which may lead to intrauterine growth retardation (IUGR). It also increased the thickness of the basal zone in the placenta which may cause hormonal imbalance in mothers and fetuses. PCB126 significantly reduced number of viable fetuses and increased number of non-viable fetuses. It reduced the fetal body weight and increased implantation sites (sign of miscarriage) possibly due to observed dysregulation of estradiol homeostasis. The fetal sex ratio was skewed towards males in PCB126 exposed groups compared to controls. Therefore, our results show that even short time (6 days) *in utero* exposure to PCB126 impaired successful embryo development and produced endocrine and hepatic disruptions in pregnant mothers. *Supported by NIEHS: P42ES013661.*

PS 1600 Targeting Nrf2 through Lactational Transfer of Sulforaphane: Implications for Respiratory Syncytial Virus Severity in a Neonatal Mouse Model

D. B. McBee, J. Behlen, T. Mustapha, D. Pendleton, N. Drury, C. Lau, R. Shore, A. Rodrigues-Hoffmann, and N. Johnson. *Texas A&M University, College Station, TX.*

Early-life exposure to air pollution is associated with lower respiratory tract infections in infants and children. Data from our mouse model demonstrate *in utero* exposure to particulate matter (PM) causes offspring immune suppression and dampened response to respiratory syncytial virus (RSV) infection. RSV infection is the leading cause of severe respiratory illness and infant hospitalization. These data underscore the need for safe and effective strategies for mitigating oxidant-driven infant immune suppression. The Nrf2 antioxidant response plays an important role in oxidant-driven RSV pathogenesis, as well as PM-induced oxidative stress. Sulforaphane (SFN), a naturally occurring phytochemical found in cruciferous vegetables, targets Nrf2 to reduce oxidative stress. While this strategy has been employed in clinical trials and animal models, there are currently many unknowns in regards to Nrf2 activation early in life. Thus, our overall objective was to determine if maternal SFN supplementation via lactational transfer of SFN and/or its conjugates provides protection against neonatal RSV infection. Purified SFN, was incorporated into the diet of C57BL/6 female mice in 1-g aliquots of peanut butter at 200, 400 and 600 ppm for 3 days and compared to the vehicle control. Hepatic Nqo1, a prototypical Nrf2-regulated gene, showed a dose-dependent increase in expression, yet only reached statistical significance in the 600-ppm group. In subsequent experiments, SFN was incorporated in the maternal diet at 0, 300 or 600 ppm from delivery through postnatal day 5, based on the day of our neonatal RSV infection, when breast milk and plasma from dams and pooled litters was collected. Measurement of SFN and conjugated metabolites is ongoing using a modified HPLC-isotope dilution mass spectrometry method. Further evaluation of Nrf2 induction in dams and offspring and ultimately suppressed RSV infection will be completed. In conclusion, initial results indicate short-term maternal SFN supplementation enhances mRNA expression of Nqo1 and has potential implications for offspring protection during important windows of susceptibility. Future work will investigate the dual interaction of PM-enhanced RSV infection.

PS 1601 Assessing the Multigenerational Impact of Dietary Exposure to Benzo[a]pyrene

Z. Pandelides[1], C. Thornton[1], D. J. Decker[1], K. Thigpen[1], T. Smith[1], N. Aluru[2], and K. L. Willett[1]. *[1]University of Mississippi, University, MS; and [2]Woods Hole Oceanographic Institution, Woods Hole, MA.*

Polycyclic aromatic hydrocarbons, such as benzo[a]pyrene (BaP), are implicated in neural tube defects, growth deficits, cardiovascular toxicities, endocrine disruption, childhood cancers and infertility in offspring of exposed parents. However complete understanding of the molecular mechanisms for the developmental and potential multi/trans-generational effects associated with PAH exposures is lacking. Our previous work has revealed significant multigenerational effects of BaP dietary exposure on survival and developmental deformities in AB strain zebrafish larvae. The goal of this current study is to characterize the transcriptomic and epigenetic changes associated with preconceptional exposure to BaP. To accomplish this, 5D strain zebrafish were fed 78.3 or 708 µg BaP/g diet (measured) at a rate of 1% body weight twice/day (1.6 or 14 µg BaP/g fish/day) for 21 days. At the end of the 21-day parental exposure, fish were spawned using a crossover design, and the effects in F1 generation were monitored. In contrast to our previous findings, we did not observe any developmental effects in this study, suggesting that the AB zebrafish line may be more sensitive to exposure to BaP. However, a significant reduction in larval motility (96 hpf) was observed in the offspring of exposed fish. Furthermore, F1 fish were significantly shorter in length at 1 and 3 months of age. These results demonstrate that dietary BaP exposure causes adverse developmental outcomes to multiple generations that may be strain related. *Research is supported by NIEHS 1R21ES030154.*

PS 1602 Atrazine Exposure Produces Same Major Metabolites as Mammals Along with Adverse Developmental Effects

J. K. Ahkin Chin Tai[1], K. Horzmann[2], and J. L. Freeman[1]. *[1]Purdue University, West Lafayette, IN; and [2]Auburn University, Auburn, AL.*

Atrazine (ATZ) is a triazine herbicide that is the second most commonly used in the United States and heavily applied to crops in the Midwestern US. ATZ is highly mobile in soils and contaminates potable water sources. Due to contamination concerns, the US EPA has set the maximum contaminant level in potable water sources at 3 parts per billion (ppb;ug/l). Depending on the time of year and sampling location, water sources often exceed this limit. ATZ has a long half-life and has also been implicated as an endocrine disrupting chemical in multiple species. The current study used a biomedically relevant model, the zebrafish, to test the hypothesis that developmental ATZ exposure generates metabolites similar to those found in mammals and alters morphology and behavior in developing larvae. Adult AB zebrafish were bred, embryos were collected, and exposed to 0, 0.3, 3 or 30 ppb ATZ from 1 to 120 hours post fertilization (hpf). Targeted metabolomics analysis found that zebrafish produce the same major metabolites as mammals: desethyl atrazine, deisopropyl atrazine, and didealkyl atrazine with ATZ exposure. Morphology measurements show a significant increase in mean head width in the 0.3 ppb treatment group ($p<0.05$). No change in total length was found between treatment groups ($p>0.05$). The visual motor response test detected hypoactivity in the 3 and 30 ppb treatment groups with distance moved ($p<0.05$) and slowest acceleration ($p<0.05$). These findings suggest that a single ATZ exposure during early development generates metabolite profiles similar to mammals and leads to morphology and behavior alterations supporting ATZ as a developmental toxicant.

PS 1603 Holistic Models for *In Vitro* Embryotoxicity Testing: Do We Need Standardized Morphological Endpoints and Terminology?

B. Flick[1], A. Dehne[2], V. Giri[1], R. Landsiedel[1], and B. van Ravenzwaay[1]. *[1]BASF SE, Ludwigshafen am Rhein, Germany; and [2]Technische Universität Kaiserslautern, Kaiserslautern, Germany.*

To address prenatal developmental toxicity (PDT), the OECD 414 is the regulatory required study for the registration of new chemicals. Alternative methods are under evaluation to be used in test batteries or IATAs. Holistic models with their complex physiological organized organ anlagen, like the zebrafish embryotoxicity assay (ZETA), provide the opportunity to cover various mode of actions of PDT. The ZETA is in broad use for screening purposes in development of new chemicals. For practical reasons morphological endpoints are primarily used, like in the related *in vivo* test. To assess the fetal development in rats about 300 morphological parameters with harmonized terminology are used. Even the zebrafish does not offer as many morphological endpoints, in most protocols less than 20 parameters are used and no broadly accepted protocol is available. To investigate the potential consequences of non-harmonized protocols we investigated 2 chemicals with the ZETA in three test facilities. In general, the culture conditions were comparable, but the morphological scoring was based on 17, 18 or 38 endpoints. The terminology differed in almost all parameters. Only 8 parameters could be linked to comparable morphological endpoints. The NOEC were reproducible in the different test facilities and ranged between 1-4 µM for Ketoconazole, and 10-12.5 µM for Tebuconazole. But the treatment related morphological alterations determining the LOEC differed: Ketoconazole - brain, jaw, or nasal cavity; and; Tebuconazole - heartbeat, heart edema, or brain. Thereby, the pattern of

morphological alterations for the test substances was not reproducible. The prediction of PDT of the test substances in mammals as well as the detection of the craniofacial alteration expected for the investigated azoles was only determined by the test facility using the comprehensive scoring system. Even the morphological scoring provides only limited conclusion of the mode of action of test substances, the potential of morphological endpoints of the ZETA is not always used yet to describe the test substance specific pattern of alterations. A broad and harmonized morphological scoring system, based on common terminology, is needed to reach interlaboratory reproducibility and increase the acceptance of this assay used as an example of holistic models.

1604 E-cigarette Vaping Liquids and a Flavoring Chemical Perturb Bone, Cartilage, and Vascular Development in Zebrafish Embryos

B. Bhattacharya, V. Narain, and M. Bondesson. *Indiana University, Bloomington, IN.*

Electronic cigarettes are an increasingly popular smoking device, especially among adolescents and youth. E-cigarettes are perceived to be a safer alternative to tobacco cigarettes leading to that pregnant mothers may replace tobacco smoking with e-cigarette use. However, whether these products have any side effects on the developing embryo has not been thoroughly evaluated. We tested cinnamon flavored e-liquids (with 12 mg/ml nicotine and without nicotine) and the flavoring chemical cinnamaldehyde on zebrafish embryonic development. We studied possible effects on hatching success, bone, cartilage and blood vessel development in 3-4 days old transgenic zebrafish larvae. Our study showed that the e-cigarette liquids significantly affected craniofacial bone and cartilage development. Exposure also resulted in structural malformations in intersegmental blood vessels. Hatching frequency was significantly delayed by vaping liquid exposure. Presence of nicotine in the e-liquid only slightly augmented the perturbations identified. Exposure to the favoring chemical cinnamaldehyde induced similar malformations as the vaping liquids, but at ten times lower concentration. Exposure to the humectant propylene glycol, present in e-liquids, did not cause any visible effect on hatching or bone development in zebrafish larvae at the concentrations tested. In conclusion, we show that exposure to cinnamon flavored e-cigarettes or the flavoring chemical cinnamaldehyde during embryonic development cause significant structural malformations in bone, cartilage and vasculature.

1605 Transcriptional Dysregulation in Zebrafish Larvae Exposed to Sodium Arsenite and Uranyl Nitrate

P. H. Kalaniopio, R. S. Allen, M. A. Kaus, and M. C. Salanga. *Northern Arizona University, Flagstaff, AZ.*

Arsenic (As) and uranium (U) are naturally occurring contaminants frequently encountered in the Southwest United States. Human exposure to As and U comes in many forms including inhalation of contaminated dust and ingestion of contaminated food or water. Highlighting the Southwest US, exposure risk in the form of contaminated drinking water represents a major health disparity for many Native Americans living in tribal communities where barriers to clean drinking water exist. In these regions, As and U levels often exceed current EPA standards of 10 µg/L and 30 µg/L respectively, sometimes by orders of magnitude. For example, the Verde River in central Arizona has As levels documented up to 1300 µg/L. Morbidities resulting from high As or U exposure are well documented, but recent studies find that even moderate levels of exposure (levels at or near EPA limits), are associated with negative health-related outcomes. It is crucial that we understand the effects of environmentally relevant concentrations of As and/or U on an organism's health span. In these studies, we use the zebrafish (*Danio rerio*) as a vertebrate laboratory-test species and RNA-seq transcriptomics to test the hypothesis that As, U, or a mixture of the two will elicit significant differential gene expression in exposed organisms that include genes linked to human health. In our studies we used water containing inorganic arsenic in the form of sodium arsenite (75 µg/L and 750 µg/L), depleted uranium in the form of uranyl nitrate (30 µg/L and 300 µg/L), or a mixture of the two chemicals (75 µg/L and 30 µg/L respectively) to expose zebrafish embryos from 1 hour post-fertilization (hpf) to 96 hpf. Treatment solutions were not acutely toxic to embryonic zebrafish at the concentrations used. All test-subjects were collected at 96 hpf, total RNA was isolated, and RNA-seq libraries were prepared and sequenced at a depth of ~20 million reads/sample. Transcriptomic analysis showed significant differentially expressed genes for all chemical perturbations compared to the vehicle control with some occurring only at the high concentrations and others at both high and low concentrations. For example, low As altered 47 genes (29-up and 18-down), high As altered 143 genes (119-up and 24-down). Low U altered 16 genes (10-up and 6-down) and high U altered 296 genes (181-up and 115-down). Finally, concomitant exposure to low As and low U resulted in 77 differentially expressed genes (65-up and 12-down). We are further interrogating these data to determine if synergistic dysregulation of gene targets can be identified in the combined As and U exposure. *These studies were supported by NIH 1R25GM127199-01 (RSA), NSF HRD1712523 (PHK).*

1606 Assessment of Developmental Toxicity from Embryonic Exposures to the Emerging Contaminant Tris(4-Chlorophenyl) Methanol (TCPMOH)

J. M. Navarrete, A. Schwartz, P. Wilson, C. Gordon, and K. E. Sant. *San Diego State University, San Diego, CA.*

Tris(4-chlorophenyl)methanol (TCPMOH) is an emerging water contaminant with unknown etiology, but is believed to be a byproduct of DDT manufacturing. It is highly persistent in the environment and bioaccumulates, and is commonly found in marine mammals around the world. TCPMOH has also been measured in human breast milk which poses a risk for developing infants. However, almost no toxicity data is currently available. In this study, we investigate the hazard posed by developmental TCPMOH exposures using the zebrafish model (*Danio rerio*). Zebrafish (*Danio rerio*) embryos were exposed to 0, 1, or 5 µM TCPMOH beginning at 24 hours post fertilization (hpf). We assessed survival, overall growth, and morphology in embryos at 96 hours post fertilization. QPCR was utilized to assess gene expression of enzymes in phase I and phase II metabolic pathways. Developmental exposure to TCPMOH increased embryonic mortality in a dose-dependent manner. Pericardial edema, yolk edema, and craniofacial malformations were increased with TCPMOH exposure. Total growth was significantly increased in the 1 µM embryos, but significantly decreased in embryos exposed to 5 µM TCPMOH ($p < 0.05$). These results demonstrate that developmental TCPMOH exposures can negatively impact embryonic growth and development. Overall, this study demonstrates that the emerging contaminant TCPMOH is a toxicological concern, and further studies are required to elucidate the mechanisms of toxicity.

1607 Analyzing Estrogenicity of Bisphenol Analogues Using Transgenic Zebrafish

S. Karim[1], C. Pinto[2], R. Hao[2], M. Grimaldi[3], P. Balaguer[3], and M. Bondesson[1]. *[1]Indiana University Bloomington, Bloomington, IN; [2]University of Houston, Houston, TX; and [3]Université de Montpellier, Montpellier, France.*

Bisphenol A (BPA) has been widely used to make epoxy resin, polycarbonate plastics and other materials over the past decade. It is one of the most common environmental pollutants. Exposure to BPA has possible hazardous effects on the human brain, heart, liver, and blood, partly because of its estrogenic activity. BPA analogues have been synthesized to be considered as replacement molecules for BPA. These analogues need to be thoroughly evaluated for their estrogenic activity. We used transgenic *Tg(5×ERE:GFP)* zebrafish to study agonistic and antagonistic estrogenic effects of bisphenols *in vivo*. Three days old zebrafish embryos were exposed to a concentration range of BPA, BPC-CL, BPAF, BPC and BPE, incubated and imaged at day four by fluorescence microscopy. The fluorescence in images were quantified by ImageJ. The exposures to BPA, BPAF, BPC and BPE efficiently induced GFP expression first in the heart valves and at higher doses in the liver, whereas BPC-CL activated GFP expression in the liver and brain, although the GFP expression was reduced at the highest concentration. The GFP expression in fish was compared to estrogen response in reporter cells that express the zebrafish estrogen receptors driving expression of an ERE-luciferase reporter. BPC-CL preferentially activated esr2a, whereas BPA, BPAF, BPC and BPE preferentially activated esr1. We conclude that transgenic estrogen reporter fish in combination with estrogen reporter cells efficiently can be used to assess estrogenic capacity of environmental pollutants.

1608 Assessing Glutathione Utilization and Target Organs of Toxicity in a Complex PFAS Mixture

C. W. Clark, K. M. Annunziato, A. Rastogi, and A. R. Timme-Laragy. *University of Massachusetts Amherst, Amherst, MA.*

Aqueous film forming foam (AFFF) is a major source of per- and polyfluoroalkyl substances (PFAS) contamination in the environment, especially for contaminated drinking water. AFFF contains a complex mixture of at least 100 different PFAS, hydrocarbons, and solvents. We recently received a legacy 3% formulation of AFFF (manufactured prior to 2002) and have demonstrated

that this mixture is more toxic than the most abundant PFAS in this formulation, perfluorooctanesulfonic acid (PFOS). PFOS is known to cause redox stress and perturb glutathione (GSH), the most abundant endogenous redox buffer; GSH also plays key roles in organogenesis and embryonic development. Monochlorobimane (MCB) has been found to be a robust and sensitive method to detect the spatiotemporal changes in GSH utilization *in vivo* and was used in the current study to identify target tissues of low, sublethal exposure concentrations of AFFF. Zebrafish (*Danio rerio*) embryos were exposed at 3 hours post-fertilization (hpf) to two concentrations of AFFF, and solutions were refreshed daily. At 48 hpf, embryos were washed and incubated in 20 μM MCB for 1 hour and imaged on a fluorescence microscope. A treatment of 1.1e-4% AFFF (n=15 fish) resulted in a 23% increase ($p < 0.008$) in the fluorescence of the embryo's body overall, but an 18% decrease ($p < 0.03$) of fluorescence in the gut. Doubling the concentration to 2.2e-4% AFFF (n=17) resulted in a 13% ($p < 0.02$) increase in fluorescence of the embryo's body and a downward trend in the fluorescence of the gut ($p < 0.2$), a similar trend as seen in the 1.1e-4% dose. Fluorescence of the body shows an inverted "U-shaped" response curve with increasing AFFF concentration suggesting that the larvae are more sensitive to disruption of GSH homeostasis at low concentrations. MCB staining indicates disruption of redox state and sensitive changes in GSH at lower AFFF concentrations. These redox perturbations in the gut precede impaired growth of the liver and exocrine pancreas observed at 96 hpf. *This work is supported in part by the UMASS Amherst Commonwealth Honors College Research Grant, R01ES025748, and R01ES028201.*

1609 Developmental and Nutritional Impacts of Maternal Preconception Exposure to PFOS

M. Marin[1], K. M. Annunziato[1], J. Lee[1], W. Qi[1], B. Barbagallo[2], Y. Park[1], J. M. Clark[1], and A. R. Timme-Laragy[1]. *[1]University of Massachusetts Amherst, Amherst, MA; and [2]Salve Regina University, Newport, RI.*

Perfluorooctanesulfonic acid (PFOS) is a ubiquitous and persistent environmental toxicant that can be found in human urine and serum samples, including cord blood. In zebrafish (*Danio rerio*), embryonic exposures to PFOS have been shown to affect developmental endpoints and pancreatic organogenesis. However, the effects of maternal preconception exposure to PFOS on the offspring have not yet been examined. Therefore, using an evolutionary approach, this study aims to investigate and compare the effects of maternal preconception exposures to PFOS on morphological and nutritional endpoints in three different species: Zebrafish, *Caenorhabditis elegans* and *Drosophila melanogaster*. Adult female fish were exposed to either 0, 0.08, 0.14 or 0.25 μg/mL of PFOS for 7 days. Following exposures, female fish were paired with unexposed male and bred daily for two weeks. Hermaphrodite worms were exposed to 0, 10, 20 or 40 μM of PFOS. *D. melanogaster* female adults were exposed for 24 hours to either 0.2 ng/μL of PFOS or acetone prior to mating. Developmental and nutritional endpoints were measured. In all three models, exposures to PFOS caused developmental impairment. In *C. elegans*, adults exposed to PFOS (20 and 40 μM) had a significant decrease in broodsize and progeny number. Also, the offspring showed significant decrease in locomotive activity and size. In *D. melanogaster*, exposure to PFOS led to developmental delay in embryos and significant decreased weight in adults. In zebrafish, the first clutch of embryos from the 0.08 PFOS group had significant increase in yolk sac area that persisted to 120 hpf. By later collections, there was a significant decrease in length and pancreatic beta-cell area in embryos collected from the same group. Preconception exposures also influenced nutrient composition in *C. elegans* embryos, significantly decreasing triglycerides (20 μM group) and protein content (40 μM group). Interestingly, adult male and female offspring of maternally exposed *D. melanogaster* showed significant changes in cholesterol and triglycerides levels. Finally, PFOS was detected in zebrafish and *C. elegans* embryos. Together, these alterations seen in all three models suggest that preconception exposures to PFOS may impact oocyte maturation and nutrient loading in the offspring, possibly through maternal transfer of the toxicant into the eggs. *This work is funded by R01ES028201.*

1610 Bisphenol A-Induced Perturbations in Cellular Behavior during Murine Early Germ Cell Specification

S. K. Ooi, H. Jiang, Y. Kang, and P. Allard. *University of California Los Angeles, Los Angeles, CA.*

Through the environment, humans are exposed to a large number of different toxicants that have detrimental consequences on our health. A particular concern are the nature of these chemicals and their mechanism(s) of action and how they affect the normal physiology of different organs. Effects on the reproductive system, specifically the processes responsible for gametogenesis, are pertinent as any disruptions (genetic and/or epigenetic) have the potential to manifest as disease in the next generation and result in their trans-generational inheritance. Using an *in vitro* model of mouse primordial germ cell (PGC) development, we have examined the cell biological consequences of defined exposure to the chemical Bisphenol A (BPA). Exposure of Epiblast-like cells (EpiLCs) results in increased cellular proliferation, combined with reduced apoptosis and increased DNA damage. Despite transcriptome analysis of BPA-exposed EpiLCs suggesting the absence of large-scale transcriptional defects, this increase in proliferation persists during the transition into PGCLCs, indicative of an epigenetic basis for this altered behavior. Combined with the increased proportion of cells with DNA damage, this implies that BPA might result in the foundation of gametes with more germ cell precursors containing both genetic and epigenetic alterations. Our data provide novel insight into the aberrant effects of an abundant environmental toxicant during a crucial developmental stage that hitherto has been difficult to study.

1611 Validation of a Human Stem Cell-Based Biomarker Assay for *In Vitro* Developmental Toxicity Assessment

P. Racz, I. Brandsma, S. Hartvelt, T. Zwetsloot, and G. Hendriks. *Toxys B.V., Leiden, Netherlands.*

Testing for developmental toxicity according to the current OECD guidelines requires large numbers of animals, making these tests very resource intensive and time-consuming as well as raising ethical concerns. In the last 20 years, several alternative *in vitro* assays have been developed but these often suffered from a low predictivity, the lack of mechanistic information and inter-species differences. To improve *in vitro* developmental toxicity testing, we have developed a human induced pluripotent stem cell (hiPSC)-based biomarker assay that follows the differentiation during early embryonic development. The hiPSC were directed to differentiate into the three germ layer specific cell types, hepatocytes, cardiomyocytes and neural rosettes. During differentiation, expression of the pluripotency marker OCT4 decreased, while expression increased for matured tissue specific markers MYH6 in cardiomyocytes, AFP in hepatocytes and PAX6 during neural rosette differentiation. Alterations in the expression pattern of these biomarker genes upon chemical exposure indicated perturbation of stem cell differentiation and thereby teratogenicity. To test the ability of the assay to identify developmental toxicity in differentiating hiPSC cells, we first tested 10 teratogenic and 5 non-teratogenic compounds at non-cytotoxic conditions during cardiomyocyte and hepatocyte differentiation. The assay classified thirteen compounds correctly as teratogenic or non-teratogenic substance with 80% sensitivity and 100% specificity. Next, the validation was extended with 40 additional reference compounds as described by the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH S5 (R3)) and we were able to identify teratogenic compounds with different modes of action, including enzyme modulators, channel modulators and second messenger modulators. In conclusion, following the differentiation program by using selected biomarker is a suitable tool to quantify differentiation and could be used as a primary screen to identify chemicals with a high potential for DART.

1612 *In Vitro* to *In Vivo* Extrapolation for Developmental Toxicity Potency of Valproate Analogues

X. Chang[1], A. Lumen[2], J. Palmer[3], U. J. Lee[2], P. Ceger[1], B. Donley[3], S. Bell[1], D. G. Allen[1], W. Casey[4], and N. C. Kleinstreuer[4]. *[1]Integrated Laboratory Systems Inc., Research Triangle Park, NC; [2]US FDA/NCTR, Jefferson, AR; [3]Stemina Biomarker Discovery Inc., Cambridge, MA; and [4]NIEHS/NTP, Research Triangle Park, NC.*

To support implementation of alternatives to animal testing for regulatory decision-making for developmental toxicity, several case studies have been developed under the European Union ToxRisk project. In one case study, the teratogenic potency of ten valproate (VPA) analogues was investigated using an *in vitro* human induced pluripotent stem cell (iPSC)-based assay, the devTOX quick Predict assay (devTOX^{qP}). Previous work showed that the potency ranking from devTOX^{qP} was consistent with observed developmental toxicity potency *in vivo*. In this study, we applied *in vitro* to *in vivo* extrapolation (IVIVE) to evaluate the impact of pharmacokinetics and different modeling approaches on predicting relevant external exposure from *in vitro* developmental toxicity potential concentrations derived from the iPSC devTOX^{qP} assay. We used several pharmacokinetic models, including an open-source one-compartment model and both open-source and commercial physiologically-based pharmacokinetic pregnancy models. The IVIVE analysis estimated equivalent administered doses (EADs) that would result in maternal blood concentrations equivalent to the developmental toxicity potential and cytotoxic *in vitro* concentrations. The estimated EADs were compared to published lowest effect levels (LELs) from *in vivo* developmental toxicity studies.

Our preliminary results showed close agreement between EADs and *in vivo* rat LELs for two VPA analogues (within 3.5-fold), suggesting that the devTOX^{qP} assay and IVIVE approaches are suitable for quantitatively predicting *in vivo* developmental toxicity potential. This study highlights the importance of pharmacokinetic considerations in assessing a chemical's developmental toxicity potency based on *in vitro* assays. *This project was funded with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C.*

1613 Somatic Growth and Immune System Effects Observed Experimentally Following Pre- and Perinatal Exposure to Δ^9-THC

P. Iyer, Y. Niknam, M. Campbell, F. Moran, K. L. Wu, F. L. Kaufman, A. Kim, M. S. Sandy, and L. Zeise. *California EPA, Sacramento, CA.*

Legalization of adult use of cannabis and its extracts in many states has raised public health questions about use during pregnancy. Here we discuss somatic growth and immune system effects examined in experimental studies investigating the potential of Δ^9-THC to cause developmental harm. Effects on embryo development and implantation, and later stages of embryo and fetal development were evaluated in various species using *in vivo*, *ex vivo* or *in vitro* model systems. Cellular and molecular level effects were included. Study quality (e.g., methodology, group size, unit used for statistical evaluation (litter or fetus), overall reporting) was also considered. Rodent and rabbit studies of pre-conceptional or prenatal oral exposure to Δ^9-THC reported: increased fetal, perinatal, or postnatal offspring mortality (eight experiments); decreased fetal or birth weights (seven experiments); and altered hormone levels or fertility in F1 male offspring (six experiments). Similarly, in studies by parenteral routes of exposure, decreases in fetal or birth weights, and increases in fetal, perinatal, or postnatal offspring mortality were reported. Following postnatal exposure to Δ^9-THC, decreased femoral length in female pups was observed; and following exposure of mouse primary chondrocyte cultures, inhibition of chondrocyte differentiation was reported. Decreased thymic cellularity and increased apoptosis that lasted for several days were observed following prenatal Δ^9-THC exposure. Decreased T cell function in prenatally exposed mice one week after birth has also been reported. The possible role of Δ^9-THC to act via the endocannabinoid system to cause some of the observed effects is discussed.

1614 *In Utero* Exposures to Trichloroethylene and the Development of Congenital Heart Defects: A Systematic Evaluation of the Mechanistic Data

J. D. Urban[1], D. S. Wikoff[2], G. A. Chappell[2], C. Harris[3], and L. C. Haws[1]. *[1]ToxStrategies Inc., Austin, TX; [2]ToxStrategies Inc., Asheville, NC; and [3]University of Michigan, Ann Arbor, MI.*

The hypothesis that *in utero* exposures to low levels of trichloroethylene (TCE) may increase the risk of congenital heart defects (CHDs) in offspring continues to be a subject of substantial controversy within the scientific community, as the principal supporting evidence is a single, irreproducible experimental study in rats. Our previous systematic evaluation of this hypothesis focused on assessment of the risk of bias for epidemiological and experimental animal evidence streams. The objective of the current study was to conduct a systematic evaluation of mechanistic data related to *in utero* exposures to TCE and the development of CHDs. The current TCE-CHD mechanistic evidence base consists of 22 published studies, collectively comprised of more than 70 individual experimental datasets. The datasets were very heterogenous, characterizing endpoints which ranged from molecular to organismal responses in seven species, involving both *in vivo* and *in vitro* study designs in mammalian and non-mammalian models. Of these, 24 datasets were considered reliable following critical appraisal using a study quality tool that employs metrics specific to the study type. Subsequent data synthesis and integration of the mechanistic evidence led to the following conclusions: 1) the database does not support an association between TCE exposure and CHDs, 2) the database does not support the biological plausibility of a response based on assessment of a putative adverse outcome pathway for valvulo-septal cardiac defects, and 3) no datasets were found suitable to serve as candidate studies in risk assessment. Findings supportive of an association were generally limited to *in ovo* chicken studies, in which TCE was administered in high concentrations via direct injection. Results of these *in ovo* studies were difficult to interpret for human health risk assessment given the absence of avian *in vivo* studies and a lack of generalizability of the study models (including dose relevance, species-specific biological differences, variations in the construct of the study design, etc.). Integration of the mechanistic data with findings from previous evaluations of human and animal evidence streams further demonstrates a lack of association between *in utero* exposure to TCE and CHDs in humans.

1615 Linking Lipid and Cholesterol Dysregulation to Cardiac Development in Phenanthrene-Exposed Zebrafish Embryos

V. McGruer, P. Tanabe, S. M. Vliet, S. Dasgupta, D. C. Volz, and D. Schlenk. *University of California Riverside, Riverside, CA.*

In 2010, the *Deepwater Horizon* (DWH) oil rig explosion released over three million barrels of crude oil into the Gulf of Mexico. The timing of the spill coincided with the spawning of many marine species in the region including mahi-mahi. Previously, RNA-sequencing and mRNA analysis in oil-exposed mahi found significant increases in the abundance of transcripts along the cholesterol biosynthetic pathway. Cholesterol is essential for cardiac development and the disruption of cholesterol and lipid pathways through exposure to polycyclic aromatic hydrocarbons (PAHs) may contribute to the well described cardiotoxicity phenotype in developing fish embryos. To better characterize mechanisms underlying oil-induced lipid and cholesterol declines, zebrafish embryos at 6 hours post-fertilization (hpf) were exposed until 72 hpf to three concentrations of phenanthrene (a reference PAH found in oil), with subsequent qPCR analyses of several genes involved in cholesterol synthesis, as well as staining for cholesterol and neutral lipids. Fluorescence microscopy revealed a significant decrease in antibody-bound cholesterol (14.2% ± 0.6) in the larval body with an even greater reduction in the heart (43.6% ± 1.9). Oil Red O staining for neutral lipids demonstrated decreased staining in the larval head and trunk (5.7% ± 0.5). These reductions corresponded with pericardial edema and bradycardia, as well as increased yolk size. Additionally, when embryos were treated from 6 - 24 hpf with 10μM water-soluble cholesterol, followed by 20-25μM phenanthrene from 24-48 hpf, heart rate increased by an average of 10.7% ± 0.7 across all cholesterol pretreated groups, indicating that cholesterol has a protective effect against bradycardia though the rescue is not specific to phenanthrene treatment. Studies are currently underway to address whether the reduction in cholesterol observed at 72hpf is a result of the maldeveloped heart, which then impairs yolk utilization, or if changes in cholesterol may be impacting downstream development, including heart formation. *This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER).*

1616 Intratracheal Administration in Juvenile Sprague Dawley Rats

J. Laporte, H. Mirsadeghi, A. Fotovati, K. McInally, and P. Aughton. *ITR Canada, Baie-D'Urfe, QC, Canada.* Sponsor: W. Ruddock

Data generated from juvenile toxicity studies can contribute to the assessment of potential drug toxicity in the pediatric population that are not adequately assessed in reproductive toxicity risk assessments and standard toxicology studies. Direct intratracheal administration is a highly effective pulmonary delivery route bypassing first-pass metabolism and permitting a direct and local delivery of a small amount of drug to the lungs. The objective was to establish a single and repeat intratracheal administration of saline in juvenile Sprague-Dawley rats at 4, 10 and 14 days of age. Prior to intratracheal administration of saline, each juvenile rat was anesthetized by inhalation of an isoflurane / oxygen mixture. The tracheal opening was located in rats using the transillumination method. Saline (≤1 mL/kg) was delivered using a Penncentury® Microsprayer or a feeding needle (24G X 1cm). To confirm the intratracheal dosing procedure, some rats were dosed with Evan's blue dye mixed in saline and determined in lungs at necropsy. Rats were dosed once or daily with saline for 5 consecutive days. Mortality, clinical signs and body weight were monitored after dosing. Rats were euthanized upon completion of dosing and blood was collected via cardiac puncture. Lung weight was measured and bronchoalveolar lavage was collected. Rats survived a single and repeated dose of saline using the trans-illumination method with a Penncentury® Microsprayer or feeding needle administration with minimal clinical signs. In addition, dose volume, bodyweight, blood and bronchoalveolar volumes will be used as a reference for future juvenile toxicology studies.

1617 Hematology and Biochemistry Reference Data in Juvenile Rats at Four, Seven, and 21 Days of Age

B. Attalla, and J. Younan. *ITR Canada, Baie-D'Urfe, QC, Canada.* Sponsor: W. Ruddock

Due to physiologic differences between neonates, children and adults, juvenile animal models of relevant age must be used as test systems in non-clinical studies, in order to evaluate the safety of drugs targeting pediatric human patients. Inherent differences exist between mature and immature biolog-

ical systems. As such, certain markers of toxicity, like the clinical pathology parameters of juvenile animals differ from those of their adult counterparts. Therefore, for the interpretation of results observed in juvenile toxicology studies, age-specific sets of standard clinical pathology parameters are needed for reference. In order to obtain reference hematology and clinical chemistry data from naive Sprague Dawley rat pups, our laboratory collected, processed and analyzed samples from a total of 391 male and female animals at Post Natal Days (PND) 4, 7, and 21. The standard hematology and clinical chemistry parameters used in general toxicology studies were measured from rat pups at each of the critical stage mentioned above. Each parameter was statistically analyzed and compared to the datasets available from adult Sprague Dawley rats. The data analyses showed important differences in the early stages of development when compared to data obtained from adult rats. In addition, the clinical pathology data obtained from rat pups at different stages of their development can be used as a reference ranges for juvenile toxicology studies.

1618 Drug Administration in Neonatal and Juvenile Rats: Challenges and Opportunities

B. Attalla, and J. Younan. *ITR Canada, Baie-D'Urfe, QC, Canada.* Sponsor: W. Ruddock

As regulatory agencies now require that the safety of drugs aimed at treating medical conditions affecting pediatric patients be assessed in juvenile animals, there is an increasing need for neonatal and juvenile animal models of relevant age to be used as test systems in non-clinical studies. The administration of test materials to neonatal and juvenile rats presents several challenges including, the size of the animal, its fragility and the lack of acclimation to the procedures, such as dosing and handling. Our laboratory developed techniques to administer dose formulations intravenously, intramuscularly or subcutaneously to rats as young as two days of age, and as often as twice daily, and by oral gavage to rats as young as four days of age. Given the small size and the fragility of the rats at such a young age, animals are identified using a unique tattoo system that employs indelible digit ink. For dosing, animal movement is usually restrained using wet ice, which also serves as anesthetic. Animal handling prior to and during dose administration, as well as the animals' recovery following dosing are critical to the success of the techniques. Another major challenge is data interpretation, since the biological systems of neonatal, juvenile and adult populations are different. We compiled a database for clinical pathology parameters from naïve rat pups at 4, 7, 14, and 21 days of age. Such database will greatly help interpretation data obtained from pups of different ages.

1619 Effects of Toxicological Test Process on Juvenile Animal Development

M. Lee, M. Kang, H. Chung, S. Ju, J. Jeong, H. An, and D. Kim. *Biotoxtech Co Ltd, Cheongju-si, Chungcheongbuk-do, Korea, Republic of.*

In medical field, the need for safety testing of drugs treating children has been continuously demanded. Adults and children may have different tolerance or mechanisms of toxicity due to their differences in drug sensitivity. So importance of guidelines requiring safety and efficacy of drug for children is emerging because of about 70% of drugs currently on the market are marketed based on non-clinical and clinical trial results from mature individuals. In line with these trends, we continued to conduct toxicity tests on juvenile animals and investigated the impact of these toxicological treatments on juvenile animals. The effect of toxicological treatment was confirmed by using 10-12 weeks old rats which one group of rats that received oral administration of injection water for 8 weeks from 3 weeks after birth and other group of rats that received water orally for 4-6 weeks from 6 weeks after birth. As a result, we found a significant increase of weight gain in group of rats that were treated for 8weeks from 3 weeks after birth. It has been confirmed that the overall health effect of toxicological treatment is insignificant except in weight gain by comparing the relative weights of other organs, (brain, heart, kidney, liver, etc.) other parameters shown slight changes which were within the normal range. These results showed that our toxicity test process for juvenile animals could confirm stable and consistent results in toxicity test.

1620 Use of Extended One-Generation Reproductive Toxicology Studies in Safety Assessments under REACH Regulations

E. Marco-Gregori, F. Spézia, A. Decheix-Nguyen, F. Gervais, A. Sénéchal, S. Loriot, and P. Singh. *Charles River, Evreux, France.*

The safety of chemicals imported into or produced in Europe must be evaluated according to volume, within the scope of REACH regulations. Part of the testing strategy is covered by OECD test guideline 443, which describes the objectives and procedures of the Extended One-Generation Reproductive Toxicity Study (EOGRTS) in rats to be performed on chemicals with volumes over 100 tons if effects are observed in prenatal testing (OECD 414). We have validated methods for the evaluation of EOGRTS endpoints in the parental (P) generation and in three cohorts of their offspring (F1 generation): Cohort 1 to assess reproductive and developmental endpoints and to monitor reproductive performance through mating and parturition; Cohort 2 to assess the impact of chemical exposure on the developing nervous system using neurobehavioral evaluations and brain morphometry measurements; and Cohort 3 to assess potential effects on immune function. In P and cohort 1a and 1b groups, data were collected during evaluations of vehicle treated animals providing normal reference values for P and F1 reproductive and developmental endpoints. For cohort 2, a validation study of the auditory startle apparatus was performed by comparing startle reflex responses in Clonidine treated rats and untreated rats. Decreased amplitudes and increased latency in these responses were detected in clonidine treated rats, demonstrating reliability and sensitivity of the test system. For cohort 3, a reference study was conducted comparing anti-KLH IgM concentrations before and 5 days after KLH immunization. Increased serum concentrations of anti-KLH IgM were observed in animals after immunization, demonstrating a reliable, antigen-specific immune response. In conclusion, these methods show how the EOGRTS study can be used to provide relevant reproductive and developmental, neurological and immune function data for the safety assessment of chemicals under REACH Regulations.

1621 Procedure Development for Repeat Infusions in Juvenile Monkeys

N. Lalayeva, J. Reynolds, G. Aylor, J. Forget, and T. Rogers. *Altasciences, Everett, WA.*

With the increase of pediatric pharmaceuticals in preclinical studies, the ability to learn and adapt to the use of a younger and smaller test model is necessary to assure process evolution and stress reduction on the research animals. The cynomolgus macaque is a commonly used non-human primate in research. Method development for a repeated-infusion dose in juvenile non-human primates required a united effort to create a concise study and equipment design, with animal welfare at the forefront of all considerations. The routine method for infusion restraint included the use of a procedure cage where all limbs were secured, providing limited movement. This method would be highly stressful for the animals under a year of age needed for the proposed study (juvenile animals 6 to 9 months of age at initiation of dosing). To avoid stress, the "snuggle wrap" method was developed to allow young animals to remain immobile while still feeling comforted by a hugging-like sensation. Stress behaviors were noticeably reduced when using the snuggle wrap compared to manual holding as a restraint method. The snuggle wraps were designed for vein accessibility, while the remaining limbs are secure and comfortable. Given that social pairs needed to remain in proximity, the "snuggle board" was also developed. Animals were implanted with RFID chips, and the wrapped juveniles were labeled with temporary ID cards to allow for easy identification once snuggled and placed on the board. These boards hold 4 snuggled animals closely together which keeps social pairs in visual and auditory contact during dose administration. Following catheter placement, dosing limbs were secured with Velcro straps for the dose duration. Animals were visually monitored, provided treats, juice, light projections, and chewing toys throughout dose duration by trained technicians. The snuggle board restraints were used for ~13 weeks, until the animals were over a year old and large enough for the procedure cage. This method was also successfully implemented in animals as young as 3 months.

1622 Gestational Low-Dose Exposure to Arsenic Leads to Adverse Metabolic Alterations in Adult Mice: A Perspective on Fetal Reprogramming of Metabolism

S. Shukla[1,2], S. Gangopadhyay[1,3], A. Chauhan[1,3], D. C. Sharma[2], and V. Srivastava[1,3]. *[1]CSIR-Indian Institute of Toxicology Research, Lucknow, India; [2]Dr Shakuntala Misra National Rehabilitation University, Lucknow, India; and [3]AcSIR, Ghaziabad, India.* Sponsor: K. Ansari

Maternal stress or exposure to certain toxicants alter fetal growth and can have permanent effect on offspring, leading to increased predisposition to cardiovascular, metabolic and neuropsychiatric disorders. Maternal exposure to arsenic is a common health menace in many countries but little is known about its effect on disease risk in the exposed progeny. In the current experiment we evaluated the long term effect of only prenatal exposure to arsenic in terms of fetal metabolic reprogramming and its effect on adult onset obesity and dysregulation of glucose metabolism. Pregnant Balb/c mice exposed to very low environmentally relevant concentrations of arsenic (0.4 and 0.04 mg/kg body weight) showed its accumulation in the developing placenta but the levels of arsenic in the embryo were below detection limit. Male Balb/c progeny exposed prenatally to arsenic showed increased body fat mass, hyperinsulinemia, decreased glucose tolerance, insulin resistance, hyperleptinemia and an increase in relative visceral fat content at 40 weeks of age. Cytokine profile of the blood showed an elevated adipokine signature e.g. TNFα, associated with obesity. Dissecting the signaling pathways involved in glucose metabolism revealed activation of JNK1/2 pathway in the visceral fat tissue of the animals. Increased JNK activity has been earlier shown in induced and genetic (ob/ob) mouse models of obesity as well as in obese humans and is also known to regulate adipokine. Based on these observations we conclude that arsenic disrupts fetal programming of metabolism. While the evolutionary purpose of the fetal reprogramming is to optimize the fitness of the offspring for its probable environment, exposure to environmental pollutants such as arsenic during gestation may disrupt this process leading to adult onset health complexities.

1623 The Role of Dietary Zinc in Cadmium-Enhanced Non-Alcoholic Fatty Liver Disease

J. L. Young, and L. Cai. *University of Louisville, Louisville, KY.*

Environmental exposure to cadmium (Cd) is implicated in the development of several metabolic syndrome (MetS)-related diseases including non-alcoholic fatty liver disease (NAFLD), however, the ability of early-life, *in utero* Cd exposure to cause obesity-induced MetS in adulthood is poorly understood. Therefore, we developed an *in vivo* two-hit model to study the effect of whole life, low dose Cd exposure and high fat diet (HFD) on MetS with an emphasis on NAFLD. Additionally, we investigated the impact of dietary zinc supplementation and deficiency on disease outcome as both obesity and Cd disrupt zinc homeostasis. Zinc deficiency is common in both obese and NALFD patients. Adult male and female C57BL/6J mice fed normal diets (ND) were exposed to 0, 0.5 or 5 ppm Cd-containing drinking water for 1 week before breeding. Pregnant dams and offspring (F1) were continuously exposed to the same Cd concentration. At weaning, offspring were fed ND or HFD. Male mice were further grouped into diets containing 10, 30, or 90 mg zinc/4057 kcal, representing deficient, normal and supplemented zinc diet, respectively. Body weights and water consumption were recorded weekly. Prior to sacrifice changes in body fat composition were assessed using DEXA scan technology. Insulin resistance was characterized via intraperitoneal glucose tolerance tests, and serum insulin, triglycerides (TG) and cholesterol (TC) levels. Animals were sacrificed 10 or 24 weeks after weaning. Blood samples were collected and liver tissue was snap-frozen, fixed for histopathological analyses or used for metals analysis. Liver to body weight ratios, plasma aminotransferase, and hepatic TG and TC were determined. Thus far we show body weight was impacted by HFD, Cd exposure and altered dietary zinc. HFD altered body composition in males and females whereas Cd exposure altered body composition in males only. Glucose handling was altered in HFD fed males and to a lesser degree in females whereas Cd nor altered dietary zinc impacted glucose handling. HFD caused liver injury in males and Cd exposure exacerbated this injury. Overall, results from this study will provide insight into the mechanisms by which whole life, low dose Cd exposure enhances HFD-induced MetS and discern a potential therapeutic role for zinc in MetS.

1624 Gestational Exposure to Low-Dose $CdCl_2$ Sex-Specifically Induces Hepatic Insulin Insensitivity and Metabolic Syndrome in Adult Female CD-1 Mice

T. W. Jackson, G. L. Ryherd, C. M. Scheibly, T. C. Guillette, and S. M. Belcher. *North Carolina State University, Raleigh, NC.*

Obesity and type 2 diabetes (T2D) incidence is rapidly rising and is now a global pandemic that affects more than 400 million individuals. Exposure to environmental contaminants contribute to the pathogenesis of metabolic syndrome, a precursor for T2D characterized by increased body fat and circulating triglycerides, impaired insulin sensitivity and secretion, and increased blood pressure. Cadmium (Cd) is a global contaminant that is increasing in the environment due to human activities including use of fossil fuels and waste disposal. Epidemiological studies have associated prenatal Cd exposure and adult metabolic disease with some female-specific metabolic effects. In animal studies, prenatal Cd exposure at concentrations ranging from 1 - 50 ppm altered liver epigenetics and caused female-specific changes in carbohydrate and lipid metabolism. To explore the obesogenic potential of gestational Cd exposure at concentrations observed in vulnerable populations, CD-1 mice were exposed to 500 ppb $CdCl_2$ via drinking water during gestation and through postnatal day (PND) 10. The presented results demonstrate that gestational low-dose Cd exposure alters hepatic insulin signaling, induces nonalcoholic fatty liver disease (NAFLD), and causes obesity in adult female, but not male, offspring. Cadmium-exposed offspring had increased birth weight in both sexes that normalized by PND7. By adulthood, exposed females were 30% heavier and had a greater than 7-fold increase in perigonadal fat pads. Gestational Cd exposure also decreased insulin responsiveness, increased circulating triglycerides, and increased hepatic lipid accumulation in female offspring. RNA-sequencing of the hepatic transcriptome at PND42 revealed striking differences in females with over 5000 genes differentially expressed. Gene ontology and network analysis identified key pathways including hepatic insulin signaling, NAFLD, and fatty acid metabolism. These findings demonstrate that gestational Cd exposure in mice, at concentrations to which many pregnant women are exposed, induces metabolic syndrome in female offspring. Further analysis of sexually dimorphic responses to gestational Cd exposure and the ontogeny of Cd-induced changes in the hepatic transcriptome will be important for women's metabolic health.

1625 Interaction of the BCRP Transporter with Cadmium in Human Placentas and Cultured Trophoblasts

R. Zhang, X. Wen, C. Doherty, B. Buckley, E. Barrett, and L. Aleksunes. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Cadmium (Cd) is a ubiquitous environmental metal that is detectable in 97% of pregnant women. Animal and human studies have demonstrated that *in utero* Cd exposure reduces birth weight and perinatal growth. The developmental toxicity is due in part to the accumulation of Cd in the placenta which induces cellular stress, disrupts hormone production, and limits nutrients transfer to offspring. One mechanism to limit Cd accumulation in the placenta is through regulation of uptake and efflux transporters. The BCRP/ABCG2 efflux transporter is highly expressed on syncytiotrophoblasts in the placenta, however, its ability to remove Cd and protect the fetus against toxicity is unknown. In the current study, we sought to 1) assess relationships between Cd concentrations and transporter expression in healthy, term human placentas (N=28) and 2) investigate responses to Cd in cultured human BeWo trophoblasts with reduced BCRP expression. In human placentas, there was a 10-fold range in Cd (as measured by ICP/MS) with a median Cd concentration of 2.9 ng/g. Placentas with Cd > 2.9 ng/g (N=14) had higher mRNA expression of BCRP (*p=0.04),* as well as the Cd uptake transporters DMT1 (*p=0.07*) and ZIP8 (*p=0.04*) compared to placentas with Cd < 2.9 ng/g (N=14). Birthweights were also lower among offspring with placental Cd>2.9 ng/g (mean difference=285 g, *p=0.06*). Knockdown of BCRP expression and function in human BeWo trophoblasts using shRNA heightened susceptibility to Cd cytotoxicity as assessed by alamarBlue and propidium iodide staining. Taken together, these data indicate a dynamic relationship between the placental BCRP transporter and Cd accumulation in the placenta, which may impact the sensitivity of the fetus to Cd-induced developmental toxicity. *Supported by R01ES029275 and P30ES005022.*

1626 Ozone Exposure during Implantation Impairs Offspring Metabolic Processes in a Sex-Specific Manner in Rats

C. N. Miller[1], E. J. Stewart[1], M. C. Schladweiler[2], J. H. Richards[2], P. M. Phillips[2], K. L. McDaniel[2], C. J. Gordon[2], U. P. Kodavanti[2], and J. A. Dye[2]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; and [2]US EPA, Research Triangle Park, NC.*

Intrauterine growth restriction (IUGR), attributable to adverse prenatal environments, is implicated in the increasing prevalence of cardiometabolic disease. We have shown that peri-implantation ozone exposure impairs fetal weight similar to IUGR. Accordingly, this study aimed to determine if ozone-induced fetal growth restriction increases susceptibility to postnatal metabolic disease. Pregnant Long-Evans rats were exposed to 0.8 ppm ozone or filtered air during gestation days 5 and 6 (4 hr/d). Then, at postnatal day 45 subsets of male and female offspring were challenged with a 3-day high fat diet (HFD). In offspring from ozone-exposed dams, HFD challenge increased caloric intake and reduced energy expenditure. However, regardless of diet, females from ozone-exposed dams had reduced hepatic expression of lipolytic genes (*Cpt1*, *Cpt2*, *Ppara*) and bile acid regulatory genes (*Fxr*, *Fgfr4*, *Hnf4a*, *Bsep*, *Ntcp*). Furthermore, postnatal HFD challenge of female offspring from ozone-exposed dams altered hepatic gene expression related to insulin signaling (*Insr*, *Irs1*, *Irs2*), inflammation (*Tnfa*), gluconeogenesis (*Fbp1*, *G6pc*), cholesterol synthesis (*Mvd*), and bile acid signaling (*Cyp27a1*, *Cyp8b1*, *Cyp7b1*, *3βHSD3*, *βKlotho*). Female offspring from ozone-exposed dams also had reduced hepatic triglycerides and circulating insulin levels relative to controls. In male offspring from ozone-exposed dams, alterations in gene expression were mainly attributable to HFD challenge - affecting lipolysis (*Cpt1*, *Cpt2*, *Ppara*) and cholesterol synthesis (*Hmgcs1*, *Mvd1*), but not bile acid signaling. These male offspring also had reduced hepatic triglycerides, increased circulating cholesterol, and increased body adiposity. Together, these findings demonstrate a sex-specific predisposition to metabolic alterations in terms of hepatic responses to pre- and post-natal stressors, highlighting the importance of sex in risk assessment of hepatoxicity and metabolism. This study provides insight on the effects of acute gestational ozone exposure on systemic metabolic status in offspring, which may increase susceptibility to metabolic diseases when challenged with environmental stressors. *Does not reflect US EPA policy.*

1627 Exposure to Nanomaterials during Gestation Affects Cardiovascular Health for at Least 12 Months

S. B. Fournier, K. Wiersielis, V. Lam, M. Goedken, K. Reuhl, and P. A. Stapleton. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Nanosized - titanium dioxide ($nTiO_2$), is a naturally occurring oxide of titanium and is intentionally manufactured for use in a wide range of applications including industrial and personal care products. In laboratory studies, $nTiO_2$ has been used as a surrogate for ultrafine air pollution particulate. We have shown that exposure to $nTiO_2$ during pregnancy affects the cardiovascular health of the dam, fetus, and young adult offspring. It is unclear whether cardiovascular dysfunction in the progeny persists into middle age. Timed-pregnant Sprague-Dawley rats (Charles River) were exposed to $nTiO_2$ aerosols [9.65 ± 0.07 mg/m^3, primary particle size 21 nm, agglomerate size 128.45 ± 1.83 nm (SMPS, TSI), calculated daily deposition 47.27 ± 1.88 µg] for 4 hours over 6.00 ± 1.31 days of the remaining gestation via inhalation (HPGA, IESTechno). A subset of animals was exposed to filtered air as controls. Animals delivered in-house, offspring were monitored weekly, and were sacrificed at 12 months. Pressure myography (LSI, Burlington, VT) was conducted to evaluate microvascular reactivity in coronary arterioles to assess endothelium-dependent (EDR) [acetylcholine (10^{-9} - 10^{-4} M)]. Gestational $nTiO_2$ exposure significantly impaired EDR relaxation (43.80 ± 5.49 %) compared with controls, a finding maintained from previous studies of young adult offspring. Following arteriolar isolation, hearts were collected, fixed in 10% formalin, sectioned, and reviewed for histopathological analysis. Samples from exposed offspring present histopathological alterations characterized by multifocal myocardial inflammation, degeneration, necrosis, loss and/or fibrosis compared with control tissue. These findings were consistent with repeated low-grade ischemia. Anecdotally, a neurological tick and seizure activity were observed in 5 female animals exposed *in utero* to $nTiO_2$. Brains from these animals were collected, fixed for 24 hours, sectioned, and reviewed. Early observations indicate histopathological changes within the pituitary. Overall, gestational exposure to $nTiO_2$ produced coronary microvascular dysfunction, accompanied by histological changes in the heart that persist to middle age. These results may provide experimental evidence for a better understanding of the developmental onset of cardiovascular disease after gestational exposure to aerosolized xenobiotic particulates. *Supported by NIH-R00-ES024783; P30-ES005022; T32-ES007148.*

1628 Male-Specific Upregulation of Insulin-Like Peptides following Preconception Exposure to Perfluorooctanesulfonic Acid (PFOS) in *Drosophila melanogaster*

M. Johnstone[1], C. McVey[1], R. Aresco[1], S. Symington[1], A. Timme-Laragy[2], and B. Barbagallo[1]. *[1]Salve Regina University, Newport, RI; and [2]University of Massachusetts Amherst, Amherst, MA.*

The mechanisms by which preconception toxicant exposure contributes to metabolic dysfunction in later life are poorly understood. Perfluorooctanesulfonate (PFOS) is an industrial toxicant that has infiltrated water and air systems. Due to the long half-life, bioaccumulation potential, and near omnipresence in human urine samples tested, it is important to gain an understanding of the mechanism of PFOS activity and its impact on human health. Preliminary work from our collaborators in zebrafish embryos has shown that preconception exposure to PFOS alters pancreatic development and the expression of pancreatic hormones essential for metabolic regulation. Based on this work, we used the *Drosophila melanogaster* model system to test the hypothesis that preconception PFOS exposure results in dysregulation of insulin hormone expression in progeny throughout their lifespan. Virgin female animals were dosed with 2ng of PFOS 24 hours prior to mating and progeny were collected at eclosion (1 day), peak reproduction (5 day) and old age (14 day). Preliminary results using qPCR show upregulation of *Drosophila* insulin-like peptides 2, 3 and 6 at eclosion, showing a 6 fold, 6.5 fold and 2.5 fold increase in expression respectively in male progeny while female progeny are indistinguishable from vehicle controls, n=10 individuals per experimental group. This data suggests that preconception PFOS exposure has a sex-dependent effect on metabolic regulation. This study will provide insights into how exposure to environmental toxins are contributing to the increased prevalence of metabolic dysfunction and further studies aim to understand the persistence of this effect throughout the lifespan of the animal. *This work is funded by grant R01ES028201 from the National Institute of Environmental Health Sciences, National Institutes of Health.*

1629 Preconception Exposure to Perfluorooctanesulfonic Acid (PFOS) Alters Markers of Metabolic Disease in *Drosophila melanogaster*

R. Aresco[1], C. McVey[1], M. Johnstone[1], S. Symington[1], A. Timme-Laragy[2], and B. Barbagallo[1]. *[1]Salve Regina University, Newport, RI; and [2]University of Massachusetts Amherst, Amherst, MA.*

Preconception factors such as nutrition and chemical exposures influence oocyte developmental processes, potentially resulting in adverse health outcomes for offspring. Though the role of preconception nutrition is established, the effects of environmental toxicants on oocyte maturation and offspring health have been understudied. Perfluorinated compounds (PFCs) are surfactants used in non-stick surfaces that have infiltrated the environment, with related compounds detected in 98% of human urine samples. PFC exposure is linked to an increased risk of metabolic syndrome, though the mechanism by which preconception exposure to PFCs alters oocyte maturation and adult health are not well understood. We used the *Drosophila melanogaster* model system to test the hypothesis that preconception exposure to the PFC family member perfluorooctanesulfonic acid (PFOS) alters oocyte development and markers of metabolic disease such as levels of triglyceride, cholesterol and glucose throughout development. Virgin females were dosed with 2ng PFOS in acetone or acetone control 24 hours prior to mating, progeny were separated into an early group, days 1-2 post mating, and a late group, days 2-4 post mating. Our results show that preconception PFOS exposure results in significant developmental delay in the early group, with the progeny of PFOS exposed animals taking 8.4 days to reach adulthood at 25^{0}C (n=30) compared to 7 days for age matched controls (n=22). Additionally, the early group PFOS progeny showed a 30% reduction in adult body weight compared to controls. The progeny of PFOS exposed mothers also show changes in markers of metabolic disease, with female progeny showing elevated cholesterol levels at 1 and 5 days post eclosion and all progeny showing reduced cholesterol at 14 days (n=10-30 animals/treatment). Triglyceride levels were significantly increased in all progeny at eclosion but were not significantly different from controls at later timepoints (n=20-50/treatment). These results suggest that preconception PFOS exposure is sufficient to alter markers of metabolic disease and acts as a first step towards the ultimate goal of understanding how preconception toxicant exposure predispose individuals to later-life metabolic syndrome. *This work is funded by grant R01ES028201 from the NIH-NIEHS.*

1630 Pancreatic Nrf2 Expression and Organ Morphogenesis Is Altered by Modulating Glutathione in the Developing Zebrafish (*Danio rerio*) Embryo

A. Rastogi[1], H. M. Jacobs[1], S. T. Islam[1], E. G. Severance[1], S. M. Conlin[1], M. E. Hahn[2], and A. R. Timme-Laragy[1]. *[1]University of Massachusetts Amherst, Amherst, MA; and [2]Woods Hole Oceanographic Institution, Woods Hole, MA.*

Pancreatic islet growth during development is sensitive to redox-active chemicals, but mechanisms governing this are unknown. Building on differential glutathione (GSH; predominant cellular redox buffer) redox conditions during embryogenesis, we used zebrafish (*Danio rerio*) and small molecules to investigate roles of GSH and the transcription factor Nrf2a (Nfe2l2a; zebrafish Nrf2 co-ortholog) in islet morphogenesis. We visualized GSH utilization *in vivo* using monochlorobimane staining, and Nrf2a expression using whole-mount immunohistochemistry at 96 hours post fertilization (hpf), when the pancreas has formed. Chemical GSH modulation at 24 hpf (low GSH levels, reducing redox potentials), soon after pancreatic β cells form, did not induce islet morphology changes through 96 hpf. However, GSH modulation at 48 hpf (low GSH levels, oxidizing redox potentials) induced islet morphology changes persistent through 96 hpf. Decreased β cell cluster area at 96 hpf resulted from prooxidant exposures to *tert*-Butylhydroperoxide (tBOOH; 77.6 μM; 10 minutes at 48 hpf) and tBHQ (1 μM; 48-56 hpf). Conversely, exposures at this stage to antioxidants N-AcetylCysteine (NAC; 100 μM; 48-72 hpf), which bolsters cellular GSH, and SFN (20 μM; 48-72 hpf) significantly increased islet areas (n>30 fish). Nrf2a was also stabilized in the islet at 48 hpf: 10 minute high (776 μM) and low (77.6 μM) tBOOH exposures significantly increased Nrf2a protein in islets, compared to control islets that lack Nrf2a. Next, embryos were chronically exposed to 3.2 or 32 μM PFOS, an environmental toxicant. 3.2 μM PFOS increased GSH levels by 50% in GI tract at 48 and 72 hpf, 32 μM PFOS caused a 60% decrease (n>30 fish). Islets expressed significantly higher Nrf2a at both doses, rescued by concurrent100 μM NAC exposures. To assess functional implications of Nrf2a changes, we used biotinylated cell permeable GSH to visualize *in situ* protein glutathionylation. Islets had high protein glutathionylation, indicating oxidized GSH pools, congruent with low Nrf2a in the islet. The 10 minute low (77.6 μM) tBOOH exposure (induced Nrf2a in islet) decreased islet protein glutathionylation, while the 10 minute high (776 μM) tBOOH exposure (induced Nrf2a in entire pancreas) decreased global protein glutathionylation (n>15 fish). Notably, mutant fish expressing inactive Nrf2a were protected against abnormal islet morphology and aberrant Nrf2a protein expression. Our data show disrupted GSH homeostasis underlies changes in Nrf2a expression. This affects cellular GSH pools and alters protein glutathionylation, disrupting pancreatic β-cell development; significant because many chemicals impact GSH and Nrf2.

1631 Morphine Sulfate Induces Genomic Hypomethylation and Concurrently Downregulates Methyl Transferase Gene Expression in Mouse Embryonic Stem Cells

N. M. Cordero, A. J. Chintalapati, P. A. Panthagani, and F. A. Barile. *St. John's University College of Pharmacy and Health Sciences, Jamaica, NY.*

Opioid-induced perturbations in the epigenetic (EG) landscape are currently emerging as valuable biomarkers for opioid toxicity. We have previously shown that continuous exposure to morphine sulfate (MS) causes cumulative cytotoxicity and genomic DNA hypomethylation, in mouse embryonic stem (mES) cells. In this study, we hypothesize that MS induced suppression in DNA methylation is associated with concurrent down-regulation in gene expression of DNA mehtyltransferases (DNMTs) in mES cells. To determine the mechanism whereby opioids influence genomic methylation patterns, mES cells were exposed to10 μM MS for 1 to 7 days. Global DNA methylation and gene expression of DNMT1, -3a, and -3b were measured on 1-, 3-, 5-, and 7-days. The results show a constant decrease in genomic DNA hypomethylation on all days measured. Gene expression of DNMT1 were down-regulated on 1-, 3-, and 5-days, whereas gene expression of DNMT3a and -3b were down-regulated on 1- and 3- days, followed by up-regulation on day 5. To determine if these changes were reversible, cells were allowed to recover for 3 days in the absence of MS after each exposure period. Genomic methylation and gene expression analysis after the recovery period revealed a reversal of both MS-induced hypomethylation and down-regulations in gene expression of DNMTs, respectively. DNMT1 is usually referred to as the "maintenance methyltransferase" since it has a higher preference for hemi-methylated DNA. DNMT3a and DNMT3b are the predominant *de novo* MT's. Mammalian embryonic organogenesis is characterized by significant DNA methylation followed by selective demethylation. Consequently, the data suggest that MS induces EG toxicity by redirecting extensively pre-programmed genomic DNA methylation and expression of DNMTs that are normally inherently linked, thereby interfering with organogenesis during embryonic development.

1632 Developmental Exposure to Cannabidiol and Later-Life Consequences

K. Dickson[1], Z. Pandelides[1], C. Thornton[1], D. Carty[1], N. Aluru[2], N. M. Ashpole[1], and K. L. Willett[1]. *[1]University of Mississippi, University, MS; and [2]Woods Hole Oceanographic Institution, Woods Hole, MA.*

The use of cannabidiol (CBD) is rapidly increasing due to its indications for many ailments including arthritis, insomnia, anxiety, and pregnancy-associated nausea. However, there is limited knowledge of potential adverse outcomes due to CBD exposure during critical periods of development and the potential long-term effects. Using the zebrafish (*Danio rerio*) model, our goal was to determine the effects of developmental exposure to CBD on later life consequences in the exposed generation as well as subsequent F1 and F2 generations. In the F0, but not F1 or F2 generations, exposure to ≥ 2 μM CBD during development (6-96hpf) resulted in significant larval deformities and mortality. In addition, we observed significant reduction in fecundity in exposed F0 as adults (0.5 μM CBD exposure) compared to unexposed controls, but fecundity in F1 adults was not different from controls. When F0 fish reached 2.5 years of age, they were considered "aged" and CBD effects were assessed by comparing to both aged control and young (4-7 month old) unexposed groups. In the aged fish, developmental exposure to CBD significantly reduced sperm counts, and there was a reduction in size (wet weight and length) of female fish compared to aged controls. Our results support the need to consider the developmental origins of health and disease of CBD including later life-stage effects. *Supported by the National Institute on Drug Abuse R21DA044473-01.*

1633 Pre- and Postnatal Developmental and Reproductive Toxicity Study of the AV7909 Anthrax Vaccine in Rats

E. Mylchreest[1], J. Ballin[2], A. Smiley[1], and V. Savransky[3]. *[1]Battelle Memorial Institute, West Jefferson, OH; [2]Battelle Memorial Institute, Aberdeen, MD; and [3]Emergent BioSolutions Inc., Gaithersburg, MD.*

AV7909 consists of the Anthrax Vaccine Adsorbed (AVA) and the immunostimulatory Toll-like receptor (TLR) 9 agonist oligodeoxynucleotide adjuvant CPG 7909 and is similar in composition and manufacturing process to the commercial BioThrax® product. The purpose of this study was to evaluate the potential maternal, reproductive, and developmental toxicity of the AV7909 vaccine in rats. F_0 female Sprague Dawley Crl:CD (SD) rats (44/group) were dosed by intramuscular injection in the thigh muscle with water for injection, adjuvant (CPG7909/Alhydrogel in saline) or AV7909 at a volume of 0.5 mL/dose. Animals received three vaccinations: 14 days prior to start of cohabitation, on the first day of cohabitation and on gestation day (GD) 7. Half of the F_0 females in each group were randomly assigned to laparohysterectomy on GD 21 and half were assigned to natural delivery and allowed to rear offspring until postnatal day 21. There was no effect on mating, fertility, pregnancy, embryo-fetal viability, growth, or morphologic development, parturition, maternal care of offspring or postnatal survival, growth or development. There was no adverse maternal toxicity in this study; test article-related findings in F_0 females were limited to non-adverse (transient, predominantly very slight to slight severity) injection site edema and non-adverse (small, transient) injection site nodules visible grossly at necropsy. There was no systemic tissue injury or systemic inflammation in pregnant rats, based on evaluation of serum concentrations of the acute phase proteins alpha-2-macroglobulin and alpha-1-acid glycoprotein two weeks after the last of three administrations of AV7909. As expected, based on the ability of maternally derived antibodies to cross the placenta and transfer via the mother's milk, AV7909 antibodies were detected in the serum of fetuses and pups. High titers of anthrax lethal toxin-neutralizing antibodies were detected in F_0 females and their fetuses at the end of gestation and in F_1 pups at the end of lactation in the AV7909 group. Therefore, exposure of the fetuses and pups to maternally-derived AV7909 antibodies did not result in any developmental toxicity.

1634 Short- and Long-Term Effects of Perinatal Exposure to Phthalates and Phthalate Mixtures on Mouse Liver Metabolism

K. Neier[1,2], L. Montrose[3], T. R. Jones[1], L. K. Svoboda[1], C. Harris[1], P. X. Song[1], S. Pennathur[1], M. A. Sartor[1], and D. C. Dolinoy[1]. *[1]University of Michigan, Ann Arbor, MI; [2]University of California Davis, Davis, CA; and [3]Boise State University, Boise, ID.*

Phthalates have been labeled as "obesogens" and interfere with metabolism by interacting with peroxisome proliferator-activated receptors (PPARs). Development is a critical window of exposure for obesogens, including phthalates, but mechanisms linking developmental exposures and long-term metabolic health outcomes are not fully understood. We hypothesized that developmental exposures to two phthalates, diethylhexyl phthalate (DEHP) and diisononyl phthalate (DINP), and a mixture of the two (DEHP+DINP), reprogram PPAR target genes in the liver with long-lasting impacts on lipid metabolism. We used an established isogenic mouse model of perinatal exposures through the diet with an exposure window 2 weeks prior to mating until weaning at postnatal day 21 (PND21). Livers were collected from mice at PND21, at the end of the exposure period, and at 10 months (10M), long after exposure ceased. We utilized transcriptomics followed by pathway enrichment analyses to identify PPAR pathways that were altered at both time points. We found that acetyl-CoA metabolism was enriched in livers from mice perinatally exposed to DINP (FDR=0.0018), an effect that was specific to females. Of significant genes driving this pathway, 10/13 were PPAR target genes, and 9 were upregulated, including *Acly*, *Cs*, and *Fasn.* To characterize functional metabolic liver outcomes, two targeted metabolomics assays were carried out in females: a central metabolism profile and an acylcarnitine profile as a measure of fatty acid oxidation. Relative to controls, females perinatally exposed to DEHP+DINP had increased acetyl-CoA at PND21 (adjusted p=0.0005) but decreased acetyl-CoA at 10M (adjusted p=0.013), while acylcarnitines were increased only at 10M in DEHP, DINP, and DEHP+DINP females (p=0.011, 0.033, and 0.061, respectively). Together, our data indicate that perinatal phthalate exposures were associated with increased mRNA expression of PPAR target genes at both PND21 and 10M, which manifested as increased fatty acid production in early life and increased fatty acid oxidation in adulthood.

1635 The Intergenerational Metabolic and Behavioral Effects of Paternal Phthalate Exposure

M. Teffera, J. McGaunn, V. Salemmie, J. R. Pilsner, and A. Suvorov. *University of Massachusetts Amherst, Amherst, MA.*

Phthalates in plastics and cosmetics have been reported to play a role in a host of behavioral and metabolic outcomes. However, little is known about intergenerational effects of exposure. Without such knowledge, our understanding of paternal environmental determinants of offspring health is limited. We hypothesized, based on acute exposure data, that paternal phthalate exposure in mice would induce behavioral and metabolic changes in offspring phenotypically similar to ADHD and diabetes in humans. Adult reproductive age male C57B/L mice (F0) were treated with 5.0 mg/kg/day of DEHP, 5.0 mg/kg/day of DBP, or a mixture of the two (5.0 mg/kg/day of DEHP and DBP) for 70 days to cover 2 spermatogenesis cycles. Controls were exposed to the vehicle only. After exposure, F0 male mice were bred with non-exposed females, and one male and one female from each F1 litter were selected for phenotypic testing. Open field and elevated plus maze tests were conducted for all F1 mice, and a three-chamber sociability test was conducted for each F1 male mouse. A glucose tolerance test was performed on F1 male mice and glycosylated hemoglobin was measured. Statistically significant changes in exploratory behavior in the open field test were observed, with an increase in exploratory behavior-time spent in the center of the maze-for mice in the DEHP group relative to controls, with increased significance in males ($p<0.001$). However, this change in behavior related to paternal DEHP exposure was abolished in mice whose fathers were exposed to both DBP and DEHP ($p<0.01$). There were trends toward statistical significance for differences in blood glucose at multiple time points between male mice, and a statistically significant decrease in body weight for male mice paternally exposed to DEHP and DBP relative to controls ($p<0.05$), indicating faster glucose absorption by tissues in exposed animals. However, glycosylated hemoglobin levels were not statistically significant for any group, indicating that long-term levels of glucose may not be affected by paternal phthalate exposure. Therefore, significant changes in behavior and metabolism in offspring of exposed males suggest that paternal phthalate exposure influences offspring behavior and metabolism possibly through a non-genetic mechanism. Our data suggests that paternal phthalate exposure may play a role in offspring health.

1636 Elucidating Epigenetic Mechanisms Involved in the Origins of Adult Metabolic Phenotypes following *In Utero* DEHP Exposure

N. Robles-Matos, and M. Bartolomei. *University of Pennsylvania, Philadelphia, PA.*

Environmental exposure to Endocrine Disrupting Chemicals (EDCs) during fetal development may lead to molecular changes that increase susceptibility to adult diseases. For example, EDCs can alter fetal growth and metabolism *in utero* and disrupt critical set points that promote adult metabolic disorders. The EDC Di-(2-ethylhexyl)-phthalate (DEHP) is strongly associated with metabolic changes. DEHP is a ubiquitous plasticizer, present in food packaging, toys, medical devices, and personal care products. DEHP has anti-androgen functions in fetal/placental endocrine systems, interfering with hormonal action. As a result, DEHP exposure during pregnancy may result in adult metabolic defects. However, the mechanisms driving DEHP-induced changes in fetal metabolism and adult diseases are unknown. Recent evidence suggests that EDC-induced changes in metabolic gene profiles may stem from altered epigenetic landscapes. One epigenetic factor, DNA methylation, is particularly vulnerable to environmental exposures as it changes dynamically during fetal development. Thus, we hypothesize that DEHP exposure *in utero* disrupts DNA methylation in placenta, leading to abnormal cross-talk between the fetus and placenta, which in turn will predispose offspring to impaired metabolism in adulthood. To test this, dams were exposed to two DEHP doses (Lower: 50 µg/kg/BW, Upper: 10 mg/kg/BW) via their diet from pre-conception until embryonic day 10.5 (E10.5) or weaning. Post-weaning, offspring were placed on a control or Western Diet (WD) until postnatal day 182 (PND182). Global DNA methylation was assessed on E10.5 placentas using a Luminometric Methylation Assay. Maternal exposure to upper-DEHP was associated with significantly increased global DNA methylation of E10.5 male placentas. Our data suggest that DEHP alters E10.5 placental global DNA methylation in a dose- and sex-specific manner. Adult metabolic phenotyping included glucose tolerance tests, body weight and body fat. Phenotyping revealed that male offspring exposed to upper-DEHP and challenged with WD have impaired glucose tolerance at PND140 and increased body fat at PND182 while females were unaffected. These results suggest that *in utero* DEHP exposure at environmentally relevant doses disrupts glucose homeostasis in a sex-specific manner. Ultimately this work will evaluate the effects of prenatal DEHP exposure and the mechanisms through which it works to understand human health risks.

1637 The Role of the mTOR Pathway in Developmental Programing of Liver Lipid Metabolism by 2,2',4,4'-Tetrabromodiphenyl Ether (BDE-47)

J. P. McGaunn, A. A. Poluyanoff, A. Khalil, V. R. Salemme, and A. Suvorov. *University of Massachusetts Amherst, Amherst, MA.*

An emerging hypothesis links the epidemic of metabolic diseases, such as non-alcoholic fatty liver disease (NAFLD) and diabetes with chemical exposures during vulnerable windows of development. Evidence from our lab and others suggests that developmental exposure to environmentally prevalent flame-retardant BDE-47 may permanently reprogram lipid metabolism and results in NAFLD like phenotype. Additionally, we have demonstrated that BDE-47 alters the activity of both mTOR complexes (mTORC1 and 2) in hepatocytes. The mTOR pathway integrates environmental information from many different signaling pathways, and regulates key cellular functions such as lipid metabolism, innate immunity, and ribosome biogenesis. Thus, we hypothesized that the developmental effects of BDE-47 on liver lipid metabolism are mTOR-dependent. We conducted two LoxP-Cre recombinase breeding schemes to generate liver-specific knockouts of *Rptor* (a key component of mTORC1) and *Rictor* (a key component of mTORC2), as well as their respective wildtypes. Mice from all four groups were exposed perinatally to BDE-47, or to vehicle only. Liver and serum were collected from exposed offspring on PND65. Serum triglycerides were analyzed using the Cayman COX Kit, and transcriptomic analysis of hepatocytes was conducted via Illumina RNA-seq. Sequencing data was analyzed using Metascape Ontology and Gene Set Enrichment Analysis. Western blots were also conducted to analyze mTORC1 and 2 activity. Results suggest that developmental exposure to BDE-47 permanently reprograms liver lipid metabolism, innate immunity and other key cellular functions. The transcriptomic effects of BDE-47 appear to be synergistic with suppression of mTORC1, but not mTORC2 activity. Our liver-specific mTORC2 knockout abolished exposure-induced changes in blood triglycerides, while effects of exposure on innate immunity genes are primarily dependent on mTORC1. Differences in transcriptomic responses to BDE-47 exposure between wild type animals from the mTORC1 and mTORC2 breeding schemes suggest that different genetic backgrounds intersect with developmental exposures to determine the lifelong effects of exposure on the liver transcriptome. Overall, our results provide a hypothetical model of

gene-environment interaction in life-long programing of liver lipid metabolism and other functions. Our model suggests that modulation of the mTOR pathway may affect liver susceptibility to environmental exposures.

1638 *In Utero* and Lactational Dioxin Increases Noradrenergic Axon Density and Nerve-Evoked Smooth Muscle Contraction in Mouse Prostate

A. E. Turco[1], S. R. Oakes[1], T. Chathurvedula[1], K. Keil[1], N. Girardi[1], L. Hernandez[1], R. E. Peterson[1], A. Bonev[2], N. Tykocki[3], and C. M. Vezina[1]. *[1]University of Wisconsin–Madison, Madison, WI; [2]University of Vermont, Burlington, VT; and [3]Michigan State University, East Lansing, MI.*

In utero and lactational (IUL) TCDD exposure causes mouse prostatic smooth muscle thickening and urinary dysfunction in adulthood consistent with prostate-related urinary symptoms experienced by most aging men. Increased prostate smooth muscle tone and hypertrophy of prostatic smooth muscle are hypothesized to contribute to urinary dysfunction because treatment with alpha-one adrenergic antagonists that relax prostate smooth muscle relieves urinary symptoms. We hypothesize IUL TCDD exposure increases neurotrophin expression in the fetal prostate, thereby recruiting noradrenergic axons and permanently increasing their density, sensitizing prostatic smooth muscle to nerve-evoked contraction and resulting in hypertrophy. Methods: Pregnant dams (control and Myh11-GCaMP5g mice on a C57Bl6/J background) were dosed with TCDD or corn oil (vehicle) at embryonic day 13 ((e)13.5). Control prostates were collected at e17.5, postnatal day (P)9 and P50. Immunostaining was used to quantify noradrenergic axon density. Myh11-GCaMP5g prostates, harboring genetically encoded calcium sensors that fluoresce during muscle contraction, were collected at 14 weeks and stimulated with graded frequencies (1 Hz- 30 Hz) to evoke action potentials and neurotransmitter release from noradrenergic axons. Fluorescent calcium transients were quantified as indices of muscle contraction. Results: IUL TCDD exposure increases noradrenergic axon density in mouse prostate as early as P9 and continuing until early adulthood. IUL TCDD exposed prostatic smooth muscle contracted at a lower frequency than vehicle-dosed prostatic smooth muscle. IUL TCDD exposure permanently increases noradrenergic axon density, increases the sensitivity of prostate smooth muscle to contraction, and thickens prostate smooth muscle. We propose that these TCDD responses derive from an increase in neurotrophins during fetal development, which we are actively investigating. This is the first evidence developmental exposure to TCDD permanently and functionally changes prostate peripheral nerve density. *NIH grants: R01ES001332, K99 ES029537, and T32 ES007015.*

1639 Developmental Reprogramming of the Gut Microbiome and Microbial Metabolites by Early-Life Exposure to Persistent Environmental Contaminants

M. V. Gomez[1], J. Y. Cui[1], A. Suvorov[2], H. Gu[3], X. Shi[3], and M. Dutta[1]. *[1]University of Washington, Seattle, WA; [2]University of Massachusetts Amherst, Amherst, MA; and [3]Arizona State University, Tempe, AZ.*

Gut microbiome is increasingly recognized as a pivotal player in toxicological responses, and dysbiosis may worsen chemical-induced adverse outcomes such as inflammation, metabolic syndrome, and cancer. Early life exposure to environmental contaminants may produce long-lasting toxicities in adulthood. Little is known to what extent early life exposure to environmental toxicants modulate the gut microbiome beyond childhood. Therefore, this study tested the effects of perinatal exposure to 3 human health relevant environmental contaminants (BDE-47, TBBPA, BPS), on the composition and functions of the gut microbiome of perinatally exposed adult male mice. CD-1 mouse dams were orally exposed to vehicle (corn oil, 10ml/kg), BDE-47 (0.2mg/kg), TBBPA (0.2mg/kg), or BPS (0.2mg/kg) once daily from gestational day 8 to postnatal day 21. Feces from male pups were collected at 12-weeks of age (n=14-23/group). Microbial DNA was subjected to 16S rDNA sequencing, and analyzed using QIIME. Lefse was used to determine microbial biomarkers. Microbial functions as well as key taxa that drive functional changes were predicted using PICRUSt and FishTaco, respectively. To validate the functional shifts in gut microbiome, bile acids (BAs) and short chain fatty acids (SCFAs) in fecal samples were analyzed using liquid chromatography-mass spectrometry (LC-MS) and gas chromatography-mass spectrometry (GC-MS), respectively. Principle coordinate analysis showed a distinct separation among different exposure groups, especially between BPS and vehicle exposure groups. The BDE-47, and TBBPA exposure groups overlapped slightly, but remained separated from the vehicle cluster. There was a persistent decrease in many taxa of the *Clostridia* class in the *Firmicutes* phylum to all 3 chemicals, whereas many taxa of the *Bacteroidia* class in the *Bacteroidetes* phylum were persistently up-regulated. Each group had distinct biomarkers which was *Clostridiales* for vehicle, *S24-7* for BDE-47, *Rikenellaceae and LactoBacillus* for TBBPA and BPS respectively. FishTaco predicted that BDE-47 increased microbial BA synthesis, and indeed, fecal total, secondary, and unconjugated BAs were all increased in adult pups following early life BDE-47 exposure. Interestingly, TBBPA and BPS also persistently increased these BA species. Regarding SCFAs, BPS down-regulated acetic acid, whereas TBBPA up-regulated propionic acid and succinate. Together these findings suggest early life exposure to these environmental contaminants produces persistent gut dysbiosis in adult male offspring, leading to functional shifts that may play important roles in regulating certain diseases of the host.

1641 Placental Alterations following Prenatal Arsenic Exposure and Relation to Long-Term Lung Immune Effects

K. A. Rychlik, C. Kashiwagi, J. Liao, A. Maertens, and F. C. Sillé. *Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.*

More than 140 million people around the world are exposed to arsenic in drinking water at levels higher than the 10 µg/L guideline from the WHO. Inorganic arsenic is a confirmed carcinogen and associated with myriad health effects including detrimental immune outcomes. It is well established that prenatal arsenic exposure has cell-specific effects on components of the immune system, resulting in reduced immune efficacy, particularly in the lungs. Preliminary data from our prenatal arsenic exposure mouse model indicates that in adult pups, even ten weeks following exposure cessation, cytokine profiles of immune cells from the lung are altered before and after stimulation with LPS and IFNγ. Furthermore, flow cytometry data indicates a reduction in inflammatory response in macrophages from prenatally exposed animals. To better understand mechanisms driving the observed long-term immune deficit, we will examine the placenta and fetal lung tissue. The role of the placenta in mediating long-term immune effects is largely unknown. Using a mouse model of prenatal (including pre-conception) exposure to sodium (meta) arsenite, we are investigating effects on the placenta and fetal lungs through gene expression investigation (via microarray and RT-qPCR) and flow cytometry. Importantly, results from the current study could result in avenues to pursue early intervention strategies to reduce the long-term effects of early life arsenic and other heavy metal exposures.

1641a E-cigarette Exposure during Development Alters Protein Transporter Activity in Neural Pathways That Are Associated with Obesity in Mice

C. Awada, H. W. Lee, J. L. Blum, and J. T. Zelikoff. *NYU School of Medicine, New York, NY.*

Electronic cigarettes (E-cigs) are battery-powered devices that usually contain vegetable glycerin and propylene glycol as humectants, as well as nicotine and added flavors. E-cig use is dramatically increasing in popularity, particularly with adolescents and young adults. According to the CDC, more than 1 in 4 high school students and about 1 in 14 middle school students have vaped in the past 30 days in 2018. E-cigarette use increased from 11.7% to 20.8% among high school students and from 3.3% to 4.9% among middle school students from 2017 to 2018. Although cigarette smoking during pregnancy has been shown to increase the risk of childhood obesity, little research has been carried out to determine if the same obesity propensity is conferred to the offspring by maternal vaping while pregnant. Preliminary mouse data by our laboratory suggest such a connection. Neural pathways in the hypothalamus are involved in hormonal and nutritional signaling that coordinate glucose homeostasis and weight gain. We hypothesized that prenatal exposure to e-cig aerosols, with and without nicotine, alters transcriptional and inflammatory activity in known metabolic pathways in the hypothalamus that are associated with obesity. For this study, pregnant C57BL/6 mice were exposed daily throughout gestation (3h/day; 5 d/wk for about 3-wk) and postnatally from PND 4-21 to e-cig aerosols with or without nicotine and employing the same exposure conditions used during the gestational exposure. At 1-mo-of-age, the brain was removed from both male and female offspring. Expression of transporters associated with obesity, including Glucose 1,2,3, GLAST, PPARγ, AMPA, and GFAP were then analyzed in the hypothalamus of offspring exposed early in life to e-cig aerosols (with or without nicotine) or filtered air by Western blot. Results of this study demonstrated a two-fold increase in glucose transporter expression in the no-nicotine (PG/VG alone) group, and a 2.5-fold increase in the PG/VG plus nicotine group compared to control levels. Given the growing epidemics of both vaping and obesity and the lack of study in this particular scientific area, a better understanding of

the link (if any) between these two epidemic waves is critical for protecting the health of two highly-vulnerable groups, children and pregnant women. *Supported by NYU NIEHS P30ES000260-55*

1642 Application of the US EPA TSCA Study Quality Evaluation System: A Case Study of Health Effects from Residence Near Oil and Natural Gas Development

H. N. Lynch[1], K. Towle[2], and K. Mundt[1]. *[1]Cardno ChemRisk, Boston, MA; and [2]Cardno ChemRisk, San Francisco, CA.*

Under the Toxic Substances Control Act (TSCA), the United States Environmental Protection Agency (US EPA) Office of Pollution Prevention and Toxics (OPPT) has promulgated systematic review methods to allow for more transparent and objective human health chemical risk evaluation assessments. A key element is a robust and standardized method for evaluating the quality of individual studies, which is a critical step when synthesizing the available literature and drawing conclusions on potential health risks. We present a case study of the EPA TSCA study quality evaluation system for epidemiology within a review of the potential human health effects of exposures associated with residence near oil and natural gas (ONG) production sites. Our review indicated that a tiered approach to the evaluation of study quality placed appropriate emphasis on the domains of quality most relevant to the chemical exposure and health effects of interest. For example, exposure characterization was particularly weak in many ONG studies, which limited the overall confidence in the study regardless of other domain scores. We therefore used exposure assessment as the first tier criterion, moving only to other domains if exposure characterization was of medium or high quality. In our analysis, many studies were of a low overall quality, and no studies fulfilled the TSCA criteria required for a high-quality rating. Thus, while there were associations between residential proximity to ONG development and some health effects, exposure misclassification, bias, confounding, and chance could not be confidently excluded as alternate explanations for the study results. Overall, our evaluation underscores the criticality of assessing study quality in risk evaluation. While the TSCA study quality evaluation system is one of the most comprehensive frameworks available, adaptions may be necessary to ensure that it is fit-for-purpose and not unduly burdensome. Effective methods for integrating evidence across lines of inquiry are still needed.

1643 Daily Variation of Air Pollutants Near an Elevated Highway System

S. Coleman[1], M. Kong[2], J. Zhang[2], and J. Mirowsky[1]. *[1]State University of New York College of Environmental Science and Forestry, Syracuse, NY; and [2]Syracuse University, Syracuse, NY.*

Interstate-81, which is an elevated viaduct, goes right through the heart of the Syracuse, NY, with local businesses and communities located underneath it. The safety limit of the viaduct is ending, and New York State is looking for recommendations to either rebuild the roadway using its current elevated design or lower the highway to ground level to create a community grid. People living in the neighborhood below the Interstate are concerned about an increase in air pollution if the Interstate is lowered, but with no knowledge of the current air quality levels in their community at the highway level, assessing how lowering the highway would impact the neighborhood is not possible. Therefore, we have started an intensive air quality monitoring campaign to measure air pollutant levels simultaneously near the highway and on the ground below it. Models generated by the Department of Transportation suggest that traffic levels will not change if the highway is lowered, and by monitoring air quality at both the highway and ground level, results from our study will offer a glimpse of potential air quality problems that can arise if the Interstate is lowered. To assess the daily variation in traffic-related particulate matter (PM) near this highway, a sampling site adjacent to the roadway was selected. Two high-volume cascade impactors were placed at both ground and roof level of a building to collect daily fine PM for two weeks over two seasons - summer and fall. Additionally, two real-time PM monitors were placed at each location and measured PM number concentration. For fine PM, the number of particles was, on average, 1.2 times higher, and at maximum, 10 times higher, at the rooftop location. In the summer, three days were noted to have exceptionally high vehicle flow and had fine PM concentrations ranging from 4.5 to 10 times higher at the rooftop level. Results from the gravimetric analysis were in agreement with the measured number concentrations. This data shows that particle count and fine PM concentration are variable with elevation and suggests that vehicle emissions may be more influential at the rooftop location where fine PM was consistently higher than at the ground level. This implies that the air quality may be affected if the community grid option is pursued.

1644 Big Data to Knowledge Analytics Reveals the Zika Virus Epidemic as Only One of Multiple Factors Contributing to a Year-over-Year 28-Fold Increase in Microcephaly Incidence

M. P. Cifuentes[1], C. M. Suarez[2], R. Cifuentes[3], N. Doogan[4], J. Valderrama[5], R. Valdez[6], C. Colen[4], M. Langston[7], C. Phillips[7], A. Ramesh[8], P. M. Juarez[8], M. Lichtveld[9], C. P. Mouton[10], N. Przulj[11], and D. B. Hood[4]. *[1]Universidad Antonio Nariño, Bogotá, Colombia; [2]Universidad Santo Tomás, Bogotá, Colombia; [3]Universidad Militar Nueva Granada, Bogotá, Colombia; [4]Ohio State University, Columbus, OH; [5]Ministry of Health and Social Protection, Bogotá, Colombia; [6]University of New Mexico, Albuquerque, NM; [7]University of Tennessee, Knoxville, TN; [8]Meharry Medical College, Nashville, TN; [9]Tulane University, New Orleans, LA; [10]University of Texas Medical Branch at Galveston, Galveston, TX; and [11]University College London, London, United Kingdom.*

During the 2015-2016 epidemic of Zika Virus (ZIKV) in Latin America the geographical distributions of ZIKV infection and microcephaly outbreaks did not match. This raised doubts about the virus as the single cause of the microcephaly outbreak and led to research hypotheses of alternative explanatory factors, such as agrochemical use, vaccinations, and social conditions. We accomplished our main goal of discerning how variables and factors from the built, natural, physical, and social environments simultaneously shaped this ZIKV-related microcephaly outbreak, by demonstrating significant controlled associations among 382 nonredundant variables ZIKV surveillance and multiple determinants of public health from these environments obtained from 5,565 municipalities in Brazil. We compared the variables and factors directly associated with microcephaly incidence positive to ZIKV and those associated with microcephaly incidence negative to ZIKV, respectively, and mapped these in case and control subnetworks. We mapped a subnetwork of variables and factors associated with low birth weight where birth incidence served as an additional control. Nonsignificant differences in variables/factors were observed and weights of associations between microcephaly incidence positive and negative to ZIKV revealed diagnostic inaccuracies that translated to underestimation of the outbreak size. A detailed analysis of association patterns does not support a finding that vaccinations and use of agrochemicals are factors contributing to microcephaly but does raise further concerns about potential hazards and toxicity resulting from exposures from chemical and non-chemical stressors. In summary**,** comparative network inferential analysis of patterns of variables and factors associated with a Zika virus epidemic in Brazil during 2016 coinciding with a microcephaly outbreak identifies multiple contributing determinants and advances our understanding of the effects of exposures to chemical and non-chemical stressors in the built, natural, physical, and social environment.

1645 Man-Made Vitreous Fibers and Non-Malignant Respiratory Disease: A Systematic Review

N. S. Egnot[1], H. Allen[1], H. Denic-Roberts[2], M. Vater[1], R. Hazan[3], and G. Marsh[1]. *[1]Cardno ChemRisk, Pittsburgh, PA; [2]Cardno ChemRisk, Arlington, VA; and [3]Cardno ChemRisk, Brooklyn, NY.* Sponsor: M. Kreider

Man-made vitreous fibers (MMVF) are a family of inorganic fibers including insulation wools, glass filaments, and refractory ceramic fibers. Insulation wools, including glass wool (GW) and rock/slag wool (RSW), are commonly used as thermal or acoustical insulation in buildings, vehicles, and appliances. In 2002, the International Agency for Research on Cancer (IARC) classified GW and RSW as *not classifiable as to their carcinogenicity in humans* based on the results of three decades of epidemiological research. While decades of epidemiological research consistently demonstrated that individuals occupationally exposed to these fibers do not experience an elevated risk of respiratory system cancer, less is understood about the potential effects of occupational GW and/or RSW exposure on non-malignant respiratory disease (NMRD). We conducted systematic searches of PubMed and Scopus databases with an aim of identifying all epidemiological studies that evaluated the association between MMVF (specifically, GW and RSW) exposure and NMRD. We identified 280 articles, 53 of which warranted full-text review based on a relevant abstract. Additionally, we reviewed references of all relevant articles identified by our search, as well as studies included in the 2002 IARC Monograph. Ultimately, we found 23 epidemiological studies of occupational MMVF exposure and NMRDs. The mortality studies (n=10) consistently reported null findings [SMRs ranged from 54 (95% CI=33-84) to 119 (95% CI=74-182)]. The 13 non-mortality studies were predominately cross-sectional and evaluated a variety of outcomes including self-reported lower and upper respiratory symptoms, pulmonary function, subclinical disease outcomes assessed by imaging techniques, and clinically diagnosed respiratory diseases. Ultimately, the epidemiological evidence suggests that workers exposed to MMVFs do not experience increased risk

of NMRD mortality compared to the general population. The non-mortality studies reported mixed results, but overall suggest that occupational MMVF exposure is not associated with reduced lung function or pleural plaques. Conversely, multiple cross-sectional studies reported an association between MMVF exposure and chronic bronchitis among participants, but the conclusions that may be drawn from this literature are limited by the tremendous heterogeneity in the design of the non-mortality studies, and the infrequent statistical adjustment for asbestos exposure and smoking habits.

1646 Blood Pressure Control, Glycemic Control, and Dyslipidemia among Healthy Adults in the Cape Coast Metropolis, Ghana

W. E. Gato[1], S. Acquah[2], P. Nsiah[2], S. T. Opoku[1], and B. A. Apenteng[1]. *[1]Georgia Southern University, Statesboro, GA; and [2]University of Cape Coast, Cape Coast, Ghana.*

The World Health Organization recommends the implementation of interventions focused on the early detection of clinical risk factors for cardiovascular disease (CVD) as effective strategies for the control of CVD in low resource settings. However, due to health system resource constraints, surveillance capacity for the identification of high-risk populations for non-communicable diseases, including CVD have been inadequate. The purpose of this study was to describe the prevalence of CVD clinical risk factors among healthy adults residing in the Cape Coast metropolis of Ghana. The clinical risk factors assessed included glycemic control, insulin sensitivity, lipid control and blood pressure. The study participants included 70 healthy adults without a previous diagnosis of CVD from Cape Coast metropolis. Blood samples, blood pressure and anthropometric measurement were obtained for each participant. Serum glycated hemoglobin (HbA1c), insulin, glucose, triglycerides, and cholesterol levels were measured. Results: Approximately four out of ten participants were either overweight or obese. Almost three-quarters of the sample were considered prehypertensive or hypertensive. About three in ten were clinically prediabetic. About a third of the participants had high non-HDL cholesterol levels. Triglyceride concentration levels were found to be high in almost 10 percent of the study sample. Approximately six percent were identified as having metabolic syndrome. A significant proportion of the study participants were identified to be at risk for CVD. There is the need for adaptive and less resource-intensive CVD risk-factor screening interventions to allow for the timely detection and management of CVD risk factors in low-resource settings.

1647 Exposomics of Maternal Plasma in Women at High Risk of Preterm Birth

Y. Lai[1], A. V. Glover[2,3], R. Fry[1], T. A. Manuck[2], and K. Lu[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; [2]University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, NC; and [3]UNC Health Care, Chapel Hill, NC.*

Preterm birth (PTB) remains a leading cause of neonatal deaths and perinatal morbidity in the US and worldwide. Early diagnostics and intervention for PTB relies on accurate, comprehensive, and sensitive screening of metabolic marker and environmental risk factor during early pregnancy. In this study, high-resolution global metabolomics was used to probe a prospective cohort of women carrying a singleton, non-anomalous gestation while at high risk for spontaneous PTB. In total, 42 participants (25 cases; 17 control) were enrolled in their mid-trimester pregnancy in 2015-2018 at UNC, based on prior PTB records, cervical length, antepartum hospitalization and so forth. Upon enrollment, blood plasma was collected by venipuncture into an acid-citrose dextrose tube. The samples were extracted, analyzed on liquid chromatography quadrupole-orbitrap mass spectrometry, and processed in XCMS for aligning ion features detected in all samples. Partial least square discriminant analysis identified a distinct group pattern, separating cases and control with 32% for t1, 7% for t2, and 0.846 for Q^2Y. Welch *t*-test revealed 812 features of group difference (fold change>1.2, $p<0.05$), out of which a predominating 570 were higher in PTB than in TB control. A novel cheminformatics pipeline was applied, yielding 131 unique structures related to PTB. Remarkably, metabolome shifts spanned from lipids (e.g. cholesterol, acylcarnitines, lysophospholipids, fatty acids, ceramide), amino acids, purines, glycolytic and tricarboxylic acid cycle intermediates, to sex hormones (e.g. estrone) and aryl hydrogen receptor ligands (e.g. biliverdin). While, a number of xenobiotics were discovered, including food components, microbial metabolites, drug derivatives, environmental pollutants (e.g. PAHs), suggesting a role of dietary intake, lifestyle, and exposures in PTB pathogenesis. Overall, the study characterized important metabolome and exposome shifts in maternal plasma for future research seeking countermeasures for PTB.

1648 Total Dioxin Toxic Equivalency and Sex Are Associated with Biomarkers of Liver Disease in ACHS-II Participants

B. Wahlang[1], C. M. Pinkston[1], S. N. Rai[1], M. Pavuk[2], M. C. Cave[1], and L. S. Birnbaum[3]. *[1]University of Louisville, Louisville, KY; [2]CDC/ATSDR, Atlanta, GA; and [3]National Cancer Institute, Research Triangle Park, NC.*

Persistent organic pollutants including polychlorinated biphenyls (PCBs) and dioxins can activate the aryl hydrocarbon receptor (AhR) and promote non-alcoholic fatty liver disease (NAFLD). Previously, our group demonstrated high prevalence of suspected NAFLD in Phase I and Phase II participants of the PCB-exposed Anniston Community Health Survey (ACHS) cohort. The purpose of this study is to analyze a subset of ACHS-II participants who demonstrated abnormal CK 18 levels (suspected liver disease), and determine associations between *i*) total dioxin toxic equivalency (TEQ) which represents AhR activation, or *ii*) sex and serological biomarkers of liver disease. Two hundred nine (62%) ACHS II study participants with abnormal CK18 (CK18 M65>300 U/L) were included in the present analyses. Biomarkers (log_e-transformed) of interest were assessed for their joint association with total dioxin TEQ (low/high) and sex (male/female) using a linear model. Results: Participants with high total dioxin TEQ tended to be older (68 y *vs.* 56 y) and were more likely to be female (84% *vs.* 52%), African-American (52% *vs.* 37%), and have a history of diabetes (53% *vs.* 34%). In models without adjustment, high total dioxin TEQ was positively associated with VLDL, TNFα, and hyaluronic acid and negatively associated with albumin. The association with male sex was positively associated with VLDL and albumin. After adjusting *p*-values, associations between high total dioxin TEQ and TNFα (p_{adj}=0.047), and hyaluronic acid (p_{adj}<0.001) remained. In lipid-adjusted models, high total dioxin TEQ was not associated with any biomarker, except albumin. However, persistent sex associations with VLDL and albumin were observed in both unadjusted and adjusted models. Mechanistic biomarkers for lipid metabolism, inflammation, fibrosis and liver function were associated with high total dioxin TEQ, implicating the role of AhR activation by environmental chemicals as a potential mediator in liver disease. The results also suggested that sex plays a crucial role in determining NAFLD outcomes and confirmed our previous findings that dioxin-like chemicals are associated with mechanistic fatty liver disease in ACHS-II participants.

1650 Proximity and Density to Hydraulic Fracturing Wells and Birth Outcomes in Northeastern British Columbia, Canada

E. Caron-Beaudoin[1], K. W. Whitworth[2], D. Bosson-Rieutord[1], G. Wendling[3], S. Liu[4], and M. Verner[1]. *[1]Université de Montréal School of Public Health, Montreal, QC, Canada; [2]The University of Texas Health Science Center at Houston, School of Public Health, San Antonio, TX; [3]GW Solutions, Nanaimo, BC, Canada; and [4]Wuhan University School of Health Sciences, Wuhan, China.*

Northeast British Columbia (Canada) is an area of intensive hydraulic fracturing for natural gas exploitation. Concerns have been raised regarding the potential health effects of contaminants emitted by gas exploitation. Some epidemiological studies have found associations between proximity/density of wells and negative birth outcomes. Our objective was to assess associations between proximity/density of wells and birthweight, small for gestational age (SGA), preterm birth and head circumference. We used birth records from the Fort St John hospital from January 1 2007 to December 31 2016 (n = 6333 births). We constructed three exposure metrics by calculating the inverse distance-weighted (IDW) sum of wells within three buffers around maternal postal code centroid: 2.5, 5 and 10 km. IDWs were categorized into quartiles. We then used linear or logistic regression to evaluate associations between IDW quartiles and birth outcomes. Models were adjusted for infant's sex assigned at birth, parity, maternal age and smoking status. We found increased adjusted odds of preterm birth associated with proximity/density of wells in the 2nd (odds ratio [95% confidence interval] = 1.60 [1.30, 2.43]) and 3rd quartiles (1.34 [0.90, 2.08]) of the 2.5-km buffer. We found significant negative associations between birthweight and proximity/density of wells in the 2nd (adjusted beta [95% confidence interval]: -40.9 g [-78.0, -3.7]) and 3rd (-42.0 g [-79.2, -4.9]) quartiles of the 5-km buffer;, and in the 3rd quartile of the 10-km buffer (-47.3 g [-84.3, -10.3]). We found no significant association with SGA or head circumference. This is the first epidemiologic study in Northeastern British Columbia on the association between proximity/density of wells and birth outcomes. Our results provide some evidence of a potential association with more preterm births and reduced birthweight, but effect estimates did not match expected dose-response relationships.

1651 Pathogenicity and Antimicrobial Susceptibility of *Aeromonas hydrophila* Isolates from Fish in Abuja, Nigeria

N. Bawa, S. Mailafia, O. H. Olabode, and M. M. Onakpa. *University of Abuja, Abuja, Nigeria.*

The adverse effects of *Aeromonas* species have been reported in aquatic organisms, humans and food spoilage globally especially in developing countries like Nigeria with *Aeromonas hydrophila* as the most common and toxin producing species. Pathogenicity studies of infections caused by aeromonads is often neglected and under reported which necessitated this study to establish the virulence factors and effectiveness of selected antimicrobials on isolates obtained from fresh and ready to eat fish in Abuja-Nigeria. Fish samples were collected and processed from major markets in some Area Councils in Abuja for conventional culture and identification methods at the Public Health Bacterial Zoonosis Laboratory, Faculty of Veterinary Medicine, Ahmadu Bello University Zaria, Kaduna State. The presumptive *Aeromonas* hydrophila isolates were further subjected to extracellular virulence factors determination assay based on protease production, DNase production, hemolysin production and enterotoxin production using Suckling Mouse Test (SMT). Antimicrobial susceptibility testing on isolates was also conducted using Kirby Bauer disc diffusion method. Results showed that all the isolates produced 100% DNase, gelatinase, and hemolysin while few (40%) produced exotoxins. Distended abdominal-body weight ratio and black necrotic gastrointestinal tract lesions further confirmed evidence of enterotoxins. Isolates also dissipated array of resistance to different antimicrobial agents. These virulent factors could have been involved in the pathogenicity and resistance of isolates. In conclusion, *Aeromonas* hydrophila is highly pathogenic and resistant to commonly used antibiotics. Hence, the need create public awareness on the health implication of this organism and design of appropriate measures for *Aeromonas* menace control in Abuja and Nigeria.

1652 Automated Mining of Vaping-Associated Health Effects Reported in Online Forums

M. Hua, S. Sadah, V. Hristidis, and P. Talbot. *University of California Riverside, Riverside, CA.*

Vaping-associated pulmonary illness (VAPI) has reached epidemic proportions in the United States. To better understand VAPI, we used computer automated methods to extract and analyze over 41,000 posts from a major EC online forum. The posts spanned 7.5 years and were used to identify the health effects associated with EC use. Extracted data were annotated with a set of medical concepts from the Unified Medical Language System (UMLS), using a modified version of the MetaMap tool. Posts were used to analyze symptoms (undiagnosed conditions) and disorders (physician diagnosed terminology) associated with EC use. Symptoms and disorders were then categorized into 12 organ systems/anatomical regions. Data were further analyzed for: (1) frequency of symptoms and disorders, (2) sentiment, (3) changes in reported health effects between 2008 and 2015, (4) linkage between symptoms, and (5) similarities between our data and VAPI case report symptoms. Symptoms and disorders were most often reported in the neurological, respiratory, digestive, integumentary, and mouth/throat systems, over the 7.5-year period studied. The most common symptoms were: headaches (N=939), coughing (N=852), pain in throat (N=643), dermatitis (N=565), and heartburn (N=327). The most commonly reported disorders were asthma (N=916), pharyngitis (N=565), chronic obstructive pulmonary disorder (N=471), dehydration (N=403), aptyalism (N=377), and pneumonia (N=367). Overall, most symptom and disorder posts contained negative sentiment across all years. Several symptoms were linked (e.g., coughing and headache). Additionally, many commonly reported symptoms in this dataset are present in the current VAPI cases. Online forums are a unique repository of data that can track health effects over time. This is the first study to use automated methods to retrieve EC health data online, and it demonstrates the importance of medical Internet surveillance. Our data agree well with the symptoms of reported for VAPI cases. This suggests that health problems have existed among vapers for at least 7.5 years, although this has not been widely recognized by the medical community until now. Our data also suggest that there are many other EC users with pulmonary illness due to vaping who are not yet part of the statistical data reported by the Centers for Disease Control.

1653 Exposure Assessments and Cancer Epidemiology: Will the Past Work for the Future?

J. LaKind[1], J. Naiman[2], C. Burns[3], Z. Yan[4], and C. Terry[4]. *[1]LaKind Associates LLC, Catonsville, MD; [2]University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; [3]Burns Epidemiology Consulting, Sanford, MI; and [4]Corteva Agriscience, Indianapolis, IN.*

Of the many chemicals assessed under US EPA's Integrated Risk Information System (IRIS) program, a small number have been classified as known human carcinogens. The classifications are based in part on epidemiological studies with various types of exposure assessments. We reviewed the underlying epidemiology studies that support ten carcinogen determinations and examined methods used in the exposure assessments. We found that the studies have four common features: (1) predominantly retrospective, (2) occupational-based, (3) presumably high exposures (compared to general population exposures) and (4) exposure assessments including limited to no chemical measurement data or methods documentation. Chemical-specific examples (e.g., nickel subsulfide, benzene, arsenic) highlighting various issues (e.g., peak versus average exposures, temporal variability) with exposure assessments in research used as part of IRIS assessments will be described. Although many recent meta-analyses and literature reviews on carcinogens have not uniformly incorporated quality appraisals, some agencies are presently using formal, systematic approaches to assessing study quality as part of decision-making and this is becoming the state-of-the-art for both regulatory decision-making as well as literature reviews. Current methods and approaches developed for conducting these kinds of appraisals will be discussed. These include systematic review approaches developed as part of EPA's IRIS program and Toxic Substances Control Act risk evaluations as well as approaches developed by the National Institute of Environmental Health Sciences. These examples can assist investigators who wish to develop studies that consider newly emerging risk of bias assessments.

1654 E-waste in Ghana: An Assessment of Health and Psychosocial Effects on Communities in and around Agbogbloshie

R. Awuah[1], O. Avenbuan[2], C. Awada[2], N. Louis[2], J. Zelikoff[3], and A. de-Graft Aikins[1,A]. *[1]Regional Institute for Population Studies, University of Ghana, Legon, Accra, Ghana; [2]New York University Langone Health, New York, NY; [3]New York University Langone School of Medicine, Environmental Medicine, New York, NY; and [4]Institute of Advanced Studies, University College London, United Kingdom.*

Electronic waste (e-waste) is a term coined to describe the end-of-life remnants of electronic equipment. This form of waste, shipped mostly from high-income to low-and middle-income countries (LMICs), is used particularly for mining of valuable metals - and thus is an integral part of the economy of many LMICs. This type of waste, however, has also become an emerging health concern. E-waste processing poses a threat to human health, due to lack of personal protective equipment, unsanitary conditions, and improper handling of hazardous metals. One area in Ghana in particular -Agbogbloshie- is home to one of the largest e-waste sites in the world. Past studies in this area have discovered elevated levels of organochlorines, pesticides, and heavy metals in the environment. To better understand the health and psychosocial effects of e-waste, a study involving 623 individuals in the e-waste enterprise and those who live close to the e-waste site in Agbogbloshie was conducted in October 2018. Findings from the surveys revealed that 51% of respondents experienced more than one symptom associated with heart disease, and 67% experienced symptoms associated with lung disease. The study also found that 27% of those working in the e-waste business experienced regular periods of work-related stress, 83% of the workers from this study said they knew the dangers of e-waste, and over 90% of workers would be interested in getting more information on how e-waste relates to their health. Given that cardiovascular and lung-related diseases are among the leading causes of death globally, there is increasing concern about how e-waste may contribute to the overall health burden of Ghana and other countries that are also economically-supported by e-waste. Given the increase of e-waste processing sites around the world and the toxicity of most e-waste constituents such as cadmium, nickel, arsenic and plastics which are often burned after the pile is 'scrounged', highlighting the health implications associated with exposure to e-waste, possible solutions and policy changes will help better understand and educate the populations being impacted. *Supported by NYU Global College of Public Health Affinity Grant; NYU NIEHS P30ES000260-55.*

1655 Antibacterial Effects of Antiretrovirals: Implications for Aquatic Systems and Public Health

V. J. Wallace, E. G. Sakowski, S. P. Preheim, and C. Prasse. *Johns Hopkins University, Baltimore, MD.*

Antiretroviral (ARV) drugs are used as treatment or prophylaxis for human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) by over 23 million persons worldwide. Nucleoside reverse transcriptase inhibitors (NRTIs), one class of ARVs, are analogs of the biological nucleosides adenosine, guanosine, thymidine, and cytidine and are designed to inhibit the HIV reverse transcriptase enzyme. One NRTI in particular, azidothymidine (AZT), a thymidine analog, possesses not only antiretroviral capacity but also antibacterial capacity. However, little is known about the antibacterial capacity of other NRTIs. In this study, we compared the impacts of AZT and six other common NRTIs on the growth of the model bacterium *Escherichia coli* in culture. Effects of NRTIs individually and in combination were assessed at concentrations ranging from 0.001 ug/ml to 100 ug/ml over 48 hours. AZT concentrations as low as 0.001 ug/ml decreased the growth of *E. coli* by one-third within 5 hours of incubation compared to controls. The NRTIs lamivudine, stavudine, and didanosine also demonstrated antibacterial capacity. *E. coli* treated with these NRTIs showed reduced growth compared to controls within 10 hours at concentrations between 0.1 and 100 ug/ml. Interestingly, *E. coli* quickly developed resistance to stavudine, didanosine, and lamivudine, and resistance to one NRTI conferred resistance to other NRTIs when challenged despite chemical structural diversity, suggesting the mode of action of NRTIs on *E. coli* may be similar. Previous work has revealed presence of ARVs in wastewater, river water, and drinking water throughout the world. ARVs have the potential to affect the natural bacterial and viral ecosystems of aquatic environments as well as the beneficial biota of the human gut microbiome. As this work highlights, the antibacterial effects of ARVs, and the potential for developing resistance, have important implications for the public health, from water systems to human physiology.

1656 Respiratory and Cognitive Outcomes of Puerto Rican Children Exposed to Traffic-Related Air Pollutants

L. B. Mendez, and N. G. Medina. *Universidad Ana G. Méndez Carolina, Carolina, PR.*

Traffic-related air pollution (TRAP) emissions are a major source of air pollutants in urban areas. Puerto Rican children are considered a high-risk population due to high poverty rates, high asthma prevalence, and low academic achievement. Thus, the main goal of this study is to evaluate the impact of TRAP in lung function and neurocognition in Puerto Rican children living in urban areas. Specifically, to examine short- and long-term impact of living near two sources of TRAP in lung function and neurocognitive processes of 6 to 9 years-old schoolchildren. We conducted an exploratory longitudinal study (3 years) in which we recruited 46 children living upwind and downwind TRAP sources. During the academic year, lung function was measured on a weekly basis using a spirometer; and neuropsychological assessments were conducted every semester with the Spanish translation of the Cognitive Assessment System 2nd edition (CAS2). Environmental monitoring included meteorological variables (temperature, relative humidity, wind speed and direction) and pollutant concentrations ($PM_{2.5}$, CO_2, VOCs). Parents and legal guardians filled a questionnaire about health, environmental factors and sociodemographic information. The median age at recruitment was 6.3 years. Participants were 57% female, 100% Hispanic, and mostly of low socioeconomic status (79.5% from households with incomes below $25,000 and 68.9% enrolled in public health insurance). Lung function measurements revealed lung volumes lower than predicted for their age, sex, height, and ethnicity based on NHANES III reference values. Lung volumes were consistently lower in participants living downwind TRAP sources, mostly for forced expiratory volume in 1 second (FEV1). Similarly, children scored below average in all cognitive tests, mainly in the planning and successive processing assessments. Overall results suggest impairments in respiratory and cognitive health of Puerto Rican children living near TRAP sources.

1657 Indoor Dust Assessment of Endotoxin and B-Glucans Levels in the Aftermath of a Major Hurricane

K. Casillas Pagan[1], and L. B. Mendez[2]. *[1]Universidad Ana G. Méndez Cupey, San Juan, PR; and [2]Universidad Ana G. Méndez Carolina, Carolina, PR.*

Hurricane-related water damage can lead to an increase in indoor growth of microorganisms such as bacteria and mold. Indoor exposure to these microbes and its components, such as endotoxin and β-glucans, can cause respiratory illness such as allergic rhinitis, exacerbation of asthma, hypersensitivity pneumonitis, and respiratory infections. Therefore, the purpose of this study is to characterize the potential risk of exposure to endotoxin and β-glucans in occupational settings that sustained water-damage due to the landfall of Hurricane María in Puerto Rico. We collected indoor dust from horizontal (i.e. desks) and vertical surfaces (i.e. walls) 21 months post-hurricane since Puerto Rico is still not fully recovered. Dust samples were obtained from buildings located in municipalities with varying degrees of water-damage. A total surface area of 100cm^2 was assessed for desks and 900cm^2 for walls. Each area was sampled in triplicate. Samples were collected with sterile foam swabs, extracted by sonication with endotoxin-free water, and analyzed for endotoxin and β-glucans using the kinetic Limulus Amebocyte Lysate and Glucatell assays, respectively. Results revealed that β-glucans were >5,000 pg/m^2 in all samples. Endotoxins concentrations varied between 0.001 EU/m^2 and 1000 EU/m^2. Higher concentrations of endotoxin (up to 700X) were observed in areas that presented more damage from the hurricane when compared to the other sampling sites. Therefore, our results suggest that almost two years after the hurricane, workers are at risk of being exposed to endotoxin and β-glucans concentrations that can induce adverse health effects.

1658 Maternal Serum Folate Concentrations Modify the Association between Prenatal Arsenic Exposure and Birth Outcomes in the Biomarkers of Exposure to ARsenic (BEAR) Cohort

J. Clark[1], P. Bommarito[1], M. Stýblo[1], M. Rubio-Andrade[2], G. G. García-Vargas[2], M. V. Gamble[3], and R. C. Fry[1]. *[1]UNC Gillings School of Global Public Health, Chapel Hill, NC; [2]Universidad Juárez del Estado de Durango, Gómez Palacio, Mexico; and [3]Columbia University Mailman School of Public Health, New York, NY.*

Women of reproductive age, especially those planning to become pregnant, are advised to consume folate for the prevention of neural tube defects among offspring. As a methyl-donor nutrient, folic acid may also be critical to the metabolism of inorganic arsenic (iAs), a ubiquitous environmental contaminant and carcinogen commonly found in drinking water. iAs is biotransformed to monomethylated (MMA) and dimethylated (DMA) arsenic through the addition of methyl groups, and folate supplementation among adults has been shown to improve metabolism efficiency. We previously identified associations between iAs exposure during pregnancy and birth outcomes in the Biomarkers of Exposure to Arsenic (BEAR) cohort (n = 200). To identify whether these associations are attenuated by increased folate consumption, multivariable-adjusted linear regression models were fit. Likelihood ratio tests were implemented to evaluate the goodness-of-fit of interaction models as compared to main effects models. Additionally, to compare the magnitude of each association according to folate status, strata-specific mean differences and 95% confidence intervals were estimated. Overall, the prevalence of folate deficiency, defined as less than 9 nM, was low (< 2%). Still, significant (p < 0.10) effect modification by folate was observed on the additive scale for the associations between U-tAs (β: 2.89, p: 0.06), U-MMAs (β: 41.70, p: 0.07), and U-DMAs (β: 3.19, p: 0.06) and birth weight (g) and between DW-iAs (β: 0.01, p: 0.07), U-iAs (β: 0.19, p: 0.03), and U-MMAs (β: 0.19, p: 0.02) and head circumference (cm). Despite a high prevalence of folate sufficiency, increased folate uptake modified the association between drinking or urinary arsenical metabolites and birth outcomes. The results from this cross-sectional study suggest that infants born to women living in regions with high iAs-contaminated drinking water may benefit from increased prenatal folic acid supplementation, at levels exceeding current recommendations.

1659 ToxPi*GIS: Translation of Multi-Stream Data into Interactive Visual Profiles within a Geospatial Context

S. Marvel[1], S. Bhandari[2], F. Wright[1], I. Rusyn[2], W. Chiu[2], and D. Reif[1]. *[1]North Carolina State University, Raleigh, NC; and [2]Texas A&M University, College Station, TX.*

Creating effective policies to support public health and respond to environmental emergency-related events require accessible tools and models that address complex data on exposures and relevant pre-existing stressors. To support this objective, we have created a ToxPi*GIS tool that integrates diverse data streams into interactive profiles atop geographic information system (GIS) layers. The Toxicological Prioritization Index (ToxPi) framework creates visual profiles that communicate scores and an accompanying statistical framework for comparison, clustering, and evaluation of model sensitivity to component data streams. The ToxPi*GIS tool combines this profiling framework with ArcGIS to create a web interface that can handle data from any geographic region of interest. Here, we present results from analysis of environmental data on contaminants, health, socioeconomics, and flooding for census tracts in the greater Houston, TX area. The ToxPi*GIS results highlighted areas of high concern (statistically significant collections of census tracts according to the Getis-Ord Gi* statistic) in our integrated model. By comparing ToxPi profiles across all tracts to identify clusters of multivariate profile similarity, we also found geographically disparate areas that showed similar drivers of concern. Thus, ToxPi*GIS helps identify both geographically-adjacent and geographically-distinct clusters, where integrated profiles can be assessed to promote creation of targeted, effective community policies. Users can upload models for any geographic area of interest, explore global patterns, perform multi-criteria filtering, and export results for sharing from the free, interactive ToxPi*GIS interface at https://toxpi.org/gis.

1660 Association between Thyroid Cancer Risk and Exposure to Heavy Metals: A Systemic Review and Meta-Analysis of Cohort Studies

W. Yu[1], J. Li[2], X. Du[3], M. D. Cohen[1], B. Li[4], and L. Chen[1]. *[1]New York University School of Medicine, New York, NY; [2]University of Hong Kong School of Public Health, Hong Kong, Hong Kong; [3]Peking University First Hospital, Beijing, China; and [4]The Second Hospital of Shandong University, Jinan, China.*

Thyroid cancer is one the most common endocrine malignancies whose incidence rate has rapidly increased in the past few decades. However, the risk factors contributing to the rise of thyroid cancer remain not well-elucidated. Animal studies and clinical evidence have suggested that increased exposure to heavy metals could disrupt thyroid homeostasis and function, alter peripheral metabolism, and accelerate thyroidal tumorigenesis. Nevertheless, epidemiological evidence regarding effects of heavy metals on thyroid carcinogenesis has been inconsistent. Therefore, the aim of this study was to perform a meta-analysis to assess the potential effects of heavy metal exposures on thyroid cancer risk. A comprehensive literature search was conducted to identify eligible studies based on the guidelines of MOOSE and PRISMA. Summary relative risk (RR) and confidence intervals (CI) were used to compute thyroid cancer risk by random-effects models. The heterogeneity was assessed for statistical significance using I^2-based-Cochrane Q test. Overall, 4917 bibliographic records were identified; 8 cohort studies were eventually included for analysis. Exposure to heavy metals is associated with a significant rise in thyroid cancer risk (RR = 1.40, [CI 1.16- 1.69], $p < 0.001$). Subgroup analysis revealed an increased thyroid cancer risk from heavy metal exposure in both sexes, with the effect more pronounced in females than in males (RR = 2.01 [CI 1.73 - 2.34] vs RR = 1.86 [CI 1.63 - 2.12], respectively). Elevated thyroid cancer risk is associated with exposure to a mixture of multiple heavy metals simultaneously (RR = 1.83, [CI 1.62- 2.05], $p = 0.003$), while more evidence is needed to conclude such association with exposures to single heavy metals (RR = 1.88, [CI 0.95- 3.71], $p = 0.2$). Pooled relative risks for environmental exposures and occupational exposures were 1.88 ([CI 1.62 - 2.16], $p < 0.001$) and 1.69 ([CI 1.40 - 2.03], $p = 0.532$), respectively. No publication bias was detected. Our study indicates that heavy metal exposure, both environmental and occupational, is associated with an elevated thyroid cancer risk. Therefore, heavy metal exposures should be further evaluated as a potential risk factor for the global upward trend of thyroid cancer incidence.

1661 The Associations between Primary Ovarian Insufficiency and Environmental Pollutants in Korea

Y. Kim[1,2], E. Lee[1], J. Song[3], K. Kwack[4], and K. Baek[4]. *[1]Korea University College of Medicine, Seoul, Korea, Republic of; [2]Korea University Graduate School, Seoul, Korea, Republic of; [3]Anam Hospital, Korea University, Seoul, Korea, Republic of; and [4]CHA University, Gyeonggi-Do, Korea, Republic of.*
Sponsor: J. Park

The prevalence of primary or premature ovarian insufficiency (POI) is about 1% in women before the age of 40. As the prevalence of POI continues to increase, exposure to environmental pollutants is being discussed as one of the factors causing POI. The purpose of this study is to investigate the associations between environmental pollutants and POI in Korea. The subjects were one hundred and fifty six women who were recruited in Anam Korea University Hospital (IRB No.2016AN0251). Because POI is characterized by increase of follicle stimulating hormone (FSH) with decrease of anti mullerian hormone (AMH), the subjects were evaluated by the serum level of FSH and AMH with other gynecological examinations. The subjects were classified into three groups as POI patients, borderline POI patients, and non-POI normal subjects. Their urinary concentrations of metabolites of phthalates, bisphenol A, volatile organic compounds (VOCs), and polycyclic aromatic hydrocarbon (PAH) were determined for the evaluation of exposure to environmental pollutants. POI patients showed highest concentrations of phenyl glyoxylicaid (PGA) and 1-hydroxypyrene (1-OHP) among three POI/normal groups. And subjects were stratified into 26-30, 31-35 and 36-40 years old age groups to compare urinary concentrations of pollutants among three POI/normal subjects in the same age group. All age subgroups showed that POI patients had the highest 1-OHP levels among three POI/normal subjects. And both mandelic acid (MA) and PGA concentrations of POI patients were significantly increased only in the 31-35 years old age group. To evaluate the association of AMH levels and exposure to environmental pollutants only in normal subjects, the subjects were divided into high and low exposure groups based on each urinary metabolites of pollutants. Significantly lower levels of AMH showed in high exposure groups of 2,4-Dichlorophenoxyacetic acid (2,4-DCP), N-Acetyl-S-(benzyl)-L-cysteine (BMA) than low exposure groups. And decreasing trend of AMH levels were found in high exposure groups of phthalate, BPA and VOC than low exposure groups. Our study suggests that several environmental pollutants might be risk factors to POI or decrease of AMH.

1662 Identification of Metal Mixtures in Pregnant Women and Associations with Offspring Weight and Blood Pressure Outcomes at 4-6 Years of Age

S. S. Park, J. Tzeng, and C. Hoyo. *North Carolina State University, Raleigh, NC.*

Toxic metals including arsenic, cadmium, and lead are chemical pollutants that often co-occur in the environment. Prenatal exposure to heavy metals can affect proper fetal growth and development, which is a risk factor for obesity and its co-morbid conditions. Our study objectives are to: 1) identify metal combinations present in the blood of pregnant women in our birth cohort; and 2) determine whether prenatal exposure to metals either individually, or as a mixture, are associated with an increased risk for offspring obesity and elevated blood pressure. To address these questions, we measured the blood concentrations of 24 metals which include heavy, trace, and potentially nutritive metals in n=310 women during their first trimester of pregnancy and applied both unsupervised and supervised statistical methods. We used Factor Analysis to identify metal mixtures in maternal blood and ran sex-stratified regression models including Partial Least Squares and Elastic Net to assess associations between potential key metals and their effects on weight and systolic/diastolic blood pressure in offspring between 4-6 years of age. We identified consistent and significant ($p<0.05$) associations between metals, including arsenic and chromium, and increased weight and blood pressure. Further analysis and characterization are needed for metals speciation and to ascertain exposure sources.

1663 Applying the Key Characteristics Approach for Identification and Analysis of Toxicological and Mechanistic Evidence on Benzo[a]Pyrene-Induced Male Reproductive Toxicity

X. Arzuaga[1], I. Druwe[2], E. Yost[2], C. Gibbons[1], J. Congleton[1], and H. Andrew[2]. *[1]US EPA, Washington, DC; and [2]US EPA, Durham, NC.*

Hazard evaluation of chemical-induced adverse responses in the male reproductive system involves qualitative analyses of epidemiological, toxicological, and mechanistic studies. Inclusion of mechanistic evidence in this analysis can inform the biological plausibility and human relevance of effects observed in experimental models. However, the diversity of research methods and models, and the variety of proposed and known pathways for chemical-induced reproductive toxicity can add difficulty to the practice of screening and analyzing mechanistic outcomes. The ten key characteristics of carcinogens provide a tool for identifying, organizing, and evaluating chemical-specific mechanistic evidence. Here we apply the eight key characteristics of male reproductive toxicants to identify and analyze the toxicological and mechanistic evidence on benzo[a]pyrene (B[a]P)-induced male reproductive effects. A literature search was performed to capture mechanistic studies and literature inventories were developed to extract evidence from the identified studies and facilitate the qualitative review process. Preliminary analysis suggests that several key characteristics are involved in B[a]P-induced male reproductive effects, including: alters somatic cell development, functions, or death; alters germ cell development, function, or death; is genotoxic; induces oxidative stress alters production and levels of reproductive hormones; and alters hormone receptor levels/functions. A qualitative evaluation is underway to identify potential pathways of B[a]P-induced male reproductive toxicity and ascertain the biological plausibility and human relevance of the effects reported in experimental analysis. The B[a]P case study demonstrates that the key characteristics approach serves as a practical and objective tool for identifying, organizing, and evaluating chemical-specific mechanistic studies and evidence on male reproductive toxicity. *Disclaimer: The views expressed are those of the authors and do not necessarily represent the views or policies of the US EPA.*

1664 Evaluation of Hair Breakage following Repeated Grooming of a Personal and Care Cosmetic Product

C. Register[1], K. M. Towle[2], E. S. Fung[3], and A. D. Monnot[2]. *[1]WEN by Chaz Dean, Los Angeles, CA; [2]Cardno ChemRisk, San Francisco, CA; and [3]Cardno ChemRisk, Aliso Viejo, CA.*

There have been reported adverse event claims associated with the use of WEN by Chaz Dean (WCD) cleansing conditioners, resulting in an investigation by the US Food and Drug Administration (US FDA). Specifically, users of WCD cleansing conditioners have reported hair loss, hair breakage, and skin irritation reactions. Therefore, this analysis performed a dry repeated grooming study to assess if application of WCD cleansing conditioners was associated with changes in hair tensile strength and hair breakage. Ten European medium brown hair tresses (9% bleached, 3.0 g, 8" length, 1" wide) were used in each treatment group. The control hair was treated with 15% sodium lauryl ether sulfate, typical control conditions, for a 30 seconds lather and 30 seconds rinse, while the test hair was treated with the top 3 selling WCD cleansing conditioners (Sweet Almond Mint, Lavender, and Pomegranate) for 10 minutes (to simulate a typical shower application), followed by a 30 seconds rinse. Hair was equilibrated overnight and then was groomed using an automatic comber for 2,000 cycles, with broken hair fibers collected every 200 cycles. Hair treated with WCD cleansing conditioners had a statistically significant fewer number of broken hair fibers in comparison to the control. The mean number of broken fibers after 2,000 brush strokes were: 43 fibers (control), 22 fibers (Sweet Almond Mint), 28 fibers (Lavender), and 28 fibers (Pomegranate). The WCD cleansing conditioners exhibited beneficial qualities of acting as surface lubricants that reduced stress from grooming, and thus, reducing hair breakage. Overall, findings from this analysis provide evidence that under the conditions tested, the use of WCD cleansing conditioners is not associated with hair breakage following repeated grooming.

1665 Mucosal Damage and Gamma-H2AX Formation in the Rat Urinary Bladder Induced by Aromatic Amines with Structures Similar to That of *o*-toluidine

T. Toyoda[1], T. Yamada[1,2], K. Matsushita[1], T. Morikawa[1], and K. Ogawa[1]. *[1]National Institute of Health Sciences, Kawasaki, Japan; and [2]Tokyo University of Agriculture and Technology, Tokyo, Japan.*

Although some of aromatic amines are closely associated with the risk of bladder cancer, the bladder toxicity and carcinogenicity of many aromatic amines remain unknown. Our recent study demonstrated distinct differences in the mechanisms of mucosal damage in the urinary bladder of rats receiving *o*-toluidine and *o*-anisidine, which are bladder-carcinogenic aromatic amines. In the current study, we examined histopathological changes and formation of γ-H2AX, a biomarker of DNA damage, in the urinary bladder of rats in order to examine the bladder toxicity and carcinogenic potential of several aromatic amines with structures similar to that of *o*-toluidine. Methods: Six-week-old male F344 rats were administered 1.0% 4-chloro-*o*-toluidine (4-CT), 0.5% 5-chloro-*o*-toluidine (5-CT), 0.5% *o*-aminoazotoluene (AAT), 1.0% 2-aminobezyl alcohol (ABA), or 1.0% *o*-acetotoluidine (*o*-AT) in the diet for 4 weeks. Five animals in each group were necropsied on day 2 and weeks 1, 2, and 4, and histopathological and immunohistochemical analyses were performed. In the 4-CT and *o*-AT groups, bladder lesions similar to those induced by *o*-toluidine, including hemorrhage, interstitial necrosis, perivascular inflammation, granulation tissue formation, and simple hyperplasia, were observed from week 1. In the AAT and ABA groups, simple hyperplasia without degenerative and inflammatory changes was detected from week 1, similar to *o*-anisidine. γ-H2AX-positive epithelial cells in the urothelium were significantly increased in the 4-CT, AAT, ABA, and *o*-AT groups from week 1 or week 2. No apparent bladder lesions or significant increases in γ-H2AX formation were observed in rats receiving 5-CT, despite having a structure similar to that of 4-CT. Our results suggested that 4-CT, AAT, ABA, and *o*-AT may induce DNA damage in the urinary bladder of rats. Moreover, histopathological examination revealed that there were two distinct mechanisms of bladder mucosal damage, similar to *o*-toluidine (4-CT and *o*-AT) and *o*-anisidine (AAT and ABA), respectively. Further studies are needed to clarify the molecular mechanisms of bladder toxicity associated with these aromatic amines.

1666 Stepwise Safety Evaluation Process for Natural Complex Substances

D. J. Botelho, G. Ritacco, A. Lapczynski, Y. Thakkar, K. Joshi, S. Gadhia, M. Na, N. Sadekar, M. Daté, C. Deodhar, M. Lavelle, F. Rodríguez Ropero, D. Selechnik, M. Cancellieri, S. Biserta, M. Kolman, and A. Api. *Research Institute for Fragrance Materials, Woodcliff Lake, NJ.*

The Research Institute for Fragrance Materials, Inc. (RIFM) has evaluated the safety data for fragrance materials for over 53 years. The process to evaluate fragrance materials and available data has evolved as new scientific approaches emerge. Since 2013, RIFM has focused its efforts to evaluate discrete, synthetic materials, but in 2019 and beyond the primary focus has shifted to evaluating Natural Complex Substances (NCS). A common misconception is that "natural" inherently means safe and simple, but determining the safety of NCS is an issue facing many industries. RIFM will leverage the latest science as well as the extensive knowledge compiled over the years concerning the components of NCS. The basic premise is the same as for discrete fragrance materials in that all of the same endpoints (Genotoxicity, Phototoxicity and Photoallergenicity, Skin Sensitization, Repeat Dose Toxicity, Developmental and Reproductive Toxicity, Local Respiratory Toxicity, as well as Environmental Risk and Hazard) will be addressed (Api, et al., 2015). A series of decision trees, reflecting advances in approaches in risk assessment of mixtures as well as classical toxicological methodologies will follow a similar four-step process with testing only as a last resort: Step 1) evaluate the available data on the NCS, 2) can Threshold of Toxicological Concern (TTC) be applied, 3) can the NCS risk assessment be achieved on a component basis, 4) data may need to be generated. For each endpoint, a tiered approach was developed based on this 4-step premise. Using *in silico* tools, RIFM examined NCS similarities based on plant part, processing (distillation, mechanical extraction, and solvent extraction), and composition of materials across 81 plant families in an effort to address data gaps. Data generated from the Creme RIFM Aggregate Exposure Model for over 900 fragrance NCS demonstrates that dermal exposure is the primary route of human health exposure, and over a third of the materials are below the most conservative TTC limits. This process provides a comprehensive and robust safety assessment of NCS. Api, et al., 2015. Criteria for the Research Institute for fragrance materials, Inc. (RIFM) safety evaluation process for fragrance ingredients. Food Chem. Toxicol. *82, S1-S19.*

1667 A Safety and Effectiveness Evaluation of a Callus Softener Containing Potassium Hydroxide

D. Galbraith, J. Kozal, A. Monnot, and K. Towle. *Cardno ChemRisk, San Francisco, CA.*

Limited safety information has been described in the peer-reviewed literature for callus softening products containing potassium hydroxide. This pilot human use study evaluated the safety and effectiveness of a commercially available callus softener, containing less than 10% potassium hydroxide by weight. Baseline callused skin was scored (grade 1-4) on each study participant's feet (n=10). Participant's feet were soaked and then a licensed manicurist applied a callus softener product to the right foot, which remained on callused skin for 3 to 5 minutes (no callus softener was applied to the participant's left foot). Both feet were then wiped with a wet towel, and a foot rasp was used to file the callused skin, beginning on the left foot. Callused skin was scored and participant's feet were evaluated by a physician immediately post use, 1-day post use, and 1-week post use for the presence/absence of skin irritation, adverse skin reactions, and chemical burns. No adverse events were reported by study participants or the physician for all evaluation time points. Each participant's highest callus grade score on the treated foot either improved or remained the same following product use (compared to baseline). Mean callus grade scores were 1.75 at baseline, 1.55 immediately post use, 1.25 1-day post use, and 1.50 1-week post use. Results from this pilot study suggest that callus softening products containing less than 10% potassium hydroxide are likely to be safe and effective products under intended use scenarios of 3-5 minute application times, as dictated by product label instructions.

1668 Glyphosate Safety Assessment through Ames Test

P. Kaldhone, J. Yan, T. Chen, and M. Manjanatha. *US FDA/NCTR, Jefferson, AR.*

Glyphosate is widely-used herbicide to control unwanted grass and broadleaf weeds. It is one of the active ingredients in Roundup, a ubiquitous organophosphorus compound. A recent lawsuit in California associating glyphosate with lymphoma generated media interest regarding the safety of glyphosate. US EPA and IARC (International Agency for Research on Cancer) have conflicting views associated with the risks related to glyphosate. We conducted the Ames test, a gold standard test the FDA uses as a part of a battery to access mutagenicity of test compound. Four different *Salmonella* Typhimurium strains were used to screen the genotoxicity of glyphosate. Treatment with and without S9 activation were conducted to understand the toxicity potential under metabolic activation. OECD (Organization for Economic Co-operation and Development) protocol 471 was followed to perform this assay. Two strains of *Salmonella* Typhimurium, 1535 and 1537 showed higher number of revertants with S9 activation. At higher concentrations, 500 and 5000 µg/ml, colony count were decreased as compared to controls, indicating toxic effect of glyphosate. The remaining two strains, 98 and 100, did not show toxic potential of the glyphosate. Overall, Ames test using these four strains did not reveal mutagenic potential of glyphosate. However more studies including additional *Salmonella* enterica and *E. coli* strains are required to explain risk associated with glyphosate. *In vitro* and *in vivo* studies using various cell lines and animal models respectively can shed more light on risk associated with glyphosate.

1669 Human Health Hazard Assessments of Alkyl Dimethyl Benzyl Ammonium Chloride and Didecyl Dimethyl Ammonium Chloride

P. DeLeo[1], A. Luz[1], N. Pechacek[2], and H. Lu[3]. *[1]Integral Consulting Inc., Annapolis, MD; [2]Ecolab, Eagan, MN; and [3]Lonza, Morristown, NJ.*

Quaternary ammonium compounds (Quats) are a large group of permanently charged cationic chemicals that are used in a variety of consumer and industrial products. Alkyl (C12, C14, C16) dimethyl benzyl ammonium chloride (ADBAC) and didecyl dimethyl ammonium chloride (DDAC) are two of the most widely used biocidal Quats that are representative of two structurally distinct classes. In Europe, biocidal Quats are regulated by ECHA under the Biocidal Products Regulation (BPR), while US EPA regulates biocidal Quats under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA). Both agencies require substantial amounts of human health hazard data to support registration. Available data indicate that ADBAC and DDAC are poorly absorbed via the oral and dermal routes (≤10%), are not systemically distributed, undergo limited metabolism, and are primarily excreted in the feces. ADBAC and DDAC are not dermal sensitizers, genotoxic, carcinogenic, or specific developmental or reproductive toxicants. ADBAC is acutely toxic via the oral (LD_{50}s = 154 to 550 mg/kg), dermal (LD_{50}s = 704 to 3,413 mg/kg), and inhalation (0.054 mg/L < LC_{50} < 0.51 mg/L) exposure routes. DDAC is acutely toxic via the oral (LD_{50}s range from 238 to 329 mg/kg) and inhalation (LC_{50} = 0.07 mg/L) exposure routes, but not via the dermal route. In terms of inhalation toxicity and potential exposure via this pathway, ADBAC and DDAC are both considered nonvolatile, and do not readily become airborne during most applications. Both ADBAC and DDAC are irritating/corrosive to the skin, and can cause non-specific toxicity in subchronic and chronic repeated dose oral toxicity studies. Reported NOAELs for ADBAC and DDAC range from 3.7 to 188 mg/kg-day and 10 to 93.1 mg/kg-day, respectively, in subchronic and chronic toxicity studies conducted with mice, rats, and beagles. Adverse effects associated with reported NOAELs are consistently characterized by local irritation of the stomach, reduced body weight gain, and reduced food consumption, indicative of portal-of-entry effects commonly associated with irritating/corrosive chemicals. Based on available data, local irritation is the main hazard associated with ADBAC and DDAC, which is consistent with hazard assessments conducted by ECHA and US EPA under BPR and FIFRA, respectively.

1670 Effect of Exposure to Commercial Hair Care Products on Primary Human Hair Follicle Dermal Papilla Cells

J. A. Parker[1], K. M. Towle[2], A. D. Monnot[2], and E. F. Fung[1]. *[1]Cardno ChemRisk, Aliso Viejo, CA; and [2]Cardno ChemRisk, San Francisco, CA.*

Dermal papilla cells (DPCs), which are often described as stem cell-like cells, are specialized mesenchymal cells located inside human scalp hair follicles. DPCs play a key role in regulating development and growth of both the hair and hair follicle and have remained a topic of interest in the last few decades. More importantly, any adverse effect on DPCs may directly impact the growth and health of the entire hair. Recent allegations of hair loss due to use of hair care products have prompted interest in the potential impact on DPCs. Although no validated assays using human hair follicle dermal papilla cells (HFDPCs) exist, we designed an exploratory assay to evaluate the potential effects of product exposure on HFDPCs. Primary HFDPCs isolated from a female donor were cultured and treated with a range of dilutions of three commercial hair care products. These dilutions represent concentrations above that which is expected to come into contact with the hair follicles on the human scalp during product use (e.g., in the shower). In order to simulate a typical product use scenario, HFDPCs were treated for 15 minutes each day for five consecutive days. Repeated exposure to ≤ 0.001% hair care product did not significantly induce cytotoxicity compared to untreated (media only) controls, while significant cytotoxicity was observed upon treatment with 0.02% sodium dodecyl sulfate (SDS) (positive control). Additionally, no significant differences in cell morphology were observed following repeated exposure to the hair care products. Overall, this study indicates that exposure to commercial hair care products at the tested concentrations does not adversely impact overall viability and morphology of HFDPCs.

1671 Feasibility Assessment of Subcutaneous Radio-Telemetry Device Implantation in Cynomolgus Monkeys

M. Campbell, J. Forget, S. Nechev, A. Celori, B. Megrath, T. Hernandez, and T. Rogers. *Altasciences, Everett, WA.*

With the goal of potentially reducing the trauma caused by surgical implantation of telemetry units without negatively impacting the quality of information obtained from studies involving such implants, Altasciences investigated the feasibility and quality of data capture of two different methods of telemetry device implantation in non-human primates (NHPs): the standard intra-abdominal implant method vs. a less invasive subcutaneous implant method. Four animals (2 per gender) were assigned to each group. Animals were implanted with radio-telemetry transmitters to allow for continuous capture of cardiovascular and body temperature data. All animals recovered for a minimum of 21 days prior to the beginning of monitoring. Rectal temperature and clinical pathology (hematology, coagulation, and serum chemistry) were also captured on a weekly basis. Telemetry data obtained in weeks 1 through 6 showed no marked differences in cardiovascular readings between intra-abdominal and subcutaneous implants. Blood pressure, heart rate, and ECG were all found to be within normal ranges for both groups. There was a notable difference in body temperature readings obtained between the two implant sites during the first 3 weeks of monitoring. Mean temperatures recorded in the intra-abdominal implants were 1.5 degrees lower than rectal temperatures recorded on the same day, while temperatures in the subcutaneous implants were often 3 to 4 degrees lower. There appeared to be a gradual loss of accuracy over time in intra-abdominal tem-

perature readings after week 3. Minimal changes in clinical pathology observed during the post-implantation phase in both groups were consistent with low-grade inflammation. The pattern and extent of the alterations were comparable across implantation sites, indicating little difference in surgical trauma between methods. The feasibility of sustaining subcutaneous implant placement was limited by animal size. Larger male animals (4.5-5 kg) tolerated the subcutaneous implants well while the smaller females (~3 kg) did not due to the lack of a subcutaneous space that would allow the device to sit comfortably. One female was euthanized after 5 weeks of monitoring due to repeated exposure of the device. Subcutaneous telemetry implants appear to be a viable alternative to intra-abdominal implants in NHPs of sufficient size, but are not ideal for smaller animals.

1672 Does the Cytotoxicity of E-liquids Increase with Age?

J. H. Lauterbach. *Lauterbach & Associates, LLC, Macon, GA.*

Many users of e-vapor products favor highly flavored e-liquids. Such e-liquids are often contain aromatic aldehydes and other species that react with the glycerol and propylene glycol, the major constituents of e-liquids, to form acetals and other reaction products. E-liquid composition at the time of use depends, in part, on time since manufacture and what the user does with the bottles of e-liquid after purchase. Is it loaded into the vaping device as is, or is it modified by the user by steeping it by placing the container of e-liquid in an ultrasonic bath before use (a process that can cause chemical changes)? Moreover, there is a trend to providing e-liquids in larger containers than were formerly available. 120-mL bottles are common and one manufacturer is selling e-liquids in 1-liter containers. At 5-mL per day, are they any changes over the 24 days the 120 mL of e-liquid are used. Research to be presented covers these questions as well as addition of acids (so-called nic salts) for ten commercial e-liquids. For example, two vanilla-flavored e-liquids (one with nicotine salts and the other without nicotine) were forced aged (11 days at 64^{0}C), and the chromatographic (HPLC with several columns and conditions) and cytotoxic (NRU with CHO cells done by commercial laboratory) properties compared with each other and their unaged controls. Differences in the chromatographic processes were not reflected in the NRU data. A new sample of a highly flavored e-liquid in a 120-mL bottle was received from the manufacturer, and 5-mL aliquots were removed daily and stored in the freezer until the bottle was empty. Changes in composition were typical for those observed in steeping experiments; however, changes in cytotoxicity were unremarkable. Based on the data obtained changes in chemistry during aging are not reflected in the cytotoxicity assay.

1673 Therapeutic and Safety Evaluation of Flex Choice in Moderately Osteoarthritic Dogs

R. E. Webber[1], R. C. Gupta[2], R. B. Doss[2], T. D. Canerdy[1], A. Srivastava[3], and R. Lall[3]. *[1]Murray State University, Murray, KY; [2]Murray State University, Hopkinsville, KY; and [3]Vets Plus Inc., Menomonie, WI.*

Osteoarthritis (OA) is a chronic inflammatory degenerative joint disease that inflicts humans and animals alike. Currently, >20% of the adult and 80% of the geriatric dog population in the US (>90 million) suffer from OA. The pathophysiology of OA is very complex as it involves multiple mechanisms and molecular pathways. Currently, there are many choices to manage OA, but many veterinarians choose nutraceuticals because of lesser or no side effects compared to pharmaceuticals. The present investigation was undertaken to assess anti-arthritic efficacy and safety of FLEX CHOICE™ chews (a product of Clinics Choice, LLC) in dogs with moderate OA. FLEX CHOICE™ is composed of krill oil, hyaluronic acid, astaxanthin, *Boswellia serrata* extract, green lipped mussel, and iron transport tocopheryl polyethylene glycol succinate (ITPGS). Dogs with OA received FLEX CHOICE™ chews b.i.d. for 150 days. Each month, dogs were given a full exam and were evaluated for arthritic pain (overall pain, pain upon limb manipulation, and pain after physical exertion) using the Glasgow scoring system, CBC, and serum biomarkers of liver (bilirubin, ALT, and AST), kidney (BUN and creatinine), and heart and skeletal muscle (CK) functions. Dogs receiving FLEX CHOICE™ showed marked reductions in overall pain (52%), pain upon limb manipulation (35%), and pain after physical exertion (40%). The active ingredients in FLEX CHOICE™ exert anti-inflammatory, immunomodulatory, and anti-osteoarthritic effects. ITPGS, in addition to being a bioenhancer, exerts its effects such as antioxidative and anti-inflammatory. No significant (P>0.01) change occurred in physical parameters, CBC, and serum biomarkers of liver and kidney functions. Findings revealed that FLEX CHOICE™ significantly ameliorated OA-associated pain, and it was well tolerated by dogs with moderate OA.

1674 Systemic and Genetic Toxicity Evaluation of Fermented *Citrus sunki* Hort. ex Tanaka Peel Extract

J. Park[1], E. Cho[1], Y. Kim[1], E. Kwon[1], K. Han[2], S. Ku[3], C. Jung[3], J. Yun[4], J. Che[5], and B. Kang[1,6]. *[1]Seoul National University Hospital Biomedical Research Institute, Seoul, Korea, Republic of; [2]Dongguk University Ilsan Hospital, Goyang, Korea, Republic of; [3]Seoul National University Hospital, Seoul, Korea, Republic of; [4]Catholic University of Korea, Bucheon, Korea, Republic of; [5]Biomedical Center for Animal Resource and Development, Seoul National University College of Medicine, Seoul, Korea, Republic of; and [6]Graduate School of Translational Medicine, Seoul National University College of Medicine, Seoul, Korea, Republic of.* Sponsor: K. Lim

Citrus sunki Hort. ex Tanaka peel is known as a rich source of various flavonoids, showing therapeutic activity on obesity, inflammation and allergy, and neuronal damage. Despite the increasing consumption of *C. sunki* peel products as herbal medicine and supplements due to the beneficial effects, their toxicity remained largely uncharacterized. In this study, we assessed the potential health risk of fermented *C. sunki* peel extract (FCPE) by conducting acute and 90-day repeated oral toxicity studies in Sprague-Dawley rats, and genotoxicity tests according to the OECD test guidelines. Single oral administration of FCPE did not cause abnormal clinical signs nor lethality in rats, establishing LD50 to be >2000 mg/kg BW. Administration of up to 2000 mg/kg BW FCPE for 90 days revealed no test substance-related toxicity as observed in analysis of body weight gain, food/water consumption, blood, serum biochemistry, weight and histopathology of organs, determining that NOAEL for FCPE is >2000 mg/kg BW. Additionally, FCPE showed no mutagenicity and clastogenicity at 5000 μg/plate in the reverse mutation and chromosome aberration assays, and 2000 mg/kg BW in *in vivo* micronucleus test. Collectively, our results demonstrated that FCPE lack systemic and genetic toxicity in the dose range we tested, suggesting its safety for human consumption.

1675 A Skin Sensitization Risk Assessment Framework for Evaluation of Metal Contamination in Personal Care Products

E. S. Fung[1], K. M. Towle[2], M. T. Hoang[1], and A. D. Monnot[2]. *[1]Cardno ChemRisk, Aliso Viejo, CA; and [2]Cardno ChemRisk, San Francisco, CA.*

Metal contaminants have been reported in a variety of personal care and cosmetic products. At sufficient exposures, metals can produce a variety of effects including skin sensitization. The goal of this analysis was to determine whether metals known to induce or elicit skin sensitization are found in commercially available hair care products and, if present, pose a health risk to consumers. Ten commercial hair care products were evaluated for the following metals: Ag, As, Be, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Sn, and Zn via inductively coupled plasma mass spectrometry (ICPMS). A total of 6 metals (Be, Cd, Cu, Mn, Ni, and Zn) were identified between 4 of the products. Only 1 products were found to contain more than one of the metals. Of the metals identified, 1 has a cosmetic regulatory limit in the US (Zn), and 4 have cosmetic regulatory limits in the EU (Be, Cd, Ni, Zn). A survey of on-market consumer products revealed that 3 of the metals detected (Cu, Zn, Mn) were listed as ingredients in more than 4,000 products. Three of the detected metals (Be, Cu, Ni) were identified to have skin sensitization potential according to the ECHA and SkinSens databases and were evaluated further via a quantitative risk assessment. Daily consumer exposure levels to metals in hair care products were estimated using the amount of product applied per application, number of applications per day, metal concentrations in the products, a retention factor, and body surface area values. Estimated consumer exposure levels (mean and 95th percentile) were compared with metal-specific no expected sensitization induction levels or no observed effect levels in humans. Margins of safety (MOSs) were determined for products containing Be, Cu, and Ni. Similar methodology was used to calculate daily exposure to Be and Cu in shower water, assuming that the shower water contained the EPA drinking water standard concentrations for Be and Cu. All calculated MOSs were >1 for hair care products (MOS range: 4,776-47,619) and shower water (MOS range: 88-216,535). Interestingly, exposure to Cu in shower water alone was higher than exposure to Cu detected in the products evaluated. These results show metal contamination, at the levels detected, in the hair care products tested do not pose a skin sensitization induction concern.

1676 Safety Assessment of Acacia Seyal Gum for Use in Mascaras

N. Habeeb, E. Theophilus, J. Tobia, V. Rana, D. Mihai, D. Aharoni, and T. Suwa. *Shiseido Americas Innovation Center, East Windsor, NJ.*

Acacia gums are edible ingredients used in foods and cosmetics. Acacia Seyal Gum (CAS# 9000-01-5) is an ingredient of interest for use in cosmetics (eye products/mascara). A typical pre-market safety review of cosmetics includes: 1) a public literature and vendor information review and 2) a test battery to fill any data gaps. Public toxicology-related literature was limited for Acacia Seyal gum. The literature review indicated that the Cosmetic Ingredient Review panel (CIR) has evaluated similar ingredients (Acacia Senegal gum and Acacia Senegal gum extract) and declared them safe as used in cosmetics (up to 9% in mascaras). However, Acacia Seyal gum was not specifically included in this review. The literature review also indicated that there were similarities between the previously CIR-reviewed Acacia Senegal gum and Acacia Seyal gum in terms of chemical, biochemical and structural characteristics. Acacia Senegal and Acacia Seyal gums are hyperbranched polysaccharide biopolymers rich in arabinose and galactose, similar in global biochemical and structural properties and somewhat different in the macromolecular conformation. Both are structured into polyproline type II helices. Both ingredients have high molecular weights (> 10^5 Da) and, thus, negligible potential for dermal absorption. Data from the CIR review have been incorporated into weight of evidence review and contributed to substantiating the safety of this botanical ingredient. However, to further substantiate the safe use of this ingredient in mascaras up to 1% at the final formula level, a robust test battery was designed to include chemical characterization (elemental impurities analysis), microbiological characterization, *in vitro* eye irritation (BCOP/CAMVA), clinical skin irritation (48-Hour Patch Test), clinical skin sensitization (Human Repeat Insult Patch Test), *in vitro* phototoxicity (UV spectrum, 3T3 assay). Results indicated that this ingredient conformed with Shiseido standards for elemental impurities, was of appropriate microbiological formula quality (met USP 51 criteria), was not an eye irritant, not a skin irritant, not a skin sensitizer, and not phototoxic. Consequently, Acacia Seyal Gum is safe for consumer use in the tested mascara formula up to 1% maximum use level under normal use conditions.

1677 The Toxicological Profile of Reklemel: A Reduced Risk Nematicide

S. Gehen, A. Sarma, and C. Terry. *Corteva Agriscience, Indianapolis, IN.*

Reklemel™ is the commercial name for fluazaindolizine (CAS # 1254304-22-7), a new crop protection active ingredient for control of parasitic nematodes in various vegetable and fruit crops. Reklemel belongs to the sulfonamide class of chemistry and acts through a mode of action distinct from other commercial nematicides. Currently, fumigant products requiring specialized handling and stewardship approaches are highly represented in this market segment; thus, there is a significant opportunity to bring forward new products that will reduce human risk both from a hazard and exposure perspective. During development, the mammalian toxicology and human risk profile of Reklemel was compared to that of six registered nematicide active ingredients. Reklemel has a favorable acute toxicity profile (Oral LD_{50} = 1187 mg/kg; Dermal LD_{50} <5000 mg/kg; Inhalation LD_{50} > 5.8 mg/L), is not a dermal irritant nor sensitizer and is a moderate eye irritant. This profile was more favorable relative to two competitors and similar to the other four. When comparing end-use formulations, the profile of the product containing Reklemel was more favorable when compared to four out of six competitor end-use products. Reklemel was non-genotoxic based on the outcome of *in vitro* and *in vivo* assays which was a similar profile to competitors. Reklemel was shown to be non-carcinogenic in rats and mice. This profile was more favorable compared to four of six competitors. In the rat two-generation study there were no effects on fertility or other reproductive parameters nor did Reklemel cause developmental toxicity in rats or rabbits. The other active ingredients were similarly not specific reproductive or developmental toxicants. When comparing toxicity endpoints derived from sub-chronic and chronic toxicity studies, Reklemel had higher NOAEL values compared to all competitors. In summary, Reklemel has a favorable toxicity and reduced risk profile relative to several existing nematicides.

1678 A 13-Week Rat Inhalation Study of Aerosols Generated from Two Flavor Mixtures

J. Zhang[1], J. Randazzo[2], T. B. Langston[1], and K. M. Lee[1]. *[1]Altria Client Services LLC, Richmond, VA; and [2]Charles River, Ashland, OH.*

Two nicotine-free flavor mixtures (one containing 10.76% w/w menthol flavors and the other containing 1.15% non-menthol flavors) and a carrier mixture (glycerin and propylene glycol [PG]) were evaluated via a 13-week rat inhalation study in general accordance with OECD TG 413. Male and female Sprague Dawley rats were randomly assigned to groups for exposure to 1, 3, or 5 mg/L of aerosols of each flavor mixture, 5 mg/L carrier, or filtered air for up to 6 hours per day on a 5-day per week basis for 13 weeks, followed by a 6-week recovery. In addition, a satellite group of male rats were exposed on a comparable regimen to evaluate micronuclei (MN) in bone marrow (mammalian erythrocyte micronucleus test; OECD 474) and potential DNA damage in liver, lung, and nasal tissue (mammalian alkaline Comet assay; OECD 489). Plasma PG, a marker of exposure, increased with the increased aerosol exposure in both males and females at both weeks 4 and 11. There were no flavor- or carrier-related effects on survival, clinical observations, ophthalmic findings, or respiratory physiology after 13 weeks of exposure. In addition, no flavor- or carrier-related alterations in hematology, coagulation, serum chemistry, urinalysis parameters, or bronchoalveolar lavage fluid chemistry values and cytology were observed. Non-adverse, minimally lower mean body weights were noted in males and females exposed to 5 mg/L menthol flavor as compared to the filtered air groups, which correlated to slightly lower food consumption. Thymus weights in females exposed to 3 and 5 mg/L menthol flavor were lower than the 1 mg/L group and marginally lower (not statistically significant) than the filtered air and carrier groups. The decreased thymus weights were considered non-adverse given the lack of correlating histologic observations and the reversibility suggested at the recovery necropsy and may have represented a secondary stress response. Non-degenerative histologic changes of minimal to mild severity grades were observed in various nasal levels of males and females in all flavor and carrier groups at both the terminal and recovery necropsies. Both flavor mixtures and carrier were negative for the induction of MN in bone marrow and DNA damage in liver, lung and nasal tissue. Based on these findings, the no-observed-adverse-effect-concentration (NOAEC) was established to be 5 mg/L (the high-dose level) for each flavor mixture and the carrier.

1679 Toxicological Evaluation of Acrylonitrile Butadiene Styrene (ABS) 3D Printer Emissions

M. T. Farcas[1,2], A. B. Stefaniak[2], W. McKinney[2], A. K. Knepp[2], L. Bowers[2], W. K. Mandler[2], M. Kashon[2], L. Battelli[2], T. A. Stueckle[1,2], M. Orandle[2], A. Winn[2], S. A. Friend[2], S. R. Jackson[2], C. Qi[2], D. R. Hammond[2], R. Mercer[2], R. LeBeouf[2], D. Burns[2], A. Ranpara[2], T. A. Thomas[3], J. Matheson[3], V. Castranova[1], and Y. Qian[1,2]. *[1]West Virginia University, Morgantown, WV; [2]NIOSH, Morgantown, WV; and [3]Consumer Product Safety Commission, Rockville, MD.*

Fused filament fabrication 3D printing with acrylonitrile butadiene styrene (ABS) filament emits billions of particles and numerous volatile organic compounds (VOCs). This study sought to investigate the toxicity of ABS emissions from a 3D printer both *in vivo* and *in vitro*. For the *in vivo* studies, Sprague Dawley rats were exposed to real-time ABS printing emissions or air (control) for 4 h/day, 4 days/week for 1, 4, 8, 15, and 30 days. The average aerosolized particle concentration was 0.24 ± 0.09 mg/m^3, and the average median particle electric mobility diameter was 85 nm with an average geometric standard deviation of 1.6. Benzene was the predominant VOC released during printing. At 24 h after the last exposure, rats were assessed for pulmonary injury, inflammation, and oxidative stress as well as systemic and other organ toxicity. Results showed that among the measured cytokines in bronchoalveolar lavage, only IL-10 and IFN-γ at day 1 and 4, and IL-13 at day 30 of the exposure were increased when compared to the air-control. Moreover, neither pulmonary oxidative stress responses nor histopathological changes of the lungs were found among the exposed rats. There were no significant differences in serum cytokines levels or hematological indices, except for an increase in platelets and monocytes at day 15. Several serum biomarkers involved in liver damage were significantly higher at day 1 of the exposure. For the *in vitro* study, both particles and VOCs were collected into serum-free cell culture medium using an impinger sampler inside a chamber while printing for 1.5 h, followed by characterization of the physicochemical properties, as well as assessment of cytotoxicity, oxidative stress, and cytokine production in human small airway epithelial cells (SAEC). Results showed that particle numbers and VOC concentrations varied between print runs. The particle dose range was 1.42 x 10^6 - 4.72 x 10^6 particles/cm^2, and the average median hydrodynamic particle diameter was 168 nm with an average arithmetic standard deviation of 53. Styrene was the predominant VOC collected in the medium. Based on mixed model regression analyses, at 24 h post-exposure, ABS emissions in-

duced significant dose-dependent cytotoxicity, oxidative stress, and production of pro-inflammatory cytokines in SAEC. In conclusion, our *in vitro* studies indicated that the emissions from ABS 3D printing induced toxicological effects, which were not substantiated by the *in vivo* studies with the current low exposure concentrations. Thus, more *in vivo* studies with higher dose-response are needed to verify the *in vitro* findings.

1680 Retrospective Review of Safety Data for the Vehicle Sulfobutyl-ether-β-cyclodextrin (SBE-β-CD) in the Nonclinical Studies

S. Cao, Z. Chengen, and S. McPherson. *WuXi AppTec, Suzhou, China.*

Sulfobutyl-ether-β-cyclodextrin (SBE-β-CD), also known as Captisol. SBE-β-CD is used in several commercial drugs and also as a common vehicle in non-clinical studies. Sixteen studies involved SBE-β-CD in mice, rats, dogs and monkeys were reviewed and the data analyzed to further evaluate the safety of Captisol when used as part of the vehicle formulation. In eleven studies (5 rat studies; 4 dog studies; and 2 monkey studies) 198 mg/kg/day to 1000 mg/kg/day SBE-β-CD was dosed for 28 consecutive days. No vehicle related adverse effects were noted up to 1000 mg/kg/day oral dose in rats, dogs and monkeys in all above studies. Base on the study results the NOEL of SBE-β-CD for oral dose in rats, dogs and monkey was considered as 1000 mg/kg/day. Mice were more sensitive to the oral exposure to the SBE-β-CD in three exploratory studies. The duration was from 5 days to 28 days and the dosages were from 850mg/kg/day to 1960 mg/kg/day. Increased alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBIL) were noted in these studies along with histopathology changes as hepatocellular necrosis accompanied by neutrophilic infiltration. In two GLP studies when SBE-β-CD (from 960 to 4800mg/kg/day) was administered by intravenous in rats and dogs, vacuolations and foamy macrophases in various tissues or organs were noted in the histopathology. In the dosing phase, histopathologic findings associated with the SBE-β-CD included vacuolation of the renal tubular epithelial cells and epididymis along with an infiltrate of foamy macrophages in a variety of lymphoid organs, spleen, liver, lungs, cecum, heart, urinary bladder and uterus. The histopathological changes in morphology due to SBE-β-CD were not associated with any cellular degeneration and/or necrosis. Histopathologic findings associated with SBE-β-CD in the heart, cecum, lungs, spleen urinary bladder, kidney, epididymis, mandibular lymph node and mesenteric lymph node were revisable. There was no recovery of the histopathologic findings in the liver and uterus. In conclusion the toxicity of SBE-β-CD is dependent on the species and route of administration in the non-clinical studies. Oral dose was safe for most of the species such as rats, dogs and monkey but except for mice which could induce liver related changes in both clinical pathology and histopathology data. Intravenous infusion administration resulted vacuolations and foamy macrophages in various tissues or organs but not associated with any cellular degeneration and/or necrosis.

1681 Hazard Potential of Perfume Products Assessed by a Combination of *In Vitro* Methods and Chemical Analysis

H. Bendova[1], M. Dvorakova[1], K. Kejlova[1], L. Svobodova[1,2], M. Rucki[1], J. Chrz[1], and D. Jirova[1]. *[1]National Institute of Public Health, Prague, Czech Republic; and [2]Univerzita Palackého v Olomouci Faculty of Medicine and Dentistry, Olomouc, Czech Republic.* Sponsor: H. Kandarova

Alternative *in vitro* methods and studies on human volunteers are the only hazard assessment approaches available, as animal testing is prohibited in the EU for cosmetic ingredients and final products. In our study we tested 10 samples of deodorants, EDT and EDP and combined results from biassays, suitable for detection of cytotoxicity (ISO EN 10993-5), skin sensitization *in chemico* (OECD TG 442C) and *in vitro* (OECD TG 442D), genotoxicity (Comet assay on 3T3 Balb/c fibroblasts) and endocrine activity (YES/YAS assay; Xenometrix®). Samples 1, 2, 3, 5 exhibited the highest cytotoxicity. The skin sensitization was identified by a method *in chemico* for samples 5, 6, 7, 8 and a method *in vitro* at 12.5 µg/ml for sample 6, resp. at 100 µg/ml for samples 7, 8, 9. Comet assay detected no genotoxicity at 250 µg/ml, however, a concentration dependent DNA fragmentation was observed (samples 6, 8, 9, 10). Samples 1, 2, 5, 6, 7, 8, 9, 10 exhibited endocrine activity. 24 allergens (INCI names: D-limonene, linalool, benzyl alcohol, citronellol, methyl 2-octynoate, geraniol, citral, hydroxycitronellal, cinnamal, anise alcohol, cinnamyl alcohol, eugenol, alpha-isomethyl ionone, isoeugenol, butylphenyl methylpropional, coumarin, farnesol, amyl cinnamal, hydroxyisohexyl 3-cyclohexene carboxaldehyde, amylcinnamyl alcohol, hexyl cinnamal, benzyl benzoate, benzyl salicylate, benzyl cinnamate) were determined by GC/MS. Although the hazard of individual components is known, the hazard of the final mixture may be variable, depending on either total load of ingredients or the content of specific active substances. Combination of bioassays and chemical analysis seems to be promising for risk assessment of cosmetics. *The work was supported from ERDF/ESF project "International competitiveness of NIPH in research, development and education in alternative toxicological methods" (No. CZ.02.1.01/0.0/0.0/16_019/0000860).*

1682 Comparative Subchronic Inhalation Toxicity 2-Pentanoneoxime

G. M. Rusch. *J.S. Held, Jericho, NY.*

Oximes are formed by the reaction of hydroxylamine with the carbonyl group of either an aldehyde or a ketone. In the body, the reaction reverses and the hydroxylamine is released. Hydroxylamine then causes hemolysis of the red blood cells resulting in the release of hemoglobin and an increase in platelets. As the liver and spleen filter the hemolyzed red blood cells, this can cause an increase in cell turnover. The carcinogenic potential of 2-pentanoneoxime (2-PO) was evaluated in a genomics study following a 90-Day exposure study. Groups of 10 male and 10 female Sprague Dawley rats were exposed to levels of 0 (control), 50, 150 and 300 ppm of 2-PO 6 hours/day, 5 days/week for 13 weeks and then sacrificed. Two recovery groups of 5 male and 5 female rats were also included. They were exposed to 0 and 300 ppm of 2-PO for 13 weeks and then held for a 4 week recovery period. 2-PO was metabolized to methylpropylketone (MPK). Clearance from the body was rapid. At 6 hours post exposure, neither 2-PO nor MPK was seen in the blood. Hemoglobin levels showed a slight decrease (4.4%), reticulocytes showed a increase (31,3%) and platelets showed an increase (27.9%) in the high exposure level males, no differences were seen in females. In the rats sacrificed at the end of the 13 week exposure period, increases were seen in the relative kidney weights in both male and female rats exposed to 300 ppm. Also relative spleen weights were increased in female rats exposed to 300 ppm. All organ weight effects were reversible following the 4 week recovery period. No treatment related histopathological alterations were seen in any of the organs evaluated. Since the changes were minimal, only seen in one sex and fully reversible in the rats held for the 4 week recovery period, they were considered to be non-adverse. It was therefore concluded that the No Adverse Effect Level for a 13-week exposure to 2-PO was 300 ppm. In the 2-PO exposed rats, there were no observations of treatment related effects during necropsy. In the microscopic examination of tissues from the 300 ppm exposure level group, the only observation that may have been related to the exposure was a reversable increased frequency of mild mononuclear inflammation of the liver in the female rats. This would not have caused a significant increase in apoptosis. 2-PO was evaluated in a genomics assay by a highly competent laboratory and found to not activate the genes associated with liver cancer. This assay has been used for over a decade and found to accurately predict carcinogenic potential. The results from this assay should be trusted for the safety evaluation of 2-PO.

1683 Comparing Cytokine Data to In-Life Parameters on Nonhuman Primates in Nonclinical Toxicology Studies

V. Bunker, C. Do, J. Forget, and T. Rogers. *Altasciences, Everett, WA.*

Cytokines are important immunoregulatory proteins that have gained attention in safety assessment associated with innate or adaptive immune responses. Interpreting cytokine data comes with challenges due to the variable nature of their stimuli and responses. Contributing factors to the variability in cytokine expression include species-specific reactions, individual variations, dose-response relationships, and unanticipated immunotoxicity. For these reasons, cytokine measurements should not be used as standalone biomarkers for immunotoxicity assessment. However, in conjunction with additional parameters such as clinical observations, body weights, and clinical pathology data, cytokine interpretation can be used to provide more definitive assessments in nonclinical safety studies. In several case studies, cytokines were evaluated for a dose response relationship. Multiplex platforms such as Luminex or MSD® were used to determine cytokine levels in non-human primates including IL-1β, IL-2, IL-4, IL-6, IL-8, IL-10, IL-12/IL-23p40, MCP-1, IFN-γ, and TNF-α. In several instances, measurable levels of IL-6 or IL-12 correlated with clinical observations of bruising, injury, or abnormal feces, not necessarily considered test article-related. Elevated TNF- α and IL-6, pro-inflammatory cytokines, were detected in animals observed as dehydrated with elevated BUN, creatine, and decreased electrolytes. In cases of test article-related effects, animals becoming moribund also had elevated TNF-α and IL-6 levels. Increased levels of MCP-1, a monocyte chemotactic factor, was observed in one study with an animal with petechial bruising, and another study with a cohort with test-article associated renal failure, characterized by hypoproteinemia, azotemia, and hyperkalemia. In conclusion, cytokines are useful markers

when assessing potential toxicity when evaluated with other measurements. Clinical observations, body weights, and clinical pathology parameters should also be considered in addition to the test article-related effects.

1684 Neurobehavioral Assessments of Juvenile Male and Female Wistar Han IGS Rats, Hsd:Sprague Dawley SD Rats, and CD-1 IGS Mice

A. J. Filgo, Q. Wang, and C. K. Lanphear. *Charles River, Mattawan, MI.*

The objective of these studies was to generate juvenile neurobehavioral historical control data in Wistar Han IGS (WH) rats, evaluate prepulse inhibition (PPI) testing protocol in Hsd:Sprague Dawley (SD) rats and CD-1 IGS mice, and compare these to positive control-treated animals. Motor activity evaluations were conducted on WH rats between Postnatal Day (PND) 70 - 80 and between PND 120 - 130, after dosing with 0 or 2.0 mg/kg amphetamine. Learning and memory were evaluated using passive avoidance, conducted on WH rats between PND 80 - 90 and between PND 125 - 135, after dosing with 0 or 2.0 mg/kg scopolamine, and Morris Water Maze testing with WH rats between PND 75 - 85 and between PND 120 - 130, after dosing with 0 or 2.0 mg/kg scopolamine. Auditory startle habituation was conducted on WH rats between PND 70 - 80 and between PND 120 - 130, after dosing with 0 or 1.0 and 0 or 0.3 mg/kg MK-801, respectively. Auditory startle habituation with PPI was conducted on SD rats and CD-1 mice between PND 60 - 70, after dosing with 0, 0.3 mg/kg MK-801 or 1.0 mg/kg Midazolam. The vehicle and control articles were administered on neurobehavioral testing days via intraperitoneal injection. All control articles were administered at a dose volume of 1.0 mL/kg. The saline -treated animals received the vehicle in the same manner, at the same volume, and within the same time frame prior to each neurobehavioral test. Amphetamine increased motor activity parameters in both sexes of WH rats at both ages. When assessing learning and memory, scopolamine altered the parameters tested in the Morris water maze in WH rats to a larger degree than compared to passive avoidance parameters in both male and female and at both ages. MK-801 reduced acoustic startle habituation in the male WH rats at PND 70 - 80, females at both ages, and to a lesser extent in males at PND 120 - 130. In male and female SD rats, PPI was reduced by MK-801 and Midazolam decreased the amplitude of the peak response in male SD rats only. In male and female CD-1 mice, MK-801 did not affect PPI and increased the mean peak response. Midazolam did not affect males or females PPI or mean peak responses. These results demonstrate the ability to detect the effects of chemicals on neurobehavioral parameters and the differences in the responses of the test animals based on species, age, and sex and provided historical background data for juvenile neurobehavioral studies.

1685 Understanding the Differences between *In Vitro* versus *In Vivo* Results: The Role of Kinetics and Tissue Dose Metrics

W. Cheng, T. Liu, and T. Pastoor. *Boragen, Durham, NC.*

With the increasing emphasis on moving from animal-based toxicity testing to *in vitro* assays, there is also an increasing need to determine the characteristics that make *in vitro* screening assays predictive and reliable. In this case study, we determined that differences between positive *in vitro* and negative *in vivo* results were due to rapid *in vivo* clearance of the test compound. The test compound, BAG8, is a benzoxaborole broad-spectrum fungicide that was tested for *in vitro* mutagenic activity (Ames assay) and *in vitro* clastogenic potential (micronucleus). Whereas BAG8 was negative in an Ames assay, it was negative at all doses without metabolic activation and positive with metabolic activation in an *in vitro* micronucleus screening study in a dose responsive manner below cytotoxic concentrations. Therefore, BAG8 was evaluated for *in vivo* clastogenic activity and/or disruption of the mitotic apparatus by counting micronuclei in reticulocytes in rat peripheral blood. No significant increase in the incidence of micronuclei was observed in BAG8 exposed animals. In a separate study, BAG8 demonstrated rapid clearance *in vivo*, with an oral Tmax of 15-30 minutes. Therefore, the positive *in vitro* finding with metabolic activation may be attributable to one or more BAG8 metabolites which may be short-lived *in vivo*. *In vitro* studies are valuable, inexpensive, animal-sparing test systems, which may be leveraged to focus *in vivo* research such as verification of positive results, kinetics, metabolism and tissue exposure levels.

1686 Cytoplasmic Vacuolation and Tapetal Changes Induced by a Novel Analgesic Agent in Beagle Dogs

K. Takahashi[1], Y. Morita[1], S. Udagawa[1], M. Nakajima[1], E. Higashi[1], Y. Miyamoto[2], and K. Oshida[1]. *[1]Toray Industries Inc., Kanagawa, Japan; and [2]Toray Industries Inc., Tokyo, Japan.*

Drug-induced unique cytoplasmic vacuolation was found in the subchronic oral toxicity study of 4-dimethylamino-1-{3-(1-methyl-1H-imidazole-2-yl)propanoyl}piperidine (DMIP), a potential therapeutic agent for neuropathic pain, in beagle dogs. In the first study, DMIP was administered at a dose of 250, 500, or 1,000 mg/kg/day once daily for 14 days. Discoloration of tapetum lucidum accompanied by tapetal swelling was observed at ≥ 250 mg/kg/day. The tapetal swelling was correlated to the light microscopic observation of cytoplasmic vacuolation in tapetal cells, and similar vacuolation was observed in several other tissues, including the coronary artery and aortal arch, in a dose-dependent manner. Immunohistochemistry for lysosomal-associated membrane protein 2 indicated that the vacuoles were enlarged lysosomes. However, the nature of these vacuoles was different from that of phospholipidosis because no lamellar bodies were observed. In the second study, DMIP was administered at a dose of 10, 50, or 250 mg/kg/day once daily for 14 days followed by a 14-day recovery period. Tapetal changes and systemic vacuolation were not observed at ≤ 50 mg/kg/day, and vacuolation observed at 250 mg/kg/day was reversible. A few reports have described the enlargement of lysosomes not attributable to phospholipid accumulation. Our findings provide further information about the toxicological implications of drug-induced lysosomal swelling.

1687 Establishment of a 3D Human NASH Model for High-Throughput Drug Efficacy Testing

S. Ströbel, J. Rupp, K. Fiaschetti, K. Sanchez, K. Sanchez, A. Pajak, M. Bieri, A. Wolf, E. Thoma, and R. Kostadinova. *InSphero, Schlieren, Switzerland.*

Nonalcoholic fatty liver disease (NAFLD) is characterized by excessive accumulation of lipids within the liver and can progress from simple fatty liver to more serious chronic diseases ranging from nonalcoholic steatohepatitis (NASH) to liver fibrosis, and cirrhosis. Currently, there are no approved, safe therapies for NASH and the development of novel therapeutics is impeded by the lack of predictive *in vitro* models to help decipher the complex mechanisms underlying the disease progression. The aim of this study was to develop a 3D human NASH model containing primary hepatocytes, Kupffer cells, endothelial cells, and hepatic stellate cells for high-throughput compatible compound efficacy testing. The microtissues models were cultured in high-throughput 96- and 384-well plates, enabling reproducible tests and screening. Using a defined cocktail of free fatty acids and LPS in medium containing high levels of sugars, we sought to recapitulate NASH pathogenesis *in vitro*. For drug efficacy testing, we simultaneously treated the 3D microtissue model with clinical NASH drug candidates (Firsocostat and Selonsertib), then measured endpoints related to the hallmarks of the disease. Upon treatment with NASH stimuli, liver microtissues displayed key pathophysiological characteristics of NASH, such as increased tissue triglyceride levels as well as increased secretion of inflammatory and pro-fibrotic markers. Consistent with clinical trial data, results showed a decrease of triglyceride levels and secretion of inflammatory markers, respectively. Additionally, we demonstrated that the TGFRβ1 inhibitor ALK5 inhibitor dose-dependently decreased the release of pro-collagen type I and deposition of fibril collagens. In summary, this 3D human NASH model for preclinical, high-throughput compound screening, represents a promising approach for early selection of the most effective and least toxic drug candidates for advancing in the clinical drug development pipeline.

1688 Evaluation of Whole Blood T Cell Receptor Codon Usage as Biomarker for Rorg-Related Thymic Lymphoma

S. Chen, S. Ruepp, R. Denton, R. A. Westhouse, Y. Song, K. S. Granaldi, C. W. Hasson, and L. D. Lehman-McKeeman. *Bristol-Myers Squibb Company, Princeton, NJ.*

RORγT is a sequence variant of the nuclear hormone receptor RORγ that is expressed exclusively in the thymus. RORγT $^{-/-}$ mice develop thymic lymphoma with high penetrance and short latency, but the pathogenesis is not well understood. We sought to determine whether T cell receptor alpha (TCRα) variable region rearrangement correlated with the development of thymic lymphoma. TCRα variable region usage was evaluated in blood and in thymi of constitutive RORγT knockout (KO) and inducible RORγ KO mice by quantitative PCR analysis. In RORγT $^{-/-}$ mice, the 5′ TCRα variable regions 1 and 2 (Trav1

and v2) were undetectable, whereas the 3′ region Trav21 was markedly elevated in thymus and blood samples relative to wild type (WT) littermates, indicative of a less mature genotype of TCRα. In inducible KO mice, the skewed TCRα codon usage in thymus correlated with similar changes in blood and with development of lymphoma. RORγT $^{+/-}$mice, which do not develop lymphomas, showed reduced, but clearly detectable Trav1 and Trav2 and a slight increase in Trav21. Our results show that genetic RORγT loss in mice causes strong perturbations of T cell receptor codon usage (TCRα phenotype), as well as development of thymic T cell lymphomas, whereas mice with an incomplete knockdown had an intermediate TCRα phenotype and no development of lymphoma. These results also indicate that peripheral blood can be used to monitor for a level of RORγT-related change in TCRα usage which is associated with a risk of developing thymic lymphomas.

1689 Validating Proposed Improvements to Phototoxicity Expert Alerts against Proprietary Data

D. J. Ponting[1], M. P. Payne[1], H. H. Gerets[2], J. S. Harvey[3], J. R. Howe[3], A. D. Parenty[4], A. V. White[3], and R. V. Williams[1]. *[1]Lhasa Limited, Leeds, United Kingdom; [2]UCB BioPharma SPRL, Braine l'Alleud, Belgium; [3]GlaxoSmithKline plc, Ware, United Kingdom; and [4]Novartis AG, Basel, Switzerland.*

Development of expert alerts for toxicological endpoints is a time-consuming process, especially if changes are subsequently requested to these alerts based on proprietary data which for legal reasons cannot be shared with the original implementer even under strict confidence. We present a method for the acceleration of this process, analogous with the student-teacher model[1] used for statistical methods in similar situations. In order to demonstrate this method, the endpoint of phototoxicity was chosen. This has become of increasing regulatory concern for pharmaceuticals, as evidenced by the ICH S10 guidelines[2]. A dataset of 400 publically-available structures with phototoxicity data was collated, and, working from the knowledge base of expert alerts contained within Derek Nexus 2018.1 (Lhasa Limited, Leeds, UK), a number of alerts were created or modified on the basis thereof. These modifications improved the performance of the alerts against this public dataset from an F1-score of 75% to 83% and Matthews correlation coefficient from 45% to 49%, including an increase in sensitivity from 63% to 77%. A pre-release version of the improved knowledge base was provided to three pharmaceutical companies who evaluated performance against their proprietary datasets. Specific recommendations for modifications to structure-activity relationships were returned and collated. Information from confidential structures was therefore absorbed without these structures being disclosed, improving predictive performance against both public and proprietary chemical space prior to the main release of the knowledge base to a wider set of users. This poster serves not only to demonstrate the method used but also to highlight the toxicophores considered in this process. *[1] Papernot et al, arXiv:1610.05755v4 [2] ICH Guideline S10, available at https://database.ich.org/sites/default/files/S10_Guideline.pdf.*

1690 Novel 3D Liver Microtissue Reactivity Assay Reveals Causal Link between Glutathione Status and Cytotoxicity

K. Sanchez, A. Pajak, A. Wolf, E. Thoma, R. Kostadinova, and M. Kijanska. *InSphero, Schlieren, Switzerland.*

Formation of reactive drug metabolites and reactive oxygen species (ROS) is linked to a high risk for the development of Drug-Induced Liver Injury (DILI). Reactive drug metabolites can bind covalently to proteins, inactivating important cellular functions or leading to hapten formation triggering immune reactions. The glutathione (GSH) system in the liver plays an important detoxification role by scavenging reactive metabolites. The role of reactive metabolites and ROS formation in cytotoxicity has not been fully characterized. The model toxicant acetaminophen (APAP) forms reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI), which is detoxified by the GSH system. APAP treatment, in the absence of the GSH depleting agent, L-buthionine-sulfoximine (BSO), leads to concentration-dependent decrease of cellular ATP levels, without increase of the cytotoxicity marker LDH. 3D Human liver microtissues (LiMTs) consisting of primary hepatocytes, Kupffer cells, and liver endothelial cells offer high translational value for de-risking drug development due to their longevity, stable metabolic competence and preserved functionality. Microtissues are cultured in high-throughput (HT) 96- and 384-well plates, enabling reproducible tests and screening. The aim of this study was to demonstrate the feasibility of causality assays by the increased sensitization of microtissues to APAP in the presence of BSO treatment. We determined experimental conditions under which BSO reduced cellular GSH levels but did not affect cellular viability allowing for longer compound exposure. Changes in APAP cytotoxicity profiles in the presence of BSO were monitored with a set of parameters, such as a shift of the ATP IC_{50} and LDH leakage indicating membrane damage. Additionally, we showed that release of LDH correlates with release of clinically relevant AST in our *in vitro* model, providing an HT-compatible alternative for cytotoxicity monitoring. These results indicate a causal link between cellular GSH levels and cytotoxicity in 3D human liver microtissues. The liver microtissues in the HT format, combined with the cytotoxicity assays (ATP and LDH), provide a basis for screening compound libraries in early phase drug development to eliminate the most toxic compounds, which might trigger DILI.

1692 Development of an Automated Target Knowledge Review Application to Accelerate Target Safety Evaluations

D. Pelletier. *Pfizer Inc., Groton, CT.*

Pfizer's Drug Safety Research and Development (DSRD) division has been systematically evaluating information on drug targets for the last 15 years to drive a deeper understanding of safety risks at all stages of development. Best practice workflows contributing to these Target Knowledge Reviews (TKRs) were honed over time into a well-defined process involving manual curation of data and information on targets from a number of public and private sources and databases. Historically a manual, time consuming process, DSRD has worked recently to automate as much of the process as possible to make it more efficient and standardize the TKR content. A MySQL database containing target-centric data from external (e.g. Ensembl, NCBI, Uniprot, MGI, GTEX, HPA, ChEMBL) and internal (e.g. TOE/Human Genetics, Tissue Map mRNA expression, Linguamatics I2E) sources and application code (R, Shiny) were deployed as part of the automation solution. The application provides a simple user interface (UI) for target search and selection, followed by either web-based tab display of target information or generation and download (~ 20 seconds) of the Automated TKR (AutoTKR) report. The architecture of the application (database, code, UI) allows for rapid and seamless integration of new data and functionalities as they are developed. AutoTKR uptake in DSRD has been broad, contributing to virtually all new TKRs in the portfolio.

1693 Target Safety Assessments: Evaluation of the Toxicological Risk of Targeting Plasmepsins in the Treatment of Malaria

C. Sadler[1], J. Barber[1], P. Sikakana[1], D. Baud[2], J. Valentin[3], and R. Roberts[1,4]. *[1]ApconiX, Alderley Edge, United Kingdom; [2]Medicines for Malaria Venture, Geneva, Switzerland; [3]UCB Biopharma, Braine-l'Alleud, Belgium; and [4]University of Birmingham, Birmingham, United Kingdom.*

Plasmepsins are aspartic proteases that are important antimalarial drug targets due to their specificity to the malaria parasite and to their vital roles such as mediators of parasite egress and invasion of red blood cells (RBC). Focusing on parasite-specific targets for which no human host homologue exists reduces the chance of drug toxicity. However, adequate selectivity for plasmepsins in Plasmodium over related mammalian aspartic proteases is critical. To fully investigate the potential for host toxicity we conducted an *in silico* target safety review to understand the risks associated with host aspartic protease inhibition. We studied mammalian aspartic proteinases including pepsin, cathepsins D and E (Cap D/E), β secretase 1/2 and renin. Cap D/E appear of most toxicological relevance as Cap D is a ubiquitous lysosomal enzyme present in most cell types and Cap E is found in epithelial cells lining the gut (exposed to orally administered drugs) and in RBCs (the clinically significant site of malarial infection). Based on mammalian aspartic protease physiology and adverse drug reactions (ADRs) to FDA-approved HIV aspartic protease inhibitors, we predicted several potential toxicities including β-cell and congenital dysfunction, hypotension, hypopigmentation, lipideamia, increased infection risk and respiratory, renal, gastrointestinal, dermatological and other epithelial tissue toxicities. This target review indicated that ADRs to the HIV treatments are likely a result of host aspartic protease inhibition due to a lack of specificity for the HIV protease and that plasmepsins are much more closely related to human Cap D than to HIV proteinase. Plasmepsin inhibition presents an opportunity to specifically target Plasmodium as an effective antimalarial treatment. However, adequate Plasmodium selectivity is critical. Plasmepsin inhibitors should be assayed for inhibitory activity against the main human aspartic proteases, with priority given to cathepsin D and E. As the targets are plasmodium specific enzymes, a safety assessment plan would depend on which (if any) mammalian aspartic proteases are inhibited by the lead compound(s). It would be useful to conduct an investigative rodent study early in drug development to identify whether the risks we have identified would occur *in vivo* with a plasmepsin inhibitor.

1694 Effects of Diminazene Aceturate and Ivermectin on Semen and Serum Parameters of the Red Sokoto Buck

V. D. Iorchir, M. M. Onakpa, and J. O. Okwoche. *University of Abuja, Abuja, Nigeria.*

The effects of diminazene aceturate and ivermectin on semen parameters, serum testosterone and serum follicle stimulating hormone levels of the red Sokoto buck was investigated. Twenty seven red Sokoto bucks, at the age of 2 years and weighing between 32 - 34kg were used. After administration of the drugs, semen and sera samples were collected 1, 24, 72, and 192 hours for analysis. The parameters studied *viz* semen volume, percentage motility of sperm, sperm concentration, live sperm percentage, semen glucose level, serum testosterone and serum follicle stimulating hormone were found to decrease significantly ($P<0.05$) when compared with the control group throughout the collection period. However, the drugs did not affect the live sperm percentage and ivermectin did not affect semen glucose level. A relationship was established between spermatological characteristics and serum testosterone and follicle stimulating hormone levels. These findings indicate that the drugs investigated in this study decreased semen parameters and serum testosterone and follicle stimulating hormone. It was concluded that diminazene aceturate and ivermectin should be used cautiously in red Sokoto bucks meant for breeding due to the deleterious effects they were observed to have on fertility parameters.

1695 Uncoupling NRF2 Activation from Induction of Hyperkeratosis: Keap1 Inhibitors with Different Binding Modes Show Discriminating Histopathological Profile

S. Busch[1], A. Leijon[1], K. Balogh Sivars[1], E. Sand[1], Y. Andersson[1], S. Öhlin[1], S. Östman[1], A. Vidal[1], A. Smailagic[1], C. Hamblet[1], E. Hornberg[1], C. Astbury[2], A. Westin Eriksson[1], P. Parris[3], J. Hornberg[1], and M. Larsson[1]. *[1]AstraZeneca, Gothenburg, Sweden; [2]AstraZeneca, Barcelona, Spain; and [3]AstraZeneca, Cambridge, United Kingdom.*

Oxidative stress is a key driver for many chronic diseases and induction of a cytoprotective, anti-oxidant program via NRF2 activation is thus therapeutically attractive. KEAP1 KO mice are postnatally lethal due to malnutrition, correlating with NRF2-mediated hyperkeratosis in oesophagus and forestomach. Hyperkeratosis is associated with epidermal thickening and dysregulation of differentiation-specific keratins. Here we set out to investigate whether pharmacological inhibition of KEAP1-mediated degradation of NRF2 via different mode of actions, using a protein-protein interaction inhibitor (PSTC) and an electrophile (Bardoxolone), induces similar downstream molecular events and physiological effects. Female C57Bl/6 mice were orally dosed at 10, 30 and 100mg/kg/day for 4 days and key target organs were sampled for assessment of gene expression and histopathology. Target engagement was confirmed with both compounds as monitored by activation of NRF2-driven genes *Hmox1, Srxn1, Nqo1*. However, only Bardoxolone induced hyperkeratosis and Keratin 6 (*Krt6a*), a marker for proliferating keratinocytes, in oesophagus and forestomach whereas PSTC did not. Thus, this study demonstrates the potential for pharmacological NRF2 activation by KEAP1 inhibition without inducing hyperkeratosis and identifies that Keratin 6 may be used as a novel exploratory safety biomarker.

1696 Computational Approach for Prediction of Drug Target Safety Assessment

K. Jankovic[1], T. Krsmanovic[1], D. Mitic Potkrajac[1], G. Apic[1], and R. B. Russell[2]. *[1]Metisox Ltd, Cambridge, United Kingdom; and [2]Heidelberg University, CellNetworks, Heidelberg, Germany.*

A review of industry drug discovery and development projects showed that most important reason for drug failure in recent decades is unacceptable off-target and on-target related safety explaining more than 50% of all project closures. In order to help assessing target safety we generated a comprehensive database and software, with computable internally curated and various publicly available data on proteins, biologically active chemicals, their interactions, pathways and pathologies. We catalogued 4 million references supporting each database entry, with hyperlinked interactions to appropriate PubMed article as support while proteins and chemicals are hyperlinked to EntrezProtein, PubChem of the other appropriate public database. In order to support data integration and capture different levels of histopathological observations, we developed toxicology ontology with over 2500 toxicity endpoints. We validated the system by exploring androgen receptor (AR), a high data density target with known safety liabilities. Mapping AR onto GO function within the system promptly identified AR biological function in sex differentiation and male gonad development including prostate gland development. Mapping AR together with its protein interaction network onto Diseases and Organ and tissue pathologies, associated AR with several pathologies and toxicities related to development including Swayer syndrome and Y chromosome deletion. Furthermore, the system associated AR with other pathologies on cellular organ and organ system level related to cardiac system (heart fibrosis, cardiac hypertrophy) nervous system (neuron degeneration), male and female reproductive system (testis atrophy, oligospermia, prostate toxicity, mammary gland hyperplasia and uterus atrophy), hepatic system and endocrine system (adrenal gland hypertrophy). Analyzing AR together with its chemical interaction partners (agonists and antagonists) identified AR role in Prostate neoplasia and Prostate carcinoma toxicity that corresponds to AR antagonist therapeutic application. On this example we showed that our tool can contribute to a better understanding of therapeutic potential of a target inhibition and quick target toxicological assessment.

1697 *In Vitro* Cytotoxicity Assays: Development of a Cell-Based Model to Screen the Potential Toxicity of Chemical Compounds

S. Hwang, S. Hwang, H. Yi, J. Bang, Y. Kim, H. Kang, B. Jeon, and H. Ku. *Animal and Plant Quarantine Agency, Gimcheon-si, Korea, Republic of.*

Cytotoxicity assay is useful for screening toxicity providing predictive evidence of compound safety. In this study, we assessed three cytotoxicity assays and enzyme activity of hepatocytes to detect the cytotoxic event. Human hepatoma cell line, namely HepG2 cells, were seeded at the density of 1.5 x 10^4 cells/well on 96-well cell culture plates and were incubated at 37°C in a 5% CO_2 humidified incubator. After 24 hours post-seeding, cells were treated with acetaminophen (1, 3, 10, 30 mM), amiodarone HCl (10, 17.8, 31.7, 56.4, 100 uM), etoposide (100, 178, 317, 564, 1000 uM), orphenadrine hydrochloride (30, 53, 95, 169, 300 uM), and lovastatin (30, 53, 95, 169, 300 uM) for 24 hours. Following to the drugs treated, cytotoxicity was determined with the 4-[3(4-iodophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolio]-1,3-benzene disulfonate (WST-1), the methyl tetrazolium (MTT), and neutral red uptake (NRU) assays and alanine transaminase (ALT), aspartate transaminase (AST), and lactate dehydrogenase (LDH) enzyme activity. Cytotoxicity assays and enzyme activity were observed to depend on each drug concentration except acetaminophen. No acetaminophen-induced changes in enzyme activity were observed, whereas the cytotoxicity assays were detected depending on concentration after 24 h. It was shown that the MTT or NRU assays were more sensitive at lower concentrations in cytotoxicity assays. In conclusion, cytotoxicity assays have different sensitivity depending on the mechanism of cellular damage. The results demonstrate that the application of cytotoxicity assays enables efficient screening, and further, they suggest that certain parameters could serve as sensitive methods for predicting the cytotoxicity potential of chemical compounds.

1698 Safety Evaluation of High Concentration of Live Bacteria on Models with Compromised Physiological Barriers

D. Poulin[1], R. Samadfam[1], W. Finlayson[2], K. Ralston[2], N. Pichon[2], S. Coulson[2], and C. DeBakker[2]. *[1]Charles River, Senneville, QC, Canada; and [2]Servatus Limited, Sippy Downs, Australia.*

The frontier between commensals and pathogenic bacteria is not straightforward. It has been well acknowledged that some bacteria normally considered as commensals, can become pathogenic when they escape their original niche and start to colonize deeper tissues. Inflamed and compromised physiological barriers may facilitate the change in characteristic of harmless bacteria. The safety of high concentration of Lacto*Bacillus* formulations was evaluated in animal models where physiological barriers were altered, namely a chronic dextran sodium sulfate (DSS) induced colitis and oxazolone-induced atopic dermatitis murine models. In the colitis model, mice received DSS for 3 cycles of 5 days separated by 7 days. Bacterial dosing, individually or as a combination of the three strains, was performed daily. Stool and body weight were evaluated and a total disease activity index (DAI) was calculated. Colons were collected for histopathology evaluation. In the atopic dermatitis, formulations were topically applied for 21 days. Terminal blood samples for clinical pathology evaluation as well as histopathological evaluation of various tissues were conducted. In the AD model, the treatments were well tolerated. There was no treatment related changes in serum biochemistry or hematology parameters. Histopathological evaluation revealed no findings in the brain, liver, lungs, kidneys, spleen, muscles and heart of treated mice. In the colitis model, the treatments were also well tolerated with no sign of systemic inflammation or infection. Treatment with live bacteria markedly reduced local inflammation and progression of colitis in colon samples, confirming ef-

ficacy of the treatment. There were no microscopic changes in the spleen and liver that were attributed to treatment with test items. No abscess formation, bacterial colonies, and extensive inflammation or necrosis were observed in any treatment group suggesting significant translocation of bacteria was not associated with administration of the test items. Our data clearly indicate that treatment of mice with our combination of strains on colitis or on dermatitis compromised barriers produces no significant safety concern according to parameters evaluated. These bacterial strains present an alternative approach in treatment of colitis.

1699 Simple High-Throughput Workflows for Assessing Drug-Induced Mitochondrial Dysfunction Using Oxygen Consumption Measurements

M. Schwalfenberg[1], R. McGarrigle[1], R. Sane[1], N. Romero[2], and J. Hynes[1]. *[1]Agilent Technologies Inc., Cork, Ireland; and [2]Agilent Technologies Inc., Lexington, MA.* Sponsor: N. Romero, Society for Redox Biology and Medicine

Recent years have seen a growing appreciation of the importance of mitochondria as sites for off-target drug effects, contributing to safety-related attrition and post-market withdrawals. Robust assay workflows are therefore required to enable convenient, high-throughput identification of direct, specific mitochondrial impairment. Additionally, as some toxicity is mediated by bioactivation or bioaccumulation, longer-term drug exposures need to be facilitated, ideally with the capacity to delineate cytotoxicity from perturbed metabolism. Here we describe the development and evaluation of two discrete workflows that address these specific challenges by measuring the impact of drug-treatment using the MitoXpress Xtra Oxygen Consumption Assay. The first workflow describes a 384-well assay for acute impairment of mitochondrial function using HepG2 cells in suspension, facilitating a streamlined workflow that minimizes cell preparation time, reagent addition, and washing steps. Assay performance is evaluated using a compound panel with known mitochondrial liabilities, including Ketoconazole, Tamoxifen, Nefazodone, and Flutamide. Z' values of > 0.6 are consistently achieved and observed dose responses are consistent with previously reported data, highlighting the utility of this approach in the high-throughput detection of direct mitochondrial liabilities. To enable longer-term drug exposures, a second complementary workflow was developed and evaluated using adherent HepG2 cells in 96-well plates treated with drugs >24h prior to measurement. As non-specific cytotoxicity can confound interpretation of metabolic impairment after longer treatment times, this workflow comprises a multiplexed oxygen consumption/cytotoxicity assessment to better delineate metabolic responses after extended treatment times. Dose-dependent effects of model drugs were again consistent with reported data, while differential metabolic and cytotoxic responses are seen to distinguish non-specific cytotoxicity from specific mitochondrial impairment. Together these data illustrate the utility of oxygen consumption-based assessments of drug-induced mitochondrial dysfunction, enabling both rapid, simple, high-throughput screening for acute mitochondrial toxicants, and longer-term multiplexed assessment of drug-induced metabolic perturbation.

1700 Small-Scale Panel Comprising Diverse Gene Family Targets to Evaluate Compound Promiscuity

T. Sameshima[1], T. Yukawa[2], Y. Hirozane[1], M. Yoshikawa[1], T. Katoh[1], H. Hara[1], T. Yogo[1], I. Miyahisa[1], T. Okuda[1], M. Miyamoto[1], and R. Naven[2,3]. *[1]Takeda Pharmaceutical Company Limited, Fujisawa, Japan; [2]Takeda Pharmaceuticals International Inc., Boston, MA; and [3]Takeda California, San Diego, CA.*

Despite the recent advances in the life sciences and the remarkable investment in drug discovery research, the success rate of small-molecule drug development remains low. Safety is the second most influential factor of drug attrition in clinical studies; thus, the selection of compounds with fewer toxicity concerns is crucial to increase the success rate of drug discovery. Compounds that promiscuously bind to multiple targets are likely to cause unexpected pharmacological activity that may lead to adverse effects. Therefore, avoiding such compounds during early research stages would contribute to identifying compounds with a higher chance of success in the clinic. To evaluate the interaction profile against a wide variety of targets, we constructed a small-scale promiscuity panel (PP) consisting of eight targets (ROCK1, PDE4D2, GR, PPARγ, 5-HT_{2B}, adenosine A_3, M1, and $GABA_A$) that were selected from diverse gene families. The validity of this panel was confirmed by comparison with the promiscuity index evaluated from larger-scale panels. Analysis of data from the PP revealed that both lipophilicity and basicity are likely to increase promiscuity, while the molecular weight does not significantly contribute. Additionally, the promiscuity assessed using our PP correlated with the occurrence of both *in vitro* cytotoxicity and *in vivo* toxicity, suggesting that the PP is useful to identify compounds with fewer toxicity concerns. In summary, this small-scale and cost-effective PP can contribute to the identification of safer compounds that would lead to a reduction in drug attrition due to safety issues. *(Reprinted with permission from Chemical Research in Toxicology. Copyright 2019, American Chemical Society).*

1701 Pro-Arrhythmia Risk Assessment and Late Sustained Sodium Current (INa,L) in Adult Human Primary Cardiomyocytes

A. Ton, A. Ghetti, G. Page, P. E. Miller, and N. Abi-Gerges. *AnaBios, San Diego, CA.*

INa,L, a depolarizing current that persists throughout the action potential (AP) plateau, contributes to the AP duration and maintains intracellular Na^+ homeostasis. Increase or inhibition of INa,L is often associated with arrhythmogenicity or mitigation of pro-arrhythmia risk, respectively. Since drugs that block the hERG channel and also inhibit INa,L are not associated with pro-arrhythmia in humans, identifying the human effect of compounds on INa,L during preclinical development can aid in the determination of pro-arrhythmia risk for new drugs. In order to better understand properties of this current, we performed whole-cell voltage-clamp recording of INa,L using adult human primary cardiomyocytes isolated from ethically consented donor hearts. The current was examined by applying a pulse protocol every 5 seconds and measured using a ramp step. The data demonstrate that INa,L, under basal conditions, was activated at a membrane potential of -40mV and reached an average maximal current amplitude of -250pA around -10mV on the current-voltage relationship curve. Moreover, the basal INa,L was increased when cardiomyocytes were superfused with 0.06μM of the sea anemone toxin ATX-II, a well-known enhancer of INa,L (n=3). The stimulatory effect of ATX-II was reversible. Furthermore, we studied the effects of Ranolazine, an agent inhibiting INa,L, and found that 60μM Ranolazine inhibits basal INa,L (n=3). Moreover, in the continuing presence of ATX-II, Ranolazine elicited a pronounced reduction of INa,L (n=6). Thus, adult human primary cardiomyocytes express functional INa,L. Finally, AP and contractility experiments are currently underway to assess the actions of Ranolazine to suppress ATX-II- or hERG blocker-induced pro-arrhythmia. After a successful validation, human cardiomyocytes could potentially provide a useful strategy for the early assessment of the ability of new multichannel blocking drugs with INa,L affinity to prevent the occurrence of pro-arrhythmia.

1702 Full-Time Control of Environmental Temperatures Reduces Edge Effect in Plate-Based Cell Assays

A. Henn, Y. He, S. Darou, and R. Yerden. *BioSpherix Ltd., Parish, NY.* Sponsor: A. Henn, American Association for Cancer Research

A variety of approaches have been taken to avoid the variable results from edge wells in 96-well plates. The simplest approach is to avoid using them altogether, which eliminates 37% of the plate from the assay. This is tremendously wasteful of materials and time. Others have reported that incubation for extended periods of time at room temp during cell settling helps, although this is stressful for cells. We previously reported that plating cells at constant 37°C also reduces edge effect. Here we extend those studies to test the ability of constant thermal control of plating conditions to reduce variability in toxicity assays using human A549 lung and bone marrow Mesenchymal Stromal/Stem Cells (MSC). Our null hypothesis was that we would see no difference between the standard deviations in results from groups of wells including and excluding edge wells when comparing plates kept in uncontrolled room temp or controlled temp conditions. We used the Xvivo System to provide fully controllable gas and temperature levels for both cell incubation and handling. We performed 24-hour MSC toxicity assays with ethanol. Using the HoloMonitor M4 microscope, we showed that cell settling in edge wells was non-random when cells were plated at room temp and transferred to the incubator. MTT-based metabolic and crystal violet cell density assays showed that the cells were affected in a dose-dependent manner by ethanol. Data was normalized to its own control group and compared using a two-way ANOVA followed by Sidak's multiple comparisons test. Statistic analysis showed there was no significant difference between the group with and without the edge wells when plated at 37°C, while there was a significant difference in groups with and without edge wells when plating at RT. This suggests that variability in plate-based cell assays from use of edge wells can be reduced by plating the cells in controlled thermal conditions. Thermal imaging supports a model of heat transfer in which thermal currents form in the edge wells as cells settle

and the plate warms in the incubator, forcing cells toward the edges of the plate. We concluded that plating cells in constant 37°C may make it possible to use the whole plate, saving materials and time.

1703 Peripheral Neuropathy following a Single Exposure to a CXCR3-Depleting Antibody in Non-Obese Diabetic Mice

E. Poulton[1], J. Murray[1], D. Bangari[1], J. Gallas[2], and Z. Jayyosi[1]. *[1]Sanofi, Framingham, MA; and [2]Sanofi, Montpellier, France.*

The CXCR3 axis plays a role in autoimmune disease and CXCR3+ cell depletion shows promise as a treatment in autoimmune diseases such as vitiligo. During a study to assess the effects of CXCR3 depletion on diabetic NOD mice histopathology revealed that significant levels of inflammatory infiltrate into the sciatic nerve were noted in animals treated with a single dose of a commercially available hamster depleting antibody targeting murine CXCR3. Follow up work was conducted to further examine this finding. NOD and CD1 mice were treated with a single dose of 1, 5, or 40 mg/kg of the CXCR3 depleting antibody. Mice were sacrificed at 15, 50 or 100 days post dose and the sciatic and trigeminal nerves were microscopically examined for signs of inflammatory infiltrate and neuropathy. Immunophenotyping confirmed depletion of CXCR3 bearing cells. Nerve lesions were seen in NOD mice in all dose groups beginning at the 50 day post dose time point with no evidence of reversibility by the 100 day post dose time point. Lesions were seen in both the sciatic and trigeminal nerves, showing both inflammatory infiltrate as well as evidence of neuronal damage. Levels of NFLh (neurofilament heavy chain), a marker of structural nerve damage, were significantly higher in animals with nerve lesions. No lesions were seen in the CD1 mice at any dose or time point. A single dose of a CXCR3 depleting antibody was sufficient to induce a delayed peripheral neuropathy in NOD, but not CD1, mice that showed no signs of reversibility up to 100 days after treatment. A study in non-human primates was also conducted, and there was also evidence of inflammatory infiltrate into sciatic nerve in that study.

1704 The OrganoTEER: A Sensitive TEER Measurement Platform for High-Throughput Screening of Organs-on-Chips

J. W. Lowman[1], A. Nicolas[2], F. Schavemaker[2], S. Trietsch[2], H. Lanz[2], T. Hankemeier[3], P. Vulto[2], and R. van Vught[2]. *[1]MIMETAS, Gaithersburg, MD; [2]MIMETAS, Leiden, Netherlands; and [3]Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands.*

The study of epithelial barrier function is essential for fundamental understanding of disease processes, development of new therapeutic treatments, and investigation of compound safety. The gold standard barrier integrity measurement in epithelial models is the Trans Epithelial Electrical Resistance (TEER). The electrical properties of an epithelial layer are in a direct correlation to aspects such tight junctions, confluency, layer thickness and many morphological parameters. To address the lack of no commercially available solution for TEER on Organ-on-a-Chips, we developed a measurement apparatus to investigate epithelium cultured in a commercially available organ-on-a-chip platform. Up to 96 tubules cultured in a single OrganoPlate® have been studied by monitoring the diffusion of fluorescent probes (e.g. FITC-dextran) out of such tubes over time and calculating the apparent permeability (P_{app}). Here we investigate the relationship between TEER values measured using the OrganoTEER and P_{app} values determined using fluorescence based barrier integrity assays. We demonstrate the dynamic range for our TEER measurement method on epithelial tubes (CACO-2) including the response to toxicant exposure in comparison with Papp. The developed system makes use of an electrode interface compatible with the OrganoPlate 3-lane. Pairs are immersed in the wells connected to the inlet and outlet wells of each chip on the OrganoPlate. TEER values can be determined for up to 80 perfused tubules within 60 seconds. The instrument can be placed within an incubator to enable automated long term monitoring of TEER over the entire duration of an epithelial/endothelial study. Collagen I at 4mg/ml was layered in the gel compartment using Phaseguide technology. Caco2 tubules were formed against collagen I and under rocker-based perfusion flow. After 5 days of culture, we exposed to Staurosporine at varying concentrations (10uM, 2.5uM, 625uM, 156nM, 39nM, 9.7nM and 0nM). To investigate the relation between TEER and barrier integrity, we measured TEER on all tubules. We subsequently perfused them with a fluorescently labelled 10kDa Dextran dye and recorded its diffusion into the ECM channel using live fluorescent imaging. The results are expressed as TEER (fold change from before exposure) and P_{app} ($cm.s^{-1}$) respectively. As a result of staurosporine toxicant effect the P_{app} starts to increase at 20h exposures to 625nM staurosporine and higher (2.15e-5 +-0.79e-5 $cm.s^{-1}$ at 62nM), while TEER values was already decreasing relative to control at much lower dose and exposure times (relative change of 0.78+-0.09 at 156nM and 1 hour of exposure time, 0.38+-0.06 at 9.7nM and 20 h of exposure time). The increased sensitivity of this system is combined with the possibility to program label-free measurements throughout incubation without interruption of the experiment. We demonstrated the implementation of TEER measurements on an Organ-on-a-Chip platform and compared it to live imaging based permeability measurements. Based on these results, we propose this system for the study of healthy and damaged models of 3D barrier tissues in a non-invasive way to provides a valuable tool for drug toxicity and transport studies in Organ-on-a-Chip models.

1705 Benchmarking *In Vivo* Toxicokinetic Data against Complex *In Vitro* Models to Predict Drug Induced Liver Injury

J. Yong[1,2], M. Tse[1,2], S. Markossian[1,3], K. McLoughlin[1,4], T. Sweitzer[1,2], M. Gunshenan[1,2], A. Weber[1,2], and M. Arkin[1,3]. *[1]ATOM, San Francisco, CA; [2]GlaxoSmithKline plc, Collegeville, PA; [3]Small Molecule Discovery Center, University of California San Francisco, San Francisco, CA; and [4]Lawrence Livermore National Laboratory, Livermore, CA.* Sponsor: S. Markossian, American Association for Cancer Research

Drug induced liver injury (DILI), is a leading cause for attrition during drug development and one of the main reasons drugs are withdrawn from the market. DILI is the most common cause of death from acute liver failure and accounts for approximately 13% of cases of acute liver failure in the United States. There are currently no reliable methods to screen compounds for DILI preclinically, and the specifications used during high-throughput screening are often limited in scope. The need and importance to accelerate drug discovery, including the detection of DILI, has increased, as has the need to bring together expertise and resources from multiple disciplines and organizations. The Accelerating Therapeutics for Opportunities in Medicine (ATOM) consortium is a government, industry, and academic partnership with the goal of rapidly accelerating drug discovery by integrating high-performance computing, deep learning, and human-relevant complex *in vitro* models. ATOM is leveraging emerging phenotypic *in vitro* screening assays to generate data and creating computational algorithms to correlate *in vivo* biomarkers to *in vitro* data. In order to validate the computational models and the *in vitro* assays, data from GSK historical preclinical rat toxicity studies are used as a ground truth benchmark. This data includes histopathology, pharmacokinetic, and clinical chemistry data from 200 compounds that have been terminated. The conclusions drawn from the algorithms created and correlations found between the *in vivo* and *in vitro* datasets will allow us to establish guidelines and strategy for future toxicity screening studies in a systematic and reproducible way.

1706 An *In Vitro* Evaluation of Cytotoxicity and Mitochondrial Toxicity of Anti-Retroviral (ARV) Drugs in HepG2, SNU-475, and K562 Cells

K. Jambunathan, and J. C. Mirsalis. *SRI International, Menlo Park, CA.*

Mitochondrial toxicity (MT) is responsible for curtailed use and post-market withdrawal of many drugs; however, there is no one assay available that reliably predicts MT in early drug screening activities. We previously developed a panel of *in vitro* assays that encompass three major adverse events resulting from MT: (1) energy metabolism disruption, (2) increased oxidative stress, (3) altered apoptosis. This panel successfully characterized MT of nucleoside reverse transcriptase inhibitors (NRTI) in ten cell lines derived from liver, kidney and heart tissues. Here, we evaluated the *in vitro* cytotoxicity and MT of ARV drugs elvitegravir (EVG) and raltegravir (RTG) in three cell lines: HepG2 (liver), SNU-475 (liver) and K562 (bone marrow) with zalcitabine (ZTB) as a positive control. The *in vitro* cytotoxicity at six concentrations of EVG (0.1- 200μM), RTG (0.1-50μM) and ZTB (0.1 - 100μM) was evaluated for 72 hr by MTT assay. The EVG at concentrations higher than 10 μM resulted in ≥ 50% loss of cell viability in all three cell lines while no impact on cell viability was observed following 72-hr treatment with RTG. A ~20% loss of cell viability in all three cell lines was observed at 100μM ZTB. Based on cell viability data, three concentrations of EVG (10, 5 and1μM), RTG (50, 10 and1μM) and ZTB (100, 50 and 10μM) were selected for evaluating their MT potential. The cells were cultured with each compound for two weeks with cells harvested on Days 7 and 14 post incubation and tested in the *in vitro* assay panel. The 14-day treatment of three concentrations of RTG did not adversely impact the mitochondrial OXPHOS 1, 3-5 protein, caspase 3 and ROS/RNS levels in all three cell lines. The 14-day EVG treatment did not adversely impact the OXPHOS levels in HepG2 cells; however, a 20-100% decrease in OXPHOS1, 3-5 levels were observed in SNU-475 and K562 cells at 10 and 5μM. The 14-day ZTB treatment

resulted in a 30-100% decrease of OXPHOS 1, 3 and 4 levels in all three cell lines which confirms our previous results. *Work supported by NIAID Contract HHSN272201400006I.*

1707 Aircraft Cabin Fume Events: Is There a Toxicological Explanation?

A. Vale. *University of Birmingham, Birmingham, United Kingdom.*

Cabin air is derived in most aircraft from the compression stage of the jet engine. This bleed air is conditioned and filtered, with an exchange of 10-15 times per hour with outside air and 20-30 times per hour including outside and filtered recirculated air. On rare occasions, it is possible for the conditioned air to be contaminated by trace amounts of engine or hydraulic oil because of bearing failure or over-filling of the oil reservoir, giving rise to a "fume event" (visible smoke, haze, and/or odors) estimated to occur on 0.05% of flights overall (1 in 2,000). This Workshop will review firstly those studies that have analyzed the air of civilian and military aircraft and detected not only compounds traceable to various aviation fluids (jet fuel, lubricants, hydraulic fluid, and coolants) but also pyrethroids and ozone. Secondly, it will assess the toxicity of these identified chemicals to humans. Thirdly, a large investigation of 2,674 cabin crew conducted by the German Federal Institute for Risk Assessment (BfR) will be reported, and fourthly, a critical assessment of whether analytical investigations can assist in the diagnosis of cabin fume events will be presented. Some studies have detected tri-cresyl phosphate, an organophosphate used as a high-pressure lubricant in engine oil. However, the four meta/para isomers of tri-cresyl phosphate, which account for 99.8% of all isomers, are not neurotoxic. The six ortho-isomers account for the remainder. There is particular concern that tri-ortho-cresyl phosphate, which is bioactivated by CYP 1A2 and 3A4 to 2-(ortho-cresyl)-4H-1,2,3-benzodioxaphosphoran-2-one (CBDP), may be responsible for neurological sequelae, as this metabolite can bind both to human acetylcholinesterase (producing acute organophosphorus poisoning) and to Neuropathic Target Esterase (NTE), thereby initiating organophosphate-induced delayed neuropathy. Pyrethroid spraying on some flights to help ameliorate airborne diseases leads to clinically significant pyrethroid concentrations, which could result in nasal irritation, throat irritation, sneezing, cough, dizziness, headache, and nausea. High ozone concentrations, which are well documented, particularly during intercontinental polar flights in late winter/early spring, could produce eye, ENT, and respiratory features, such as dry mouth or lips, dry and itchy eyes, and nasal stuffiness. In the BfR study, the majority (76%) of the crew complained of odors similar to the smell of oil, "used socks," or burned material. The symptoms most frequently experienced were headache, dizziness, and nausea (>20% each). A smaller percentage (< 20%) of the patients reported symptoms such as "prickly sensations" (paresthesiae) and numbness. An adduct of CBDP with butyrylcholinesterase was first reported to be present in the serum of a group of asymptomatic aircraft passengers in 2011. More recently, adducts of the cresyl-benzodioxa-phosphorin-oxide-derived phosphyl group with tyrosine residues have been detected as well as histidine- and lysine-adducts with ortho-cresyl. Such peptides have been used as biomarkers in diverse smaller studies and case reports. However, these analytical methods are extremely sensitive, and a correlation between these biomarkers and development of signs and symptoms has not yet been firmly established.

1708 Is There a Toxicological Explanation for Features Following Cabin Fume Events?

A. Vale. *University of Birmingham, Birmingham, United Kingdom.*

It is possible for cabin air to be contaminated by various aviation fluids (jet fuel, lubricants, hydraulic fluid, and coolants), pyrethroids, and ozone. Tri-cresyl phosphate is present as a high-pressure lubricant in engine oil. However, the four meta/para isomers of tri-cresyl phosphate, which account for 99.8% of all isomers, are not neurotoxic. The six ortho-isomers account for the remainder: three are mono-ortho isomers, two are di-ortho isomers, and one is the tri-ortho isomer (tri-ortho-cresyl phosphate), which is bioactivated by CYP 1A2 and 3A4 to 2-(ortho-cresyl)-4H-1,2,3-benzodioxaphosphoran-2-one (CBDP). This metabolite can bind to human acetylcholinesterase and Neuropathic Target Esterase (NTE). As a result, exposure to substantial amounts of tri-ortho-cresyl phosphate (by ingestion not inhalation) has led to features of acute organophosphorus poisoning due to inhibition of acetylcholinesterase and to organophosphate-induced delayed neuropathy from > 70% inhibition of NTE. Ozone enters the cabin from outside the aircraft, particularly during intercontinental polar routes, and during late winter/early spring. When first installed, ozone catalytic converters decompose 90%-98% of the ozone present, but converters lose their efficiency because of other cabin contaminants ("surface poisoning"). High ozone concentrations could produce eye, ENT, and respiratory features, such as dry mouth or lips, dry and itchy eyes, and nasal stuffiness. Pyrethroid spraying (pre-flight, immediately before takeoff, and at the top of descent) on some flights to help ameliorate airborne diseases leads to clinically significant pyrethroid concentrations, which could result in nasal irritation, throat irritation, sneezing, cough, dizziness, headache, and nausea.

1709 Of Which Symptoms Do Cabin Crew Complain after a Cabin Fume Event?

N. Glaser. *Federal Institute for Risk Assessment, Berlin, Germany.* Sponsor: A. Vale

German physicians are required by law (Chemikaliengeset § 16e) to report cases of poisoning to the Federal Institute for Risk Assessment (BfR). This obligation also applies to individuals involved in a cabin fume event. Between 2009 and 2018, 1,027 cabin fume events involving 2,674 individuals were reported to the Federal Institute for Risk Assessment. All cases concerned air crew members. Women (59%) were involved more frequently than men (37%), and more flight attendants (64%) reported exposures than pilots (20%). The majority (76%) of the individuals complained of odors, mainly similar to the smell of oil, "used socks," or burned material. The symptoms most frequently experienced were headache, dizziness, and nausea (>20% each). A smaller percentage (< 20%) of the patients reported "prickly sensations" (paresthesiae) and numbness. 20% of individuals did not report any symptoms (WHO/IPCS/EC/EAPCCT Poisoning Severity Score [PSS] of 0), 66% had a PSS of 1 (minor symptoms), and 5% had a PSS of 2 (moderate symptoms). No severe symptoms (PSS 3) were reported. Patients with PSS 2 complained most commonly of severe or prolonged headaches, cognitive impairment, syncope, hypertension, or repeated vomiting. Laboratory results such as cholinesterase activity, oxygen saturation, carboxyhaemoglobin, and methaemoglobin concentrations did not show abnormal values indicating poisoning. In conclusion, symptoms reported were in general nonspecific and variable between patients. Due to this variability and lack of biomonitoring data, it was not possible to match symptoms with potential toxic agents.

1710 Can Analytical Investigations Assist in the Diagnosis of Cabin Fume Events?

H. Thiermann. *Bundeswehr Institute of Pharmacology and Toxicology, Munich, Germany.*

Tri-ortho-cresyl phosphate has been suggested as a component that might be present following cabin fume events. Although possible toxic mechanisms might be mediated by binding to acetylcholinesterase or neuropathy target esterase, only high-level inhibition of these enzymes is associated with clinical effects. A further possible target of cholinesterase inhibitors, the plasma—or butyrylcholinesterase (BChE)—shows a huge intra- and inter-individual range activity, preventing a clear assessment at low-level inhibition. Hence, more sensitive methods are needed for assessment of low-level exposure. The detection of adducts formed with cresyl-benzodioxa-phosphorin-oxide—an activated biotransformation product of tri-ortho-cresyl phosphate—with either BChE or serum albumin can be used for monitoring. BChE is present in plasma in concentrations as low as 3-4 mg/L, thus requiring its extraction from the complex plasma matrix. BChE isolation may be performed by affinity chromatography using procainamide or by immunomagnetic separation. The latter technology makes use of paramagnetic particles (beads) labeled with monoclonal antibodies against BChE that are directly added to plasma. With subsequent incubation, BChE is bound to the beads. Following enzymatic proteolysis using chymotrypsin or pepsin, small peptides are generated. If *in vivo* exposure to tri-ortho-cresyl phosphate has occurred, a characteristic phosphyl moiety is attached covalently to the serine residue of the esteratic center of BChE. This modified peptide is separated by liquid chromatography and detected by tandem mass spectrometry (MS/MS) with high sensitivity and selectivity. In addition to BChE, adducts to serum albumin may be monitored. Adducts of the cresyl-benzodioxa-phosphorin-oxide-derived phosphyl group with tyrosine residues can be detected as well as histidine- and lysine-adducts with ortho-cresyl following enzymatic degradation catalyzed by either pepsin or trypsin. Such peptides have been used as biomarkers to detect tri-ortho-cresyl phosphate exposure in pilots and flight attendants in diverse smaller studies and case reports. However, these analytical methods are extremely sensitive, and a correlation between these biomarkers and the development of signs and symptoms has not yet been established.

1711 Globally Harmonized Guidance for Dose-Response Analysis and Derivation of Health-Based Guidance Values for Chemicals in Food. Part I—What's New

J. Zang. *US FDA, College Park, MD.*

The World Health Organization (WHO) recently coordinated an international effort to update its guidance document on dose-response assessment for chemicals in foods, including additives, contaminants, natural toxicants, and residues of pesticides and veterinary drugs. This guidance also provides practical recommendations in deriving health-based guidance values, such as acceptable daily intake and acute reference dose, as the basis of establishing food safety regulations and safety standards in international food trade. Although the purpose of the guidance is related to the WHO food safety programs, the guidance reflects the latest expert thinking on dose-response assessment and benchmark dose (BMD) modeling, including some key areas of consensus among international experts, and so will be broadly applicable to areas beyond chemicals in food. Key motivators for the update were newly available modeling technology and the need for harmonization of the BMD approaches used by the US Environmental Protection Agency (US EPA) and the European Food Safety Authority (EFSA). This two-part Workshop includes presentations and demonstrations given by scientists who played essential roles in an international working group charged with drafting this harmonized guidance. Part I of the Workshop will focus on the basic elements and key updates in the new guidance, while Part II is designed as a practical demonstration session that builds on presentations in Part I. Part I will begin with an introduction that provides an overview of this guidance, the objectives of the working group, and a summary of notable updates. The second presentation will address the need for global harmonization with some food-related case studies and will present the new consensus decision tree scheme for dose-response analysis designed to aid in harmonizing approaches. The decision tree scheme, embracing a new tiered approach for the benchmark response for continuous endpoints, provides a practical guide to risk assessors and managers by illustrating how key decision points are affected by a variety of practical scenarios. The third presenter, who played a leading role in the incorporation of model averaging into the US EPA BMD software, will focus on the harmonization of BMD methodology by specifically outlining important considerations in the practice of BMD, explaining recommendations of modeling strategies for different types of data, and presenting challenges and solutions in harmonizing different methods. The session will conclude with an interactive panel discussion with all speakers, Chairs, and a moderator who collectively represent end users of this guidance from different sectors.

1712 Bring Together Multidisciplinary Expertise: Highlights of Updates in the New Dose-Response Analysis Guidance for Chemicals in Food

A. Boobis. *Imperial College London, London, United Kingdom.*

For chemicals in food, health-based guidance values (HBGVs), such as acceptable or tolerable daily intakes and acute reference doses, represent a range of oral exposures that are expected to be without appreciable health risk. The WHO original guidance, "Principles and Methods for the Risk Assessment of Chemicals in Food" (i.e., Environmental Health Criteria [EHC] 240), had limited context related to benchmark dose modeling, a field that has since rapidly evolved into different perspectives and approaches. By convening toxicologists, epidemiologists, mathematical modelers, risk assessors, and regulators, a multidisciplinary approach was used to update the guidance to provide a practical and harmonized recommendation to perform dose-response assessment (DRA) and establish HBGVs. Notable updates to the contents include dose-response modeling methodology (e.g., software, statistical issues, model evaluation criteria), a tiered approach to determining a benchmark response (BMR); a decision tree diagram for DRA leading to the establishment of HBGV or margin of exposure, new sections on dealing with epidemiological and *in vitro* data, incorporating new methods to derive chemical-specific adjustment factors, and revised terminology to improve consistency, clarity, and accuracy. The update also includes an appendix of examples based on dichotomous, continuous, and epidemiological data and additional information and references detailing model components, statistical fitting methods, and uncertainty. This overview will set the stage for the subsequent speakers to illustrate important technical applications of the new guidance, including choice of BMR and how model averaging and Bayesian approaches minimize issues related to model choice.

1713 Step by Step: Decision Tree for Dose-Response Analysis and Choice of the Benchmark Response

L. Haber. *TERA Center, University of Cincinnati, Cincinnati, OH.*

Key challenges in dose-response assessment have been disagreement on when it is appropriate and necessary to conduct dose-response modeling and differences in the specifics of the modeling guidance from different organizations, particularly the US EPA and European Food Safety Authority (EFSA). The importance of these differences and the need for harmonization are illustrated using case studies of two chemical food contaminants: 3-monochloropropane-1,2-diol, a contaminant in (3-MCPD) (impact of restricting models) and 5-hydroxymethylfurfural (HMF) (implications of considering visual fit, the Akaike information criterion [AIC], and scaled residuals in choosing models). An important aspect of the new guidance is a decision tree designed to aid risk assessors and managers and lead to a harmonized approach. The decision tree, agreed upon with full consensus at a meeting of international experts convened by WHO in March 2019, lays out the key steps in the dose-response assessment. Steps for conducting benchmark dose modeling and non-modeling approaches are addressed. The decision tree introduces a tiered approach for choosing the BMR for continuous endpoints, including (1) using a biologically meaningful adverse effect size; (2) expert judgment on the quantitative definition of adverse; and (3) using dose-response data to calculate a margin of exposure. Examples of application of the tiering will be provided.

1714 Bring Harmonization into Dose-Response and Benchmark Dose Modeling Guidance

M. Wheeler. *CDC, Cincinnati, OH.* Sponsor: Y. Zang

To establish a point of departure, some form of dose-response analysis (DRA) must be employed. Benchmark dose (BMD) modeling is the preferred approach over the NOAEL/LOAEL approach for a number of reasons, as identified by the WHO risk assessment guidance EHC 240. However, there are myriad choices available to the modeler, which range from the form of the dose-response curve to the type of analysis (e.g., frequentist versus Bayesian versus model average), and the question becomes, How does one make reproducible, scientifically valid decisions with all of these options? To bring harmonization and transparency into BMD modeling, the new guidance addresses these discrepancies by emphasizing the use of multi-model inference using model averaging, with a reliance on Bayesian models to implement "soft-constraints" on model parameters. The speaker will focus on how the newly developed guidance leverages new methodologies (e.g., model averaging and Bayesian dose-response modeling) while producing scientifically sound and robust results. Emphasis is made on the selection of different model suite and Bayesian priors for proper analyses of the BMD. This talk is geared toward toxicologists and BMD software users. It focuses on the practical choices when performing a dose-response analysis and is not intended to be technical in nature.

1715 Impacts on Human Health of Sunscreen Active Ingredients Used to Filter UV Light

M. Hughes. *US EPA, Research Triangle Park, NC.*

There are several known adverse health effects in the skin following overexposure to ultraviolet (UV) light from the sun. Acute effects from UV light overexposure include erythema, immunosuppression, and burns; chronic effects include photoaging and cancer. Occurrence of skin cancer from overexposure to sunlight is on the rise, alarming many health agencies. Total avoidance of sunlight and the wearing of protective clothing are the best ways to evade the harmful effects of sunlight. However, these two practices are not always the most practical way to avoid sunlight. In addition, excessive avoidance of sunlight may result in vitamin D deficiency, which has its own adverse effects, such as risk for cardiovascular disease and cancer. A more convenient means of protection from UV light from the sun is the application of sunscreen onto exposed skin. Sunscreens are basically inorganic (physical) and organic (chemical) filters of UV light. The main types of inorganic sunscreens or UV filters are zinc oxide and titanium dioxide, while several chemical classes are used as ingredients of organic sunscreens. Examples include the benzophenones, cinnamates, and others. These organic UV filters are not in sunscreens alone but also are found in other personal care products such as cosmetics and hair sprays, and clothing. Human exposure to the UV filters is primarily topical but can occur via the lungs after using spray applicators or by the gastrointestinal tract after use of lip balms containing these chemicals. Concerns have been raised about the potential adverse health and environmental effects of the UV filters. For example, the benzophenone derivative, 2-hydroxy-4-methoxybenzophenone (i.e., oxybenzone, benzophenone-3), is

one of the most predominant organic chemical-based ingredients of sunscreens currently used in the United States. Oxybenzone is detected in raw and treated wastewater and in coastal marine waters of Hawaii at low part per trillion concentration. Oxybenzone has been reported to be potentially photoallergenic, have endocrine-like effects in laboratory animals, and have a negative impact on marine organisms such as coral. The latter effect and its detection in Hawaiian waters has led the legislature of Hawaii to ban the use of oxybenzone-containing sunscreens by 2021. This session will focus on the potential human health effects from exposure to sunscreen active ingredients such as the benzophenones and cinnamanates. The first presenter will provide an overview of the dermatotoxicology of sunscreen active ingredients, with regard to past and future regulatory aspects of sunscreen active ingredients, as well as their safety and efficacy. The second presenter will summarize the results of the National Toxicology Program's efforts to characterize potential 2-hydroxy-4-methoxybenzophenone-related endocrine and developmental toxicity and carcinogenicity. Study designs utilized include *in vitro* and short-term *in vivo* (Endocrine Disruptor Screening Panel), rat multigenerational (including teratological), and two-year rodent carcinogenicity. The third speaker will present evidence on the effect of UV filters on the migration of human breast cancer cells. This effect has implications on breast cancer development and metastasis to other tissues in humans exposed to UV filters. *This abstract does not represent US EPA policy.*

W 1716 Sunscreen Dermatotoxicology: Past and Future

H. I. Maibach. *University of California San Francisco, San Francisco, CA.*

UV light exposure from the sun to human skin has a beneficial effect, the biosynthesis of Vitamin D, which is vital for normal human function. In contrast, overexposure to UV light has adverse effects, such as sunburn, early aging of skin, and skin cancer. Almost 90% of all skin cancers may be attributed to UV light exposure. Over the past several decades, the rate of melanoma, a type of skin cancer caused by UV light, has risen fivefold in Caucasian populations. The use of sunscreens can limit overexposure to UV light. They contain chemical ingredients that reflect and absorb UV light. The first commercial sunscreen was introduced in the 1920s, after it was found that UV light can damage skin. Fifty years later, the US Food and Drug Administration (US FDA) proposed a rulemaking to institute provisions for the safety, efficacy, and labeling of sunscreens. US FDA considers sunscreen ingredients as over-the-counter drugs. A final rule in 1999 established conditions where sunscreens would be generally recognized as safe and effective. In 2019, US FDA proposed to update the sunscreen regulations. This was due to the use of sunscreen with a greater number of UV light-blocking ingredients and at higher concentrations, the increased encouragement for sunscreen use, and an increased number and type of products used daily that contain sunscreens. Also, the safety of several ingredients and the extent of their systemic absorption after topical application has been questioned. Evidence suggests that the ingredient oxybenzone has endocrine activity. For systemic absorption, in the 1960s, when analytic chemistry sensitivity permitted, it became clear that the leading sunscreen of that time, para-amino benzoic acid, penetrated human skin *in vivo* in amounts equal or exceeding that observed with drugs. A recent clinical trial showed that four currently used sunscreen ingredients, including oxybenzone, had systemic concentrations greater than the US FDA guidance level of 0.5 ng/mL. These concentrations were reached after four topical applications of the ingredients on day 1 of the study. As sunscreens are used almost lifelong, we posit that their safety deserves careful evaluation. The presentation summarizes current data for US-utilized sunscreens and elaborates on data gaps, some readily obtainable and others important but not yet in progress.

W 1717 *In Vitro* and *In Vivo* Studies Assessing the Potential for 2-Hydroxy-4-methoxybenzophenone (HMB) to Affect Endocrine Activity, Reproductive Performance and Fetal Development, Endocrine-Sensitive Tissue Growth, and Tumor Incidence

B. S. McIntyre, E. Mutlu, S. Waidyanatha, H. Cunny, and M. Stout. *NIEHS/NTP, Research Triangle Park, NC.*

The National Institute of Environmental Health Sciences National Toxicology Program (NIEHS/NTP) has been studying the potential for UV sunscreens to induce adverse responses in model systems that are considered informative and predictive of potential human risk. Possible estrogenic and androgen/antiandrogenic effects of HMB (oxybenzone, benzophenone-3) were apically evaluated utilizing the Endocrine Disruptor Screening Panel Study designs. The goal of these *in vitro* and *in vivo* protocols is to determine if the test article affects estrogen or androgen receptor (ER and AR) binding, activation, synthesis, or metabolism. Potential *in vivo* estrogenic activity was assessed in the uterotrophic assay, and androgenic and antiandrogenic activity are evaluated in the Hershberger assay. Using ERs isolated from rat uteri, HMB was classified as "non-interacting." HMB displayed weak ER agonist activity with a LogPC10 of 5.5 Log[M] in the HeLa-9903 system. HMB did not induce a uterotrophic response and was classified as "equivocal" in the aromatase inhibition assay. Using ARs isolated from rat prostate, HMB was classified as an "equivocal" binder. HMB displayed antagonism of AR-mediated transactivation at ~10-4 M in the MDA-kb2 cell assay and was negative in the rat Hershberger assay. Potential HMB-mediated reproductive and developmental toxicity was assessed using the NTP Modified One-Generation study design. In this design, F1 HMB exposure is continual, beginning at the time of implantation. Endpoints examined included those that are sensitive to AR or ER modulation (e.g., anogenital distance, vaginal opening) as well as potential effects on F0/F1 reproductive performance, and developmental outcomes in the F2 generation. HMB exposure via dietary administration up to 30,000 ppm had no effect on F0 or F1 reproductive performance or anogenital distance, areolae/nipple retention (in either the F1 or F2 offspring), vaginal opening, or balanopreputial separation. HMB exposure was associated with increases in adult liver and kidney weight, and concomitant gross and histological lesions, in both sexes. There were no HMB-related effects on fetal weight or the incidence of adverse external, visceral, or skeletal findings. HMB was assessed in two-year rat and mouse carcinogenicity studies via dietary administration up 10,000 ppm. There were no apparent HMB-related increases in the tumor incidence of hormone-dependent tissues.

W 1718 Effects of Chemical Ultraviolet Filters on Proliferation, Migration, and Invasion of Human Breast Cancer Cells *In Vitro* at Concentrations Measured in Human Breast Tissue

P. D. Darbre. *University of Reading, Reading, United Kingdom.* Sponsor: M. Hughes

The human population is exposed to UV filters not only from their use in sunscreen products but also from their widespread addition to other personal care products and textiles to increase product stability. Our recent research has aimed to measure concentrations of some commonly used UV filters in human breast tissue, and then to determine whether those concentrations are sufficient to enable measurable effects in human breast cancer cells *in vitro*. HPLC-MS/MS was used to measure concentrations of benzophenone-3 (BP-3), octylmethoxycinnamate (OMC), and 4-methylbenzilidenecamphor (4-MBC) in human breast tissue taken from three serial locations across the breast from 40 women undergoing mastectomy for primary breast cancer. One or more of these UV filters were quantifiable in 101 of 120 (84%) of the tissue samples and at least one breast region for 38 of the 40 women. BP-3, OMC, and 4-MBC were detected in 69%, 74%, and 13% of samples, respectively. Using cell culture models, each of these three UV filters could increase proliferation of oestrogen-responsive human breast cancer cells at 10-7 M concentrations, which equate to levels measurable in some of the breast tissue samples. Following long-term exposure, these UV filters also increased cell migration and invasion at 10-7 M concentrations but did so in oestrogen-unresponsive as well as oestrogen-responsive human breast cancer cells. Given that many of these same breast tissue samples contained not one but multiple UV filters and together with several of the esters of p-hydroxybenzoic acid (parabens), the full potential for development of hallmarks of cancer in breast cells *in vivo* requires consideration to mixtures of these pollutant chemicals.

R 1719 Mechanistic Read-Across of Chemical Toxicants Based on Big Data

H. Zhu. *Rutgers, The State University of New Jersey, Camden, NJ.*

In 2016, the Frank R. Lautenberg Chemical Safety for the 21st Century Act became the first US legislation to advance chemical safety evaluations by utilizing novel testing approaches that reduce the testing of vertebrate animals. Central to this mission is the advancement of computational toxicology and artificial intelligence approaches to implementing innovative testing methods. In the current "big data" era, the volume (amount of data), velocity (growth of data), and variety (diversity of sources) are critical considerations when characterizing the currently available chemical, *in vitro*, and *in vivo* data for toxicity modeling purposes. Furthermore, as suggested by various scientists, the variability (internal consistency or lack thereof) of publicly available data pools, such as PubChem, also presents significant computational challenges. The development of novel artificial intelligence approaches based on massive public toxicity data is urgently needed to generate new predictive models for chemical toxicity evaluations and establish scientific confidence in

the developed models as alternatives for evaluating untested compounds. In this procedure, traditional approaches (e.g., QSAR) purely based on chemical structures have been replaced by newly designed data-driven and mechanism-driven modeling. The resulting models realize the concept of adverse outcome pathway (AOP), which can not only directly evaluate toxicity potentials of new compounds but also illustrate relevant toxicity mechanisms. The recent advancements of computational toxicology in the big data era are paving the road to future toxicity testing and will have significant impacts on public health.

1720 Individual-, Community-, and Population-Level Environmental-Associated Attributes of Disparate Health Outcomes in Vulnerable Populations

D. Hood. *Ohio State University, Columbus, OH.*

While life expectancy in the US has increased significantly over the past five decades, key indicators of chronic disease health outcomes continue to vary markedly by race, ethnicity, sex and/or gender, geographic location, and socioeconomic status (SES). Disparate health outcomes are well documented and account for a substantial proportion of preventable death and disability. In population groups defined by race/ethnicity, sex and/or gender, geography, and/or SES, disparities persist, and in some settings, they are widening. This Informational Session will present an innovation in the science of health disparities known as the Public Health Exposome (PHE) framework and its applications. This framework was devised as a means to identify important associations between chemical and nonchemical stressor exposures and chronic disease outcomes in vulnerable populations using both data-driven and hypothesis-driven methods. Using the Public Health Exposome dataset 3.0, the session will demonstrate how to use data-driven computational and hypothesis-driven statistical analytics to discover new scientific insights into associations between the natural, built, and social environments, adverse personal health outcomes, and disparate population-level health disparities. The PHE framework offers a new approach for conducting cumulative risk assessments that can be used to assess the effects of multiple, interactive, and cumulative chemical and nonchemical stressor exposures on disparate health outcomes and on population-level health disparities. By curating large amounts of disparate, heterogeneous data, the PHE approach provides environmental public health scientists, epidemiologists, and chronic disease researchers with the tools to develop, target, and evaluate current and past public health programs and policies.

1721 The Epidemic of Chronic Kidney Disease of Unknown Etiology in Agricultural Communities

A. Harrill. *NIEHS/NTP, Research Triangle Park, NC.*

Over the last two decades, occurrence of severe renal disease has dramatically increased in socially vulnerable farming communities within Central America, Sri Lanka, and India—and most recently reported in the United States. In countries such as Nicaragua and Costa Rica, chronic kidney disease mortality is over fivefold the national rates and increasing, with an overall mortality >20,000 young and middle-aged agricultural workers in affected regions. The epidemic of chronic kidney disease of unknown origin (CKDu) is not associated with classic CKD risk factors such as diabetes and hypertension. Potentiating factors are beginning to be explored, including heat stress and dehydration resulting from strenuous work in hot climates, agrochemical and metal exposures in occupational settings, and through drinking water sources. There is some evidence indicating that repeated episodes of acute kidney injury occurring during the growing season may have a cumulative effect in precipitating chronic kidney disease. A key question is whether the cause of the disease is the same worldwide or whether different factors are leading to the same manifestation in various disease hot spots. For example, well water as a primary drinking source has been implicated as a risk factor for the disease in Asian countries, but there is not sufficient evidence linking drinking water exposures elsewhere. What is clear is a strong association with strenuous work in primarily agricultural occupations. Pathologic features of the disease indicate a possible toxic nephropathy, yet systematically collected exposure data are sparse but ongoing. In this session, the key features and underlying renal pathology will be reviewed along with early investigations toward assessing the evidence of an environmental toxic mediator. A panel discussion serves as a "call to action" to engage toxicologists to consider studies that will help to mitigate the serious human health catastrophe of CKDu in economically disadvantaged communities.

1722 Evolving Technologies for Determination of Biotherapeutic Specificity

T. MacLachlan. *Novartis Institute for BioMedical Research, Cambridge, MA.*

Monoclonal antibody therapeutics evolved from low molecular weight drugs with the promise of substantially higher specificity than low molecular weight drugs, and thus with much lower potential for toxicity. Since safety of monoclonal antibodies is directly linked to the specificity of their binding to therapeutic targets, developers of monoclonal antibody therapeutics have evaluated specificity of their products using the "tissue cross-reactivity" assay, based on the immunohistochemical method, where the drug candidate is panned across a large number of human tissues. Recently, several platforms for screening for potential cross-reactivity have become available, from protein and cellular arrays to flow cytometry-based methods, and their utility as possible replacements for the immunochemistry method has been considered. This session will address the growing options that sponsors have to evaluate specificity of monoclonal antibody pharmaceuticals in the preclinical safety package.

1723 "TCR 2.0": Reviewing Experience with Methods to Detect Off-Target Binding of Monoclonal Antibodies

J. Cavagnaro. *Access BIO LC, Boyce, VA.*

Monoclonal antibodies (mAbs) and derivatives thereof have become a mainstay pharmaceutical modality. A primary benefit of these proteins is their highly targeted nature, which can reduce the incidence of side effects in patients. It is critical, however, to ascertain the specificity of antibodies prior to human clinical trials, and several country- and worldwide guidances direct sponsors to evaluate this. For the last two decades, the primary technique for determining specificity has been the immunohistochemistry (IHC)-based tissue cross-reactivity assay (TCR), where the candidate antibody is panned across 32 tissues to look for unexpected staining. In the last few years, however, other array-based platforms have emerged that allow for screening the majority of the human membrane proteome, indicating a viable alternative and/or addition to the IHC methods. Additionally, a "Q&A" to the ICH S9 guidance in 2018 indicated that TCR assays are not required in most situations for oncology biotherapeutics. The preclinical committee of the Biotechnology Innovation Organization (BIO), "Biosafe," has conducted a survey of 26 BIO member companies to understand current sponsor experience with the IHC and array techniques for determining antibody specificity. In the last 10 years, more than 650 IHC TCR assays have been conducted largely on full-length mAbs with varying impacts on programs. Protein/cell arrays have been utilized by a third of the companies surveyed and are gaining familiarity and comfort with the platform—initial experience with recent versions of these arrays has been largely positive and are integrating new modalities such as scFvs from CAR-T therapies. ICH S6(R1) guidance offers sponsors the option to use alternatives to IHC to determine antibody specificity—while most sponsors are not prepared to eliminate the IHC method, growing experience with these alternatives may allow them to confidently choose one with or without IHC in the future. Details on sponsor responses and experience will be shared in this session.

1724 Immunohistochemistry-Based Tissue Cross-Reactivity Studies: History and Current Perspective

B. Buetow. *Pfizer Inc., San Diego, CA.* Sponsor: T. MacLachlan

Immunohistochemistry (IHC) has traditionally been used as the primary method to assess tissue cross-reactivity (TCR) for monoclonal antibody and antibody-based therapeutic candidates. More recently, TCR studies have been used to determine the potential cross-reactivity of more novel therapies such as T cell-engaging bispecifics and CAR-T cells, which can have potent and potentially long-lasting effects. TCR studies have been recommended since the early 1980s by various regulatory guidance documents, which have been modified over time to the most recent "Points to Consider" (US FDA, 1997) and ICH S6(R1) (2011) documents. TCR studies incubate the candidate antibody/molecule with a wide range of tissues and detect binding of the candidate antibody using a variety of IHC techniques. In this regard, TCR studies using IHC have the unique ability to test for cross-reactivity across many tissues from both humans and animals. An evaluation can be made about which cell type is involved, as well as whether the binding appears to be on the cell membrane versus cytoplasm. While TCR studies sometimes provide key information about potentially cross-reactive targets, they also are prone to false positive results (as assessed by the presence of findings in "positive" tissues in *in vivo* toxicity studies), which can have a negative impact on drug

development. This is in part because the candidate antibodies/molecules are selected for their ability to have a desired therapeutic effect *in vivo*, and not because they are good IHC reagents. Several case examples will be presented to highlight the variable results obtained with TCR studies.

1725 Protein and Cell-Based Arrays to Assess Specificity of Biotherapeutics

A. Vicart. *Novartis Institute for BioMedical Research, Basel, Switzerland.* Sponsor: T. MacLachlan

Off-target binding of biotherapeutics to either cell surface or secreted proteins can lead to attrition in drug development. With new modalities such as antibody drug conjugates (ADCs), bispecific antibodies targeting T cells and CAR-T therapies, a lack of specificity could lead to severe side effects in patients. In the last few years, protein and cell array-based platforms have emerged that allow for screening against an extensive range of human proteins. We have and are continuing to test various platforms, including non-contact inkjet printed protein arrays and cellular arrays in slide, plate, and flow cytometry formats. While some platforms are still under evaluation, we have implemented a revised strategy to profile the specificity of biotherapeutics, including (1) profiling cross-reactivity potential on a cellular array prior to formal toxicity studies, (2) immunohistochemistry on a panel of tissues using an IHC-optimized tool antibody against the intended target, and (3) including screening results in the IND package together with the formal IHC-based TCR for non-oncology indications or as a substitute to TCR for oncology or when an immunohistochemistry method was not able to be developed. Initial experience with this strategy with more than 90 molecules profiled has been largely positive. Undisclosed on-targets were identified in more than 90% of screens and 2/3 of identified off-targets were confirmed by alternative binding and/or functional assays. Several examples will be shared, including its use for IND submissions and regulatory acceptance of these approaches, as well as how it helped selecting the best candidate or terminate nonselective lead biotherapeutics with financial and animal use reduction impacts.

1726 Genome Editing in Drug Discovery: Using the Cas9 Protein to Explore Target-Mediated Toxicity

J. Willy. *Vertex Pharmaceuticals, San Diego, CA.*

The Cas9 protein is an emerging and powerful tool for engineering the genome in preclinical models for studying disease progression. Recent advances in CRISPR/Cas9 technology has enabled biomedical research to advance rapidly on multiple fronts, including target identification and on- and off-target mediated toxicities, as well as the implementation of genome editing for innovative therapeutic approaches. The first presentation will introduce novel advances in genome-wide high-throughput CRISPR/Cas9 screens to identify unique targets for RAS-driven cancers. The second talk will provide mechanistic insight into novel applications of the Cas9 protein for identification of on- and off-target toxicities during drug development of small molecules. The final talk will focus on the immunotoxicity of Cas9 in preclinical models with the goal of understanding implications on current genome-editing therapeutics. The collective content of this session will highlight both the advances and the challenges of CRISPR/Cas9 technologies during the different stages of drug development in a rapidly emerging field.

1727 Functional Genomic CRISPR/Cas9 Modifier Screens Unveil Novel Therapeutic Targets in the Context of RAS-Driven Cancers

J. Kwon. *Broad Institute, Cambridge, MA.* Sponsor: J. Willy

The mitogen-activated protein kinase (MAPK) pathway is a critical effector of oncogenic RAS signaling, and inhibition of this pathway may be a key component of effective combination treatment strategies. We performed genome-wide loss-of-function CRISPR-Cas9 modifier screens in the presence of the MEK1/2 inhibitor (MEKi) Trametinib in KRAS-mutant pancreatic and lung cancer cell lines. We utilized STARS algorithm, a predictive model of on-/off-target sgRNA activity, to identify genes and pathways that cooperate with MEK inhibition. While we observed significant heterogeneity in genetic modifiers of MEK inhibitor sensitivity across cell lines, several recurrent classes of synthetic lethal vulnerabilities emerged at the pathway level. Multiple members of the receptor tyrosine kinase (RTK)-RAS-MAPK signaling pathway recurrently scored as sensitizers to MEKi. In particular, we demonstrate that knockout or suppression of SHOC2, a positive regulator of MAPK signaling, specifically cooperated with MEK inhibition to impair proliferation of a broad range of RAS-driven cancer cells. The depletion of SHOC2 disrupts survival pathways triggered by feedback RTK signaling in response to MEK inhibition in RAS-driven cancers. Taken together, loss-of-function CRISPR modifier screens provide rich insights into common, dynamic networks involved in MEK inhibitor resistance across a panel of heterogeneous cell lines and nominate SHOC2 as a novel combination therapeutic target.

1728 Using CRISPR/Cas9 to Explore Mechanisms of Toxicity

J. Willy. *Vertex Pharmaceuticals Incorporated, San Diego, CA.*

Drug-induced liver injury (DILI) is a major contributor to the overall clinical occurrence of acute liver failure (ALF), often leading to early termination of clinical trials, post-marketing drug withdrawals, and the need for liver transplantation, and compound-specific causality is not always clear. Despite a recent pivot toward utilization of *in vitro* tools for early safety assessment, nonclinical safety studies are still utilized to predict clinical liabilities for new drugs. However, recent advancements in genome editing coupled with network-based approaches in toxicogenomics allow new insight to explore relationships from the molecular/cellular level to pathological changes occurring at the organ in preclinical studies. Here, we will focus on recent investigations utilizing an integrated systems biology tool kit consisting of CRISPR/Cas9 and toxicogenomics to reduce uncertainty for both adaptive and progressive changes in the liver during early safety assessment.

1729 Exploring the Toxicity of Cas9 Systems for *In Vivo* Editing in the Central Nervous System

E. Stahl. *University of California Berkeley, Berkeley, CA.* Sponsor: J. Willy

Adeno-associated viruses (AAVs) are promising vehicles for genetically delivering the Cas9 endonuclease and its single-guide RNA into cells. Although AAVs are efficient at transducing various types of cells, we hypothesize that durable expression of Cas9 might cause off-target editing or prolonged presentation of bacterial antigens on MHC molecules, alerting the immune system to the presence of foreign invaders. Cas9 also can be delivered nongenetically as a ribonucleoprotein (RNP), which is a pre-formed, potent, and short-lived effector complex. Cas9 itself does not have cell-penetrating ability and so was engineered to possess multiple Simian vacuolating virus 40 nuclear localization sequences (SV40-NLS), thereby inducing transient and efficient gene editing in post-mitotic neurons in adult mouse brains (Staahl et al. 2017, *Nat. Biotech.*). To assess the toxicity associated with Cas9 editing in the murine central nervous system, we designed a sgRNA to allow expression of a reporter in targeted cells after delivering the Cas9 effector complex by AAV or RNP. We then assessed both on-target and off-target editing by state-of-the-art NGS techniques and the presence of infiltrating immune subsets, inflammation, and a peripheral host response. Our results demonstrate the inherent toxicity associated with both off-target editing and the immune response given a specific delivery route, dosage, and vector, with the ultimate goal of understanding and improving the safe and therapeutic use of Cas9 as a gene editor.

1730 Bringing Advances in Risk Science into Regulatory Decisions: Applying Data-Driven Uncertainty Analysis

G. Woodall. *US EPA, Research Triangle Park, NC.*

Confidence is improved in human health risk assessments when variability is well characterized and uncertainties are based on objective, empirically derived observations (data) instead of defaults. Uncertainty analysis, although relevant for both exposure and toxicity, increasingly focuses on the toxicity values applied in human health risk assessment (NAS 2009). In this Workshop, we will present the state-of-the-science on methods for explicitly incorporating information and judgment in the derivation of toxicity values, and corresponding characterization and communication of risks. Many of these methods can now be applied given the datasets and tools currently available. Other methods highlight specific data gaps that can be prioritized to improve risk management decision-making. This Workshop will present perspectives from regulatory, industry, and academic risk assessment practitioners on systematic review, refined dose-response analysis, data-driven distributions of uncertainty factors, and leveraging human data in toxicity assessments. *The views expressed are those of the authors and do not represent the views or policies of the US EPA.*

1731 Interpreting Dose-Response Uncertainty in a Regulatory Environment: Relationship to Decision Context

K. Raffaele. *US EPA, Washington, DC.*

Risk assessors and decision-makers at the US Environmental Protection Agency (US EPA) strive to develop risk management options designed to be protective of the general population as well as potentially sensitive populations and life stages. However, specific regulatory decisions and the populations evaluated vary considerably based on the specific language of individual statutes. Over the years, US EPA has developed robust guidelines and procedures to support the hazard and dose-response assessments that are conducted in support of US EPA risk assessments. Ideally, a single hazard assessment paradigm can provide support for multiple decision contexts; however, available toxicity and dose-response databases vary considerably among different chemical substances (including types and reliability of available data, as well as dose-response estimation). In addition to uncertainty related to available toxicity data, uncertainty related to population characteristics and exposure evaluation also may vary according to the specific decision context, and needs to be considered. Given the differences in assessment goals, the impact of uncertainty on the decision also can be quite different. For example, the type of analysis (including estimates of uncertainty) that might be needed to support an emergency response is very different from that which will be useful in supporting a national population-based regulation. The utility of various types of uncertainty analyses will be discussed in the context of a range of regulatory decisions that must be made, including the trade-offs provided by different types of uncertainty information.

1732 Survey of Case Studies in Application of Approaches for Quantitative Evidence Integration and Uncertainty Analysis

C. Ring. *ToxStrategies Inc., Austin, TX.*

The increased use of evidence-based methodologies, such as systematic review, provide a platform for quantitative integration and uncertainty evaluation in risk assessment. Herein, we survey a number of such approaches as applied to the evidence base for dioxin and dioxin-like compounds. These include (1) meta-regression, to quantitatively integrate dose-response data from a set of *in vivo* animal studies of a single endpoint of interest; (2) a Bayesian approach to applying uncertainty factors, to quantify the uncertainties in extrapolating a point of departure (derived from dose-response data) to a health-protective reference dose; and (3) a Bayesian meta-analysis approach to quantitatively integrate a database of relative potency estimates for 28 dioxin-like compounds, including the effect of relative quality of each estimate. Challenges in the use of these techniques will be emphasized, including discussion of the influence of heterogeneity in the toxicology evidence base, limitations in data reporting, and communicating results of probabilistic analyses in a way that is meaningful for decision-making. Despite these challenges, these quantitative techniques provide enhanced opportunities to characterize risk and uncertainty that ultimately provide the risk assessor and risk manager with information well beyond that from a point-estimate toxicity value.

1733 A Probabilistic Approach for Dose-Response Assessment of Human Health Effects

T. Blessinger. *US EPA, Washington, DC.* Sponsor: G. Woodall

To address the growing need for a probabilistic approach for characterizing uncertainty in dose-response assessment, a Workgroup under the World Health Organization/International Programme on Chemical Safety (WHO/IPCS) developed a step-by-step probabilistic approach for dose-response assessment of animal toxicology data. This approach derives health-based toxicity values (such as RfDs) or risk-specific doses probabilistically based on estimating a "target human dose" (HDMI). The HDMI can be calculated for a range of choices for the magnitude (M) of individual effect being protected against, the remaining incidence (I) of individuals with effects = M in the population, and the percent confidence in the HDMI estimate, thus allowing a risk manager to determine a target effect size, incidence, and confidence for a given decision. "Adjustments" to benchmark dose or other study results are made to account for uncertainty and variability. The approach allows the calculation of the dose that results in a preselected value of risk (i.e., a "risk-specific dose"). This approach can provide substantially more complete and transparent characterization of chemical hazards and support better-informed risk management decisions. *The views expressed are those of the author and do not necessarily represent the views or policies of the US EPA.*

1734 Globally Harmonized Guidance for Dose-Response Analysis and Derivation of Health-Based Guidance Values for Chemicals in Food. Part II—Intuitive Demonstrations

V. S. Bhat. *ToxStrategies Inc., Boston, MA.*

The World Health Organization (WHO) recently coordinated an international effort to update its guidance document on dose-response assessment for chemicals in foods, including additives, contaminants, natural toxicants, and residues of pesticides and veterinary drugs. This guidance also provides practical recommendations in deriving health-based guidance values, such as acceptable daily intake and acute reference dose, as the basis of establishing food safety regulations and safety standards in international food trade. Although the purpose of the guidance is related to the WHO food safety programs, the guidance reflects the latest expert thinking on dose-response assessment and benchmark dose (BMD) modeling, including some key areas of consensus among international experts, and so will be broadly applicable to areas beyond chemicals in food. Key motivators for the update were newly available modeling technology and the need for harmonization of the BMD approaches used by the US Environmental Protection Agency (US EPA) and the European Food Safety Authority (EFSA). Part I in this two-part Workshop includes presentations and demonstrations given by scientists who played essential roles in an international working group charged with drafting this harmonized guidance. Part I of the Workshop will focus on the basic elements and key updates in the new guidance, while Part II is designed as a practical demonstration session that builds on presentations in Part I. Part II will expand upon the concepts presented in Part I and provide nuts-and-bolts instruction on conducting BMD modeling with model averaging. The session will start with a brief introduction that outlines different BMD modeling platforms and highlights the need for harmonization. Then, two case studies, one with dichotomous data and the other with continuous data, will be demonstrated using both the US EPA BMDS software and EFSA PROAST software. Implications of key decisions in conducting the modeling also will be addressed. An additional case study will be provided to address more advanced topics, such as Bayesian prior selection and sensitivity analysis. Participants are encouraged, but not required, to bring their laptops with the latest version of BMDS and access to the web enabled, to get hands-on experience with the procedures and examples being demonstrated. The session will allow time for operational questions and discussion. Interested attendees can attend one or both Workshops.

1735 Benchmark Dose Modeling: Can We Bridge the Differences?

L. Haber. *TERA Center, University of Cincinnati, Cincinnati, OH.*

Benchmark dose (BMD) modeling has been generally accepted by many regulatory agencies to be the preferred approach to derive a point of departure (PoD) for risk assessment. In practice, BMD modeling can be performed on different platforms, including the BMDS software developed by the US EPA; the PROAST software that was first developed at the Netherlands National Institute for Public Health and the Environment (RIVM) and further advanced in collaboration with the European Food Safety Authority (EFSA); and Bayesian BMD (BBMD), a web-based software developed by Kan Shao, PhD, of Indiana University. In light of the need for consistency and transparency, this talk outlines key areas of differences in the practice and capabilities of these platforms, which serves as the introduction to the following interactive demonstrations that showcase the application of the harmonized WHO guideline.

1736 Benchmark Dose Analysis Using BMDS: An Interactive Demonstration

J. Davis. *US EPA, Cincinnati, OH.* Sponsor: V. Bhat

The presenter will analyze a dichotomous dataset and a continuous dataset separately, using the latest version of the US EPA BMDS software. The demonstration will be given in an easy-to-follow, step-by-step fashion that allows interactive participation from the audience. Emphasis will be given to the new developments that implement model averaging and key steps reflecting the new WHO guidance delineated in Part I. Note: if BMDS does not contain the model averaging feature for continuous responses at the time of the Workshop, a beta version will be used.

1737 Benchmark Dose Analysis Using PROAST: An Interactive Demonstration

J. Cortiñas Abrahantes. *European Food Safety Authority, Parma, Italy.* Sponsor: V. Bhat

The presenter will analyze the same dichotomous and continuous datasets used in the previous BMDS demonstration, using the latest version of the EFSA/RIVM PROAST package. The demonstration will be given in an easy-to-follow and step-by-step fashion, allowing interactive participation from the audience. Emphasis will be given to the application of model averaging and key steps reflecting the WHO guidance delineated in Part I, with additional commentary on how harmonization can be achieved in two different software packages.

1738 Boundary Cases for Bayesian Benchmark Dose Analysis

M. Wheeler. *NIOSH, Cincinnati, OH.* Sponsor: V. Bhat

In this demonstration, a case study on unanticipated results when applying Bayesian methods to dose-response analyses and benchmark dose estimation is studied. This presentation will discuss advanced considerations in BMD modeling such as model boundary conditions, priors, and flexibility. Specifically, this talk will investigate a dataset where traditional maximum likelihood methods produce unstable estimates and noninformative Bayesian analysis produces results that are not intuitive. The focus will be on the impact of prior selection on results and the importance of conducting sensitivity analysis. Means for integrating toxicological knowledge into priors for Bayesian approaches in BMD analyses will be discussed.

1739 Single Cell Applications in Mechanistic Toxicology

C. Smith. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Investigations into the mechanism of action of chemicals, pharmaceuticals, and contaminants typically rely on measurements of gene and protein expression. A change in expression of a gene, protein, or functionally related groups would indicate perturbation of suspect signaling pathways. These measurements are typically performed in whole tissues or homogenous populations of cells in culture. These "bulk" analyses do not consider the heterogeneity of cell types within a given tissue and thus provide a nonspecific average across cell populations, which reduces the specificity and sensitivity of the measurement. Different cell types exhibit variable responses to toxicant exposures that may be missed when analyzing bulk samples. For example, traditional bulk analyses cannot decipher responses in low abundant cells, which can be diluted by changes in more abundant cell types, and do not capture opposing signals in multiple cell types. To address these issues, single cell analytical tools have been developed that probe alterations in the genome, transcriptome, proteome, and metabolome of individual cells. While these methods are gaining popularity in the fields of immunology and cancer biology, among others, they have been minimally used to characterize target organ toxicities or to understand the mechanisms of action of toxicants. The purpose of this Workshop is to provide the audience an overview of the field of single cell biology through case studies of mechanistic investigations into toxicological responses in multiple systems using various single cell analytical methods. The first presentation will focus on antibody-based methods used to measure protein expression in single cells, including flow cytometry and single cell western blotting. The next presentation will focus on the use of single cell RNA sequencing (scRNA-seq) data to train a deconvolution algorithm, CIBERSORT, to estimate population size shifts from bulk RNA-seq data. The last presentation will introduce the single-cell amalgamation via latent semantic analysis (SALSA) workflow for cross-specimen integration of scRNA-seq data that is used to extract reliable exposure-induced gene expression changes from scRNA-seq data by reducing noise and addressing issues related to the sparsity of single cell data. This presentation also will complement scRNA-seq data with single cell proteomic analysis of cell surface proteins using single cell mass cytometry. Overall, this Workshop will introduce attendees to multiple single cell analytical techniques that provide a deeper view of the underlying biology driving adverse toxicological responses in diverse systems and will allow ample interaction between participants.

1740 Application of Single Cell Proteomic Analyses to Identify Pharmacological Mechanism of Action of a Novel Nitrated Fatty Acid in Acute Lung Injury

C. Smith, M. Wilkinson, A. Murray, E. Abramova, C. Guo, and A. Gow. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

The lung is a complex organ composed of over 40 cell types that are differentially targeted by contaminant exposures and respond in an intricate and coordinated manner to repair the lung after injury. Our laboratory utilizes multiparameter flow cytometry and single cell western blotting to elucidate mechanisms of action of toxicants and to identify potential targets for therapeutic intervention. This study examined the efficacy of nitrated-oleic acid (OANO2) in mitigating acute lung inflammation in mice intratracheally exposed to bleomycin (ITB). ITB treatment significantly increased total protein in bronchoalveolar lavage (BAL) (413±45.7 µg/mL) compared with controls (67±32.2 µg/mL), which was reduced by OANO2 (355±54.3 µg/mL). Histological analysis revealed cell infiltration and tissue injury in ITB mice that was reduced by OANO2. Flow cytometry of cells recovered from BAL demonstrated loss of Siglec-F+F4/80+CD45+ alveolar macrophages (37±3.6%; %CD45+ cells) relative to controls (95±3.3%; %CD45+ cells), and an increase in nonresident macrophages (48±4.1%; %CD45+ cells) compared with controls (4±3.8%) that was decreased by OANO2 (34±3.8%; %CD45+ cells). Mesenchymal cells (CD31-CD45-Sca-1+) isolated from lung digest demonstrated an increase in CD44 and CD90 expression in response to ITB (3±0.94 versus 23±1.0%; 43±2.3 versus 74±2.6%; %CD45- cells), suggesting an increase in fibrotic and proliferative potential, respectively, which was significantly reduced by OANO2 (19±0.9%; 70±2.3%; %CD45- cells). Single cell analysis of mesenchymal cells by singe cell western blot revealed ITB-induced expression of the profibrotic protein ZEB1; coadministration of OANO2 reduced the percentage of ZEB1 expressing cells. Single cell western blotting of the proinflammatory marker, HMGB1, in CD45+ cells revealed three populations of cells, cells with no HMGB1, low-expressing cells, and high-expressing cells. ITB resulted in an increase in high-expressing cells and loss of low-expressing cells. While coadministration of OANO2 did not abolish HMGB1 high-expressing cells, it increased the number of low-expressing cells. Overall, these findings suggest that treatment with OANO2 mitigates ITB-mediated proinflammatory cellular activation by altering resident cell function and promoting resolution of inflammation and highlight biphasic responses in CD45+ cells.

1741 Deconvolution of Bulk RNA-Seq Data Using Archived Single Cell RNA-Seq Data to Determine the Effects of Toxicants on Cell Population Sizes

D. Ruden, and J. Isherwood. *Wayne State University, Detroit, MI.* Sponsor: C. Smith

Lead has been used in a variety of products and industries; it is pervasive in the environment, and we are exposed to it through a variety of sources, like water from lead plumbing and dust. The developing nervous systems of children are most significantly affected by lead exposure, resulting in cognitive dysfunction and neurobehavioral deficits—for instance, learning and memory problems and lower IQ. This neurotoxicity is a result of the oxidative damage inflicted by lead, as well as ion mimicry, where lead can replace certain ions, like zinc and calcium. In our laboratory, we were interested in the effects of lead exposure on brain cell populations. To investigate this, we utilized publicly available *Drosophila* brain single cell sequencing data, from our lab and other labs, and bulk RNA-seq data of *Drosophila* heads +/- lead exposure generated in our lab. To identify the cell types most affected by lead exposure in the brain, we adapted the cell type deconvolution method CIBERSORT that was originally developed to identify blood cell type levels from bulk RNA-seq data. The single cell sequencing data from *Drosophila* brains identified 37 clusters of brain cell types, and the cluster-specific gene expression profiles were used as the input reference data for deconvolution. The results were proportions of each of the 37 cell type clusters for each of the lead exposed and control *Drosophila* head samples. Wilcoxon tests were performed, comparing the cell type cluster proportions between the lead exposed and control samples, identifying three significantly different cluster proportions: the a/ß lobe and a′/ß′ lobe of the mushroom body, and a group of dopaminergic neurons. Interestingly, the clusters corresponding to the a/ß lobe of the mushroom body, involved in long-term memory, and the dopaminergic neurons, involved in learning, both showed significant decreases in proportion comparing control with lead-exposed samples. In conclusion, we used single cell RNA-seq data to identify two neuronal cell types that decrease in number after developmental lead exposure. Further characterization of these two neuronal cell types are in progress.

1742 Peripheral Blood Monocytes of Human Smokers Exhibit Differences in M1 Macrophage-Associated Transcriptional Signatures Resolved by Single Cell RNA Sequencing

O. Lozoya, S. Martos, M. Campbell, M. Iannone, G. Pittman, and D. Bell. *NIEHS, Research Triangle Park, NC.* Sponsor: C. Smith

Smoking alters the DNA methylation and transcriptional profile in peripheral blood mononuclear cells (PBMCs). Given the large inter-individual variation that characterize scRNA-seq technologies, large cell numbers are preferred to explore the effects on targeted PBMC subpopulations, yet limited monocyte densities in PBMCs preclude confident analysis of tobacco-induced effects. Also, current scRNA-seq analytical pipelines lack resolution metrics to isolate exposure-induced transcriptional differences beyond cell-type identification across biological replicates. To circumvent these roadblocks, we exploited the advantages of the single-cell amalgamation via latent semantic analysis (SALSA) workflow for cross-specimen integration of sc-RNAseq data (doi: 10.1101/551762). SALSA is a multivariate scRNA-seq analysis method that optimizes discovery of reproducible gene expression changes from ultra-sparse single cell data across samples, statistical groups, and scRNA-seq platforms. First, we profiled >32,000 pan-monocyte enriched PBMCs isolated from multiple smoking and nonsmoking human donors (N = 4 independent specimens each group; median: 4,000 cells/donor; average: 2,800 net UMI/cell). Then, we implemented SALSA by anchoring multivariate analysis on genes that drove within-donor clustering, were shared across donors within smokers or nonsmokers, and showed statistically reproducible effect sizes and statistically significant multivariate comparisons. Altogether, our analysis revealed a minimal subset of 833 transcriptional profiling candidates among seven monocyte subpopulations, with transcriptional signature for M1 polarization downregulated in smokers. Ongoing work also includes mass cytometry characterization of equivalent pan-monocyte fractions from these donors revealing differential expression signatures of cell surface marker proteins. In sum, use of a stratified integration approach through SALSA for scRNA-seq analysis was able to ameliorate individual-specific batch effects and inter-group false-positive rates. This was accomplished while extracting the dominant sources of intra- and inter-individual variations stemming from underlying monocyte subpopulations, permitting integration with protein-level observations by mass cytometry.

1743 The More, the Better? Single Biomarkers, Panels, and/or Composite Biomarkers to Characterize Organ Injury

P. Devine. *Novartis Institute for BioMedical Research, Cambridge, MA.*

Biomarkers are critically important for disease diagnosis and for safety and efficacy evaluations during drug development. A number of traditional biomarkers, along with more recent diagnostic and exploratory biomarkers, are utilized in standard clinical pathology assessments. The Critical Path Institute Predictive Safety Testing Consortium, industry, and academic researchers have performed prospective preclinical and clinical studies on newer biomarkers that are being developed and characterized to improve differential diagnoses, especially identification of specific types of organ injury and injury or toxicity in the presence of confounding disease conditions. Examples of traditional biomarkers include amylase and lipase for injury to the exocrine pancreas, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) for hepatocyte injury, creatine kinase (CK) for skeletal muscle injury, and urinary protein for kidney injury. Specific situations can confound the interpretation of these traditional biomarkers. One example is that muscle injury or intense exercise can alter biomarkers of liver injury like ALT. In addition, another traditional liver injury biomarker, γ-glutamyltransferase (GGT), was found to be associated with cardiac damage, altering the once indisputable correlation of GGT and ALT/AST with liver injury. Greater confidence in interpretation of biomarkers may be gained by examining more than one endpoint at a time; however, this requires larger sample volumes, higher costs, and greater efforts. Furthermore, increased numbers of endpoints may lead to confusion and increased risk of false positives. More recently, panels of biomarkers have been tested for their composite diagnostic predictability. Strategies for utilization and implementation of new and exploratory biomarkers into current practices and guidelines are needed. This Workshop will describe the latest recommendations on how exploratory biomarkers should be interpreted and implemented within the context of traditional biomarkers and panels of biomarkers and whether composite biomarker readouts may improve diagnoses. Three speakers will discuss the latest in vascular injury, skeletal muscle, and kidney biomarkers and the various ways in which these biomarkers can be utilized. The session will conclude with an interactive panel discussion, driven by questions from the audience. Together, these talks will examine how to incorporate new biomarkers into current panels and strategies as they are explored, characterized, and eventually validated.

1744 Lessons Learned from the Qualification of Vascular Injury Biomarkers

J. Brumm. *Genentech Inc., South San Francisco, CA.* Sponsor: P. Devine

This talk will review and summarize the candidate biomarker identified by the Drug-Induced Vascular Injury (DIVI) Working Group (WG) of the Predictive Safety Testing Consortium (PSTC). DIVI is a poorly monitorable toxicity for which there are no specific standards to measure early onset or recovery. The selection of candidate biomarkers by the DIVI WG was based partly on the nature and breadth of the biomarker panel biology including response over duration of injury, across vascular compartments and shared response/morphologic outcome to injury regardless of pathogenesis/mechanism of the vascular insult. It is anticipated that the signature of the biomarker panel may vary according to pathogenesis, but collectively in a univariate or multivariate/combination approach, the biomarkers will be able to detect early end-organ vascular injury. To achieve specificity to the vascular system while maintaining sensitivity, we plan to have a biomarker panel with minimally at least one biomarker from each compartment (i.e., endothelial, smooth muscle, inflammation). We will review the approach that was taken to conduct and analyze the preclinical studies and highlight lessons learned with regard to bioanalytical methods and data analysis approaches.

1745 Clinical Biomarkers for Skeletal Muscle Injury and Neuromuscular Diseases

W. E. Glaab. *Merck & Co. Inc., West Point, PA.*

Skeletal muscle (SKM) injury has been reported as an adverse event as a result of a number of medications, including statins and fibrates. Conventional markers, such as creatine kinase (CK) and aspartate aminotransferase (AST), lack the sensitivity and specificity to detect SKM injury. New biomarkers of SKM injury would be useful as effective drug development tools not only to monitor toxicity and reversibility in nonclinical studies, but also to assess the safety of compounds in early clinical development. Yet another potential benefit of new SKM injury/degeneration biomarkers is that they can be used to monitor muscular disease progression and therefore be indicators of drug efficacy in clinical trials of new therapies for neuromuscular disorders. Information presented will highlight work of the Predictive Safety Testing Consortium's Skeletal Muscle Working Group and summarize the nonclinical data generated through this collaborative effort. Such data demonstrate the performance of four SKM biomarkers of drug-induced SKM injury—Skeletal troponin I (sTnI), Myosin light chain 3 (Myl3), Fatty-acid binding protein 3 (Fabp3), and Creatine kinase muscle type (Ckm). These nonclinical data were submitted to the US Food and Drug Administration and European Medicines Agency and sTnI, Myl3, Fabp3, and Ckm were endorsed with Letters of Support from both Agencies. Translation to clinical settings also will be discussed, including baseline assessment in healthy volunteers, patients with drug-induced injury, or muscular dystrophies (e.g., Duchenne muscular dystrophy, myotonic dystrophy type 1, and spinal muscular atrophy), with consideration of single biomarker versus multiple biomarker performance.

1746 Composite Measures of Multiple Urine Biomarkers as Early Drug Development Tools to Detect Renal Injury Response

R. Mogg. *Bill & Melinda Gates Medical Research Institute, Philadelphia, PA.* Sponsor: P. Devine

The Kidney Safety Project (KSP), a collaborative effort of the Foundation for the National Institutes of Health (FNIH) and Critical Path Institute (C-Path) Predictive Safety Testing Consortium, has proposed the potential use of two different composite measures in early drug development safety monitoring, each derived from a panel of urine biomarkers under a different context of use. The first composite measure, which received a positive qualification determination letter in August 2018, is to be used in early normal healthy volunteer trials to monitor group-level increases above a threshold to indicate the potential presence of renal tubular injury. The second composite measure, which is currently being prospectively evaluated for submission to regulators, also is to be used in early drug development trials, but to monitor the presence of renal tubular injury in individual patients. This presentation will detail the methods utilized to develop the two different composite measures to assess renal tubular injury and the benefits of using multiple biomarkers as opposed to a single biomarker in this context, while highlighting the limitations of the datasets that were available for the derivations and the regulatory comments received throughout the program.

1747 Variety Is the Life of Spice: The Clinical Toxicology of Synthetic Cannabinoids

S. Bradberry. *National Poisons Information Service (Birmingham Unit), Birmingham, United Kingdom.*

In the last 10 years, the abuse of synthetic cannabinoid receptor agonists (SCRAs) has caused unprecedented physical and psychological ill health among users, with an associated substantial burden on health and social care providers. Initially identified in the early 1980s, the repertoire of synthetic analogues has expanded rapidly to several hundred compounds. SCRA molecular structure consists of four components—"core," "tail," "linker," and "linked" groups—each with numerous potential analogues. Structural diversity presents challenges for nomenclature, with several systems in use, including serial designations generated by laboratories, names used by recreational users, and an alphanumeric systematic nomenclature. When applied correctly, the latter can effectively communicate detailed information about the structure and potential toxicity of these compounds. Unfortunately, this system has been inconsistently applied, and there remains a lack of international consensus on its proper usage. SCRAs are typically full agonists at cannabinoid receptors (CB1 and CB2) with potency up to one hundred times that of naturally occurring tetrahydrocannabinol. They also have the potential for many downstream signaling effects because of coupling of CB1 and CB2 to a variety of signal transduction mechanisms, including inhibition of adenyl cyclase and activation of mitogen-activated protein kinase. There is particular concern regarding the psychotic effects of these compounds, with evidence that they can affect the functioning of neurotransmitter systems other than that of endocannabinoids, including dopamine, serotonin, and glutamate, neurotransmitters known to be implicated in the pathophysiology of psychosis. Synthetic cannabinoids are typically sprayed onto plant material to be smoked. Their clinical effects are diverse and unpredictable. Central nervous system toxicity predominates with coma, seizures, extreme agitation, and psychosis. Other complications include stroke, myocardial infarction, acute kidney injury, rhabdomyolysis, and hyperthermia. Fatalities have occurred. Management is focussed on symptomatic and supportive measures, with an emphasis on maintaining staff and patient safety through conscious sedation. Poor understanding of the mechanisms of toxicity, limited dose-response data, and problems with real-time analytical confirmation contribute to the clinical challenge these patients bring to the emergency department. Where available, Ultra-Performance Liquid Chromatography with Time of Flight Mass Spectrometry (UPLC-MS/TOF) offers accurate, flexible, and specific analysis. In specialist units, this technology has been utilized to develop a vigilance system that identifies those cannabinoids in current use by analysis of drugs donated by or confiscated from users. The results are used to create a targeted, rapid turnaround drug screen pertinent to the particular cannabinoid analogues in circulation at a given time. Latest challenges surrounding SCRAs include the potential adverse health effects of long-term use, with the associated risks of addiction to and subsequent withdrawal from synthetic cannabinoids as yet inadequately clarified. Legislation aimed at limiting availability of these drugs has been implemented in several counties with questionable success. There remains a global need to focus not only on law enforcement but also on education, harm reduction, and prevention.

1748 Synthetic Cannabinoids: Chemistry, Nomenclature, and Mechanisms

S. Hill. *National Poisons Information Service, Newcastle, United Kingdom.*
Sponsor: S. Bradberry

Originally developed for legitimate scientific research, the repertoire of synthetic cannabinoids for recreational use has expanded rapidly in recent years, with at least 180 analytically confirmed compounds as of January 2019. The molecular structure of synthetic cannabinoids consists of four components: "core," "tail," "linker," and "linked" groups. Their structural complexity offers multiple opportunities for chemical modification to evade drug control legislation (itself based on chemical structure), explaining the large numbers of individual chemicals that have been developed. The structural complexity of synthetic cannabinoids presents challenges for nomenclature, with several systems in use, including serial designations generated by laboratories, names used by recreational users, and an alphanumeric systematic nomenclature that is increasingly being referenced in published literature and the recreational market. When applied correctly, the alphanumeric nomenclature can effectively communicate detailed information about the structure, and potential toxicity, of these compounds. Unfortunately, this system has been inconsistently applied, and there remains a lack of international consensus on its proper usage. Synthetic cannabinoids are typically full agonists at cannabinoid receptors, with potency up to one hundred times that of naturally occurring tetrahydrocannabinol. Moreover, they have numerous metabolites with diverse activity profiles at cannabinoid receptors (CB1 and CB2). They also have the potential for many downstream signaling effects because of coupling of CB1 and CB2 to a variety of signal transduction mechanisms, including inhibition of adenyl cyclase and activation of mitogen-activated protein kinase. There is particular concern regarding the psychotic effects of these compounds, with evidence that they can affect the functioning of neurotransmitter systems other than that of endocannabinoids, including dopamine, serotonin, and glutamate, neurotransmitters known to be implicated in the pathophysiology of psychosis. This presentation will discuss the chemical structure of synthetic cannabinoids and describe the different nomenclature used to identify individual compounds, linking where possible structure to activity.

1749 Clinical Presentation of Synthetic Cannabinoid Exposures and the US Experience

J. Brent. *University of Colorado School of Medicine and School of Public Health, Denver, CO.*

In 2014, the Toxicology Investigators Consortium noted a sharp uptick in cases of toxicity from synthetic cannabinoids (SC). The severity of toxicity ranged from mild to severe. Of 456 patients, the most common features of toxicity were neuropsychiatric, primarily manifested as agitation, delirium/toxic psychosis (41%), and central nervous system depression/coma (24%). Seizures (17%) and hallucinations (7%) occurred less frequently. 28% of cases presented with severe vital sign abnormalities: 12% tachycardia (>140 beats per minute [BPM]), 6% bradycardia (<50 BPM). 5% had rhabdomyolysis, and 3% had acute kidney injury. The death rate from synthetic cannabinoid-only exposures was 1.2%. In the US, synthetic cannabinoids are used by spraying onto plant material and smoked, added to food/beverages, or placed in electronic nicotine delivery devices. Epidemiologic data on exposures is hampered by the lack of analytical confirmation in most cases. However, the peak year for cases of presumed SC exposures reported to US poison centers was 2015. Importantly, the possibility of contamination of SC products with other biologically active molecules has been a major epidemiologic concern. For example, a recent outbreak of SC-related coagulopathy occurred due to contamination with the anticoagulant brodifacoum.

1750 Synthetic Cannabinoid Abuse: Diagnosis and Management

S. M. Bradberry. *National Poisons Information Service (Birmingham Unit), Birmingham, United Kingdom.*

While patients with mild features of acute synthetic cannabinoid intoxication may self-present with a clear history of exposure, it is not unusual for emergency physicians to be faced with an aggressive, incoherent individual from whom a reliable history is not forthcoming. In these cases, the initial diagnosis is based on the presence of classic clinical features, sometimes accompanied by circumstantial evidence or collateral information from family or friends. Analytical confirmation of synthetic cannabinoid use is not widely available since they are not detected by classic immunoassay-based screens. Diagnostic uncertainty can result in patients undergoing expensive and/or invasive investigations as part of their clinical workup. Even if more specific analysis is available, the changing pattern of synthetic cannabinoids in circulation can result in false-negative results. Analytical toxicovigilance systems utilizing Ultra-Performance Liquid Chromatography with Time of Flight Mass Spectrometry (UPLC-MS/TOF) have enabled accurate identification of "unknown" toxins and flexible, targeted modification of "routine" screening repertoires to match changing clinical need. Management of the acute phase of poisoning is focused on symptomatic and supportive measures, with an emphasis on maintaining patient and staff safety through conscious sedation. In extreme cases, paralysis and mechanical ventilation are required. Most patients make an uneventful recovery, though life-changing, permanent sequelae are increasingly documented, and fatalities have occurred. There is evidence that the latter is underreported, particularly among the homeless population, in whom use of synthetic cannabinoids is a particular public health challenge. There also is increasing concern regarding the potential adverse health effects of long-term use, with the associated risks of addiction to and subsequent withdrawal from synthetic cannabinoids as yet inadequately clarified. Legislation aimed at limiting availability of these drugs has been implemented in several counties with questionable success. There remains a global need to focus not only on law enforcement but also on education, harm reduction, and prevention.

1751 Cellular Recovery and Resilience: A New Perspective on Toxicity Testing

L. Smirnova. *Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.*

The move from whole animal-based toxicology tests to human cell-based assays has witnessed a renewed focus on toxicological mechanisms. Technological developments, including 'omic technologies, have enabled an unprecedented understanding of how cells deal with chemical insult, which is often by altering transcriptional programs to initiate specific stress response pathways. Currently, many *in vitro* toxicity studies mainly assess acute susceptibilities of cells and tissues but ignore long-term, low-dose, epidemiologically relevant exposures to chemicals, which could lead to disease manifestations. The concept of cellular resilience, in contrast, suggests studying how cells can cope with stress by activating pathways of defense, which lead to recovery and resistance (tolerance) against subsequent hits. The first presentation will demonstrate how such defense mechanisms could help us to identify vulnerable individuals or irreversible adverse outcomes that manifest as progressive diseases. Pathways such as Nrf2 (oxidative stress), p53 (DNA damage), HIF-1 alpha (hypoxia), and Unfolded Protein Response (proteotoxicity) are among the most frequent ones to provide the cell with some resistance to the initiating injury. Such pathways are by definition protective, and their activation can be used to identify the molecular initiating event and the extent of the impact. The next presentation will continue the discussion about adaptation, recovery, and resilience, with the focus on neurodegeneration. The third presentation will demonstrate how the field of cellular recovery and resilience can be addressed in a high-throughput manner by introducing the Toxmatrix, a chemical genomics method that can identify chemicals, and pathway perturbations, that protect or sensitize cells to a toxicant. Characterization of these pathways also enables us to connect dose-responses to irreversible adverse events, as detailed in adverse outcome pathways. Quantitative high-throughput screening approaches and transcriptomic biomarkers have been used to identify activation of the stress pathways. Cell co-culture and 3D models also are being developed to understand chronic adaptations such as cardiac hypertrophy, Epithelial-to-Mesenchyme Transition (EMT), neurodegeneration, and fibrosis. The fourth talk will present recent work on "tipping points" between adaptation and adversity based on high content imaging data from the ToxCast project. Tipping points are another approach for quantifying cellular resilience as the concentration and/or exposure duration beyond which a cell is unable to recover. The discussion on recovery and resilience will be completed by in the final presentation, which will introduce the methods of how to measure biomarkers of resilience. Biomarkers of specific stress phenotypes and tissue dedifferentiation also may be identified for tipping points that enable us to quantify the exposure threshold that triggers an irreversible adverse effect. Taken together, intoxicated cells may differ less in how they are hit than in how they resist stress and recover or adapt to the new homeostasis to become more resilient. Defining these mechanisms of resilience will enable us to generate better *in vitro* assays and will inform both animal and clinical studies. This Symposium will address both resilience and recovery after injury. The main findings on cellular recovery and resilience from the five presentations and future directions will be wrapped up in the summary talk.

1752 Lessons Learned from Repeat-Dose Toxicity and Recovery after Exposure

P. Jennings. *Vrije University Amsterdam, Amsterdam, Netherlands.*
Sponsor: L. Smirnova

While focused, well-carried-out, acute *in vitro* experiments can be very helpful for determining molecular initiating events, it might be expected that longer repeat exposures and recovery experiments would be required to predict effects for chronic exposures *in vivo*. Unfortunately, such experiments are rare. In this talk, specific examples of recovery and repeat dose will be presented, where stress responses, tissue-specific biomarkers, and kinetics are integrated. A specific example is that of differentiated human renal proximal tubule cells (RPTEC/TERT1 cell line), which were treated for five days with cyclosporine A (CsA), allowed to recover for eight days, and treated again for another five days. Transcriptomics, metabolomics, CsA-induced cyclophilin secretion, morphology, and CsA kinetics were measured over treatment and recovery periods. The second treatment was similar for many of the endpoints but had a dampened transcriptomics signal and CsA-induced glycolysis and CsA-induced acetate production. Since the biokinetic update of CsA was the same, this was unrelated to alterations in extrusion or metabolism genes. The value of repeat dose and recovery to add to the predictive weight of *in vitro* experiments to human safety assessment will be critically analyzed.

1753 The Cellular Resilience Concept: Application to Chemical-Induced Parkinson's Disease Model

L. Smirnova. *Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.*

Mechanisms of resilience are being examined in a repeat-dose neurotoxicology paradigm. In Parkinson's disease, the systemic effect of mitochondrial complex I inhibition by a chemical such as rotenone leads to selective degeneration of dopaminergic neurons but not other neurons. We hypothesized that these cells are less resilient and cannot cope with the same stress as other neurons and therefore are targets for neurodegeneration. We analyzed acute and delayed response of 3D dopaminergic neuronal model (3D LUHMES) to low-dose rotenone to identify early responses versus defense; recovery versus adverse outcome. We demonstrated that 3D LUHMES could functionally recover from the low-dose exposure to rotenone, with some molecular scar remaining. The recovered cells maintained a higher energy production level and higher metabolic capacity and were more resilient to the second hit. However, the fully functionality of those resilient cells was not restored. Intervention and repair of perturbed molecular pathways (scars) can stimulate functional resilience. For example, overexpression of neuroprotective microRNA-7 may help cells to stay resilient in the long-term perspective. These processes illustrate on a molecular level how chemical exposure alters cellular responsiveness, including the induction of protective means leading to resilience, but also molecular scars possibly associated with late hazard manifestations.

1754 Probing Resilience Mechanisms by Chemical Combination Screening

D. Gerhold. *NIH/NCATS, Bethesda, MD.*

Extending the neurodegenerative toxicology paradigm, we developed a chemical genomics method, the "Toxmatrix," to identify mechanisms of toxicity and resilience. Using this method, cultured cells were treated with a toxicant at 10 concentrations, and additionally pre-treated with each of 70 modulator chemicals, to identify modulators that shifted the IC_{50} for cell killing. By screening all combinations of 32 toxicants by 70 modulators, we identified 20 toxicant-modulator pairwise interactions, including 14 pairs that showed protection or sensitization in multiple neuronal cell lines. For example, the modulator buthionine sulphoximine (BSO) sensitized neuronal cell lines to 6-hydroxydopamine by inhibiting glutathione synthesis. This implies that glutathione synthesis is a resilience pathway, protecting neurons from 6-hydroxydopamine. Conversely, chelator DMPS protected three neuronal cell lines from 6-hydroxydopamine and four other toxicants. DMPS acts by chelating metal ions, implying that these five toxicants disrupt metal distribution pathway(s). Since each modulator was chosen to inhibit or activate a single annotated target in the cell, the modulator-toxicant interaction provides information about the toxicant's potential mechanism—hence, pathways of toxicity or cellular resilience. Surprisingly, several modulators were found that sensitized or protected neuronal cells from multiple diverse toxicants, identifying susceptible pathways that may be characteristic of neurons.

1755 Toxicological Tipping Points: Using High-Content Imaging Data from ToxCast

I. Shah. *US EPA/NCCT, Research Triangle Park, NC.*

This talk will explore resilience mechanisms using high content imaging (HCI), recognizing that a "tipping point" dose may be reached where adaptive responses yield to adverse events. We have studied the effects of 88 chemicals in primary rat hepatocytes using HCI to measure dose- and time-dependent perturbations in endoplasmic reticulum stress, mitochondrial function, lysosomal mass, steatosis, apoptosis, DNA texture, nuclear size, and cell number. A new computational model is proposed to describe the dynamic response of the system as cell-state trajectories based on multidimensional HCI data streams. Cell-state trajectories produced by multiple concentrations chemicals showed resilience of the primary rat hepatocyte system in many cases; however, we also found "tipping points" in system recovery. Further analysis of trajectories identified dose-dependent transitions, or critical points, in system recovery. We believe that HCI can be used to reconstruct cell state trajectories and provide insights into adaptation and resilience.

1756 Sensor-Based Assays to Measure Markers of Cellular Resilience in Real Time

C. Agu. *INanoBio, Mountain View, CA.* Sponsor: L. Smirnova

This talk will present a flexible technology for detection of cellular stresses and examples for early detection of such alarm signals. The ability to measure and study the molecular causes and phenotypic consequences of different levels of cell resilience requires the availability of tools that can detect and quantitatively measure differences in cellular resilience in real time in response to carefully controlled perturbations. We report a novel nano-sensor platform capable of *in vitro* label free measurement of markers of cellular stress and resilience (e.g., exosomal heat shock proteins) released by stressed cells in real time. Results from our nano-sensor-based real-time cell resilience assays will be presented, and their utility in investigating cell stress and resilience pathways will be discussed. The overarching goal is to scale the sensor array platform to ultra-high-throughput real-time assay of tens of thousands of single cells, simultaneously. When fully developed, this cell resilience assay platform will expand our understanding of individual differences in response to a broad spectrum of physiological stressors with the goal of promoting the development of novel therapies and interventions to preserve or enhance resiliency and promote healthy living.

1757 Cyanide as a Chemical Threat: Finding Better Antidotes

D. Jett. *NIH/NINDS, Bethesda, MD.*

Cyanide is a well-known industrial chemical that also has been used as a deadly poison throughout modern history and antiquity. Several cyanide-containing compounds, including hydrogen cyanide, potassium cyanide, and cyanogen chloride, are highly toxic and considered a threat to public health. They are considered chemical threats because of potential use by terrorists and large-scale industrial accidents like the one that occurred in Bhopal in 1984. Cyanide disrupts cellular oxidative phosphorylation via the inhibition of cytochrome c oxidase. Cyanide also inhibits several other enzymes, induces oxidative stress, and increases cellular calcium. Mitochondrial toxicity and other effects lead to death, usually from cardiopulmonary paralysis. The central nervous system (CNS) also is vulnerable to cyanide toxicity, evidenced by the nonlethal chronic effects that are usually related to deficits in motor neuron functionality, like those reported after consuming cyanogenic cassava root (Konzo disease) and the parkinsonism reported in survivors of cyanide poisoning. The wealth of knowledge gained from decades of research on the mechanisms of cyanide toxicity has resulted in the development of effective therapeutics for individual exposures including the recently US Food and Drug Administration (US FDA)-approved drug Cyanokit. However, the unmet need discussed in this session is the lack of safe and effective therapeutics for treating many individuals at once after deliberate or accidental release. United States federal agencies such as the Departments of Health and Human Services and Homeland Security have identified a need for antidotes that have better utility in these mass causality events. The currently available antidotes are effective and relatively easy to use by trained professionals to treat individual poisonings. However, they can require reconstitution before administration, and all available US FDA-approved cyanide antidotes must be delivered by intravenous injection, which is difficult and time-consuming. These and other features of current antidotes may not be ideal for rapid treatment of many individuals at once. This session will describe the unmet need for better cyanide antidotes during mass causality events and provide specific examples of current innovative research on the discovery of new lead compounds and the development of drug candidates.

1758 Introduction and Overview of the Unmet Need in Cyanide Research

D. A. Jett. *NIH/NINDS, Bethesda, MD.*

There are two US FDA-approved cyanide antidotes currently available: Cyanokit (hydroxo-cobalamin) and Nithiodote (sodium nitrite and sodium thiosulfate). Additionally, there is a third treatment, amyl nitrite, which has traditionally been packaged with sodium nitrite and sodium thiosulfate as the Cyanide Antidote Kit. Cyanokit and Nithiodote require intravenous administration by trained personnel. While these antidotes are effective for single cyanide poisonings, better antidotes for mass casualty events is a current unmet need. Some of the characteristics new and improved cyanide antidotes should have include that they (1) can be administered by minimally trained individuals, possibly with intramuscular autoinjectors or oral, intranasal, or inhalational administration; (2) have a rapid onset and long duration of efficacy; (3) possess efficacy for all forms of cyanide and routes of cyanide exposure; (4) have a ready-to-use antidote not requiring preparation in the field; (5) are stable for storage of many doses; and (6) are cost-effective. Current research on better cyanide antidotes includes basic mechanistic research to discover therapeutics targets, through preparing drug candidates for advanced development and ultimate US FDA approval and licensure. Cyanide research can be categorized as either cyanide-based or host-based. Cyanide-based research includes agents that bind cyanide and remove it from circulation, while host-based research focuses on the detoxification of cyanide by increasing its metabolism and elimination, or by direct interaction with targets of cyanide and other mechanisms that prevent or ameliorate acute and chronic toxicity. Special consideration is being given to alternate routes of administration and/or dosing regimens for new or already US FDA-approved therapies that would be safer, more effective, or easier to administer during a mass casualty scenario. Specific subpopulations (e.g., pediatric and pregnant) that are more vulnerable also are a priority for civilian exposures. Finally, clinical efficacy studies are rare because of the obvious ethical challenges; however, some studies may be possible in people who are exposed to cyanide accidentally—for example, from acute smoke inhalation or chronic cassava poisoning.

1759 Cobinamide, Sodium Tetrathionate, and Sodium Nitrite/Sodium Thiosulfate for Treatment of Cyanide Poisoning

G. Boss. *University of California San Diego, San Diego, CA.* Sponsor: D. Jett

Cobinamide is a stable vitamin B12 (hydroxocobalamin) analog that is far more potent than cobalamin as a cyanide antidote. It can therefore be administered by intramuscular injection and could be given via an autoinjector. It also is an effective antidote against hydrogen sulfide and several other toxic chemicals, making it a potentially very useful drug. We have shown that intramuscularly injected cobinamide is highly effective in mouse, rabbit, and pig models of cyanide poisoning, rescuing >80% of animals from lethal doses of cyanide. Sodium tetrathionate, like sodium thiosulfate, is a sulfur donor that neutralizes cyanide by converting it to thiocyanate. Compared with thiosulfate, which neutralizes a stoichiometric amount of cyanide, tetrathionate neutralizes two moles of cyanide, thus reducing the amount needed to treat cyanide poisoning. Like cobinamide, intramuscular sodium tetrathionate rescues >80% of animals in the aforementioned mouse, rabbit, and pig models of cyanide poisoning. Sodium nitrite and sodium thiosulfate are currently approved for treatment of cyanide poisoning via intravenous injection. We have shown that sufficient amounts of the two drugs can be given by intramuscular injection to rescue animals in the mouse, rabbit, and pig models of cyanide poisoning.

1760 DTMS: A New Nonintravenous Candidate Cyanide Medical Countermeasure

G. Rockwood. *US Army Medical Research Institute of Chemical Defense, Edgewood, MD.* Sponsor: D. Jett

In industrialized countries, cyanide exposure most commonly occurs through inhalation of combustion smoke, but dangerous exposure also can occur through ingestion, dermal contact, and/or gaseous fume inhalation. While the current US FDA-approved cyanide countermeasures Cyanokit (hydroxocobalamin) and Nithiodote (sodium nitrite and sodium thiosulfate) are demonstrably efficacious against cyanide poisoning, both require intravenous (IV) administration and are consequently unsuitable for use in treating multiple cyanide victims, particularly at or near exposure sites a distance away from a hospital. In fact, hospital resources may be strained by an emergency need for multiple IV line preparation and implementation. Dimethyl trisulfide (DMTS) is a sulfur-based molecule present in garlic and onions and is currently listed by the US FDA as GRAS (Generally Recognized as Safe) for use as a flavor additive. DMTS, as an intramuscular (IM) anti-cyanide sulfur donor, is safe and efficacious in rodent models of cyanide injection, ingestion, and inhalation. In lethal rabbit and swine models of cyanide poisoning, DMTS significantly enhances survival. Recent improvements in DMTS formulation have yielded rodent pharmacokinetic results showing peak blood levels in as little as two to 10 minutes, and peak brain levels in 10 minutes, both post-IM injection. The potential role of DMTS as a viable cyanide medical countermeasure candidate will be discussed in the context of next-generation countermeasures that are practical, efficacious, safe, easy to administer, and cost-effective.

1761 Scaling Up: Phenotypic Screens and Testing of Novel Cyanide Countermeasures

C. Macrae[1], and R. Peterson[2]. [1]*Harvard University, Boston, MA; and* [2]*University of Utah, Salt Lake City, UT.* Sponsor: D. Jett

Several cyanide countermeasures already exist and are in clinical use, but their utility is limited by challenges related to mechanism of action and mode of delivery. Novel countermeasures remain a high priority, but validated targets are few. We have used a phenotype-driven screening approach to discover new compound classes that can counteract the effects of cyanide. Foremost among these are the multivalent cyanide scavenger hexachloroplatinate (HCP) and the metabolic modulator glyoxylate. A formulation of HCP has been developed that reduces its toxicity while enhancing its scavenging of cyanide. This HCP formulation has been shown to be efficacious in zebrafish, mouse, rabbit, and pig models of cyanide toxicity. Glyoxylate also has been proven efficacious as a cyanide countermeasure in zebrafish, mice, and rabbits. It exhibits low toxicity and a broad therapeutic window. Mechanistic studies have demonstrated that cyanohydrin formation represents only part of glyoxylate's rescue mechanism and that enzymatic transformation by lactate dehydrogenase is essential for glyoxylate's function. Importantly, both HCP and glyoxylate can be delivered by intramuscular injection. These discoveries pave the way for development of cyanide countermeasures that are fundamentally different from existing countermeasures and have the potential to transform our ability to respond to cyanide exposures.

1762 New Cobalt Complexes and NO Donors

J. Peterson. *University of Pittsburgh, Pittsburgh, PA.* Sponsor: D. Jett

While several cobalt complexes have been shown to exhibit cyanide-scavenging properties, only (hydroxo)cobalamin has, so far, been US FDA labeled for use in ameliorating the harmful effects of cyanide toxicity in patients without causing life-threatening side effects. Despite its apparent safety and clinical success, cobalamin is expensive and requires the slow (~15-minute) intravenous administration of large volumes. Finding less expensive and more rapidly effective cyanide antidotes would clearly be beneficial. Recently, we have shown a cobalt complex of the Schiff-base macrocycle 2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1] heptadeca-1(17)2,11,13,15-pentaene (CoN4[11.3.1]) to be a viable option as a cyanide antidote. CoN4[11.3.1] is a low molecular weight compound that binds two cyanide anions (cobalamin binds only one cyanide under physiological conditions) and is synthesized in a single step with affordable starting materials. The reaction kinetics of cyanide association and the stability of the dicyano adduct are demonstrated to be suitable for sequestering cyanide *in vivo* and elimination of the toxicant in the urine. In a sublethal mouse model, CoN4[11.3.1] is shown to be more effective at ameliorating cyanide toxicity when compared with cobalamin, its precursor cobinamide, or a cobalt-containing porphyrin. Significantly, no long-term neuromuscular sequelae are evident in these mice more than a week later as assessed by the ability of the animals to remain on a rotating cylinder (RotaRod testing). Due to its relatively low molecular mass (~four times smaller than cobalamin), CoN4[11.3.1] can be expected to exhibit greater molar solubility than other larger cobalt-containing cyanide antidotes, leading to enhanced ameliorative capability of CoN4[11.3.1] through faster delivery of effective doses. Ongoing work is investigating the use of CoN4[11.3.1] in combination with a nitric oxide (NO) donor to reactivate cytochrome c oxidase, with further improved antidotal capability anticipated.

1763 Electronic Cigarettes and Cardiovascular Toxicity: New Friend or Old Foe?

M. Olfert. *West Virginia University School of Medicine, Morgantown, WV.*

Popularity of and interest in electronic cigarettes (e-cigs) have grown rapidly and in large part due to marketing e-cigs as "harm-free" or "reduced-harm" products compared with cigarettes. These claims are based largely on observations that e-cigs have fewer toxicants than cigarettes and some evidence the e-cigs induce lower lung inflammatory responses compared with traditional cigarettes. Such a narrowly defined perspective toward health fails to consider that use of e-cigs (also known as vaping) is likely to have effects on other organ systems, too. For example, the cardiovascular system is well known to have significant comorbidities associated with inhalation of xenobiotic particulate matter (e.g., air pollution, smoking). Given that e-cigs have only been around for little more than a decade, robust studies evaluating and reporting the effects of vaping on cardiovascular function are only now beginning to emerge. Despite the current marketing dogma, the emerging evidence paints a bleak picture toward the overall benefits versus risk from e-cigs and opens many intriguing questions, such as (1) What component(s) in, or produced from, the e-liquid may be responsible for inducing cardiopulmonary and vascular dysfunction? (2) Does secondhand exposure induce the same health concerns? (3) Does the type of device (JUUL versus other devices), and/or temperature settings (wattage), change its harm potential? and (4) Are the long-term effects on vascular function the same across different vascular beds? This Symposium brings together a group of established investigators that have specific expertise with vaping and aerosol research who have begun to address these questions. Specifically the presentations will bring together data from *in vitro* cell and *in vivo* animal studies—that provide harbinger toward long-term cardiovascular health in humans—as well as direct studies on humans examining health and cardiovascular function. Collectively the talks are designed to provide the audience a broad, but in depth, journey on current knowledge and potential mechanisms underpinning cardiovascular toxicity from vaping. We anticipate that this Symposium can provide a framework for stimulating both public and scientific discussion on the relative benefits versus harm conferred by inhalation of novel tobacco products to overall health. Given the current interest and need for establishing public policy and regulation toward novel tobacco products, and particularly e-cigs, the speakers will be asked to discuss relevant available data regarding the potential positive and negative outcomes being observed that may complement or assist regulatory evaluations. The panel discussion also will specifically ask the speakers (and invite the audience) to participate in a discussion on the potential of the findings presented during the Symposium toward issues for regulatory concern.

1764 Electronic Cigarettes: Vapors' and Flavors' Effects on Cells

P. Talbot. *University of California Riverside, Riverside, CA.*

Human embryonic stem cells (hESC), mouse neural stem cells (mNSC), and respiratory epithelial cells are used as model systems to investigate how new tobacco products affect human health and determine the effects of environmental toxicants on early mammalian development. Our recent work has focused on electronic cigarettes and thirdhand smoke. Electronic cigarettes deliver nicotine without burning tobacco and are often thought to be less harmful than conventional cigarettes, although relatively little is known about their actual effects on human health. Our studies focus on the flavor chemicals used in electronic cigarettes and metals that appear in aerosols produced upon heating. Flavor chemicals are often present in e-liquids at high concentrations that exceed those normally used in consumer products, and metals enter aerosols from both the liquid and components in the atomizing units. Upon heating, flavor chemicals and solvents (propylene glycol and glycerin) can produce reaction products that may themselves be harmful. *In vitro* studies with 2D and 3D cultured cells have shown that e-liquids and aerosols vary in their cytotoxicity, that many electronic cigarette products contain concentrations of flavor chemicals that are cytotoxic in cell-based assays, and that there is significant variability in toxicity across the broad spectrum of electronic cigarette products currently available. The components in electronic cigarette aerosols that may impact the cardiovascular system and their possible effects will be discussed.

1765 Adverse Cardiovascular Effects of Aerosols from Leaf Vaporizers and E-cigarettes

M. Springer. *University of California San Francisco, San Francisco, CA.* Sponsor: M. Olfert

It is well known that exposure to tobacco smoke and other sources of particulate air pollution lead to adverse cardiovascular consequences, including endothelial dysfunction. We have shown that both mainstream and secondhand smoke from marijuana also impair endothelial function in rats. Based on this knowledge, a variety of ostensibly reduced-harm devices have become increasingly popular. Tobacco "heat-not-burn" products and marijuana leaf vaporizers, which heat plant material to subcombustion temperatures, are thought of as less harmful than their combustible counterparts. Liquid-based e-cigarettes that deliver nicotine or THC, including JUUL, are also considered to be reduced-harm products. While presumably less harmful than smoke, the aerosols produced by these products are increasingly recognized as harmful to cardiovascular, pulmonary, and other physiological systems. We showed that endothelial function measured by arterial flow-mediated dilation (a reflection of nitric oxide [NO]-dependent endothelial function) is rapidly impaired in rats by secondhand smoke from cigarettes, little cigars, and marijuana, and by mainstream smoke/aerosols from tobacco and marijuana, heat-not-burn tobacco products (IQOS), marijuana leaf vaporizers, and liquid-based e-cigarettes, including JUUL. Neither nicotine nor THC is required for this impairment. Exposure of cultured endothelial cells to serum from chronic e-cigarette users results in lowered production of NO, as has previously been reported for serum from cigarette smokers, reflecting a common mechanism of endothelial dysfunction on the cellular level. These

results are particularly important with regard to marijuana smoke and leaf- and liquid-based vaporizers because these are all viewed by some as being less harmful than tobacco smoke. Findings such as these can play an important role in informing the US FDA policies toward regulating these products. Similarly, as marijuana is being legalized in progressively more US states and other countries, awareness that it is not just a drug but another source of secondhand smoke is important for the public and political debates over how to regulate public use. Our findings, in agreement with results from other research groups using different approaches, indicate at this point that the best way to avoid adverse cardiovascular effects of inhalation is to breathe clean air.

1766 Cardiovascular Toxicity of Electronic Cigarettes: Role of Aldehydes

D. J. Conklin. *University of Louisville, Louisville, KY.*

Electronic cigarettes have emerged as a popular electronic nicotine delivery system (ENDS). Carbonyls including short-chain, toxic aldehydes have been detected in e-cig-derived aerosols at levels found in tobacco smoke. Similarly, the cardiovascular toxicity of acute and chronic ENDS exposures in humans is understudied, but recent results are providing warning signs regarding sensitivity of the cardiovascular system to ENDS. To address this gap in our knowledge, we assessed the relationship between aldehyde exposure and cardiovascular outcomes including acute hemodynamic changes and chronic changes in atherosclerosis lesion burden in mice. AIdehydes were generated in aerosols derived from tobacco products, from propylene glycol (PG):vegetable glycerin (VG) mixtures and from commercial e-liquids with flavorants as measured using a state-of-the-art carbonyl trap and mass spectrometry. We tracked mainstream cigarette smoke (MCS) and e-cigarette aerosol exposures in mice via urinary metabolites of aldehydes using ULPC-MS/MS and GC-MS as needed. Aldehyde levels, independent of abundance (saturated: formaldehyde, acetaldehyde >> unsaturated: acrolein, crotonaldehyde), were dependent on the PG:VG ratio and the presence of flavorants. Similarly, the metabolites of three aldehydes were increased in urine after both e-cigarette aerosol and MCS exposures, but the major crotonaldehyde metabolite (3-hydroxy-1-methylpropylmercapturic acid, HPMA) was increased only after MCS exposure. Exposure to menthol-flavored e-cigarette aerosol increased both levels of urinary 3-HPMA and the sum of nicotine exposure (nicotine,cotinine,trans-3′-hydroxycotinine) relative to exposure to tobacco e-cig. Acute exposure to e-cig aerosol (with or without nicotine) led to rapid onset and reversal of bradycardia with proarrhythmic changes in the ECG. Several of these changes were phenocopied with acrolein exposure, suggesting a role of aldehydes in these changes. Chronic exposures of apoE-null mice to MCS, e-cig with nicotine, acrolein, or crotonaldehyde for 12 weeks led to significantly increased atherosclerosis in all groups when compared with filtered air control group. These results demonstrate that long-term use of tobacco products containing nicotine and/or aldehydes induce cardiovascular harm in mice and, thus, growing concern for cardiovascular disease risk in humans who use ENDS.

1767 Toxicological Effects of Vaping on Central and Peripheral Vascular Function: Insights from Intravital and *In Vivo* Studies in Animals

M. Olfert. *West Virginia University School of Medicine, Morgantown, WV.*

Novel tobacco products, such as electronic cigarettes (e-cigs) and heat-not-burn (HNB) tobacco devices, are being marketed as harm-reduction or reduced-risk smoking products. In fact, very little is known about the safety and potential for harm of these devices to overall health and in particular on vascular health. Using murine and rodent exposure paradigms, we have tested the hypothesis that e-cigs and HNB products will show evidence of reduced cardiovascular toxicity. This presentation will provide evidence from acute exposures on peripheral vascular function obtained using intravital microscopy with exposure to e-cigs and HNB. We also examine the effects resulting from individual components of the e-liquid (i.e., nicotine, VG alone, PG alone). The effects of chronic exposure (i.e., 8-month) on *in vivo* assessments of cardiac function and aortic vessel reactivity are presented, in combination with *ex vivo* myography studies on central vessel (aorta) reactivity responses. Lastly, this presentation will show emerging data on central and peripheral vasculature function in offspring of rats that have been maternally exposed (during pregnancy) to e-cig vapor with or without nicotine. This presentation will contain data from both published and unpublished studies, with the expectation that it can help to lay a foundation for understanding the mechanisms underpinning the cardiovascular toxicity associated with the evolution of these novel tobacco products.

1768 Electronic Cigarettes versus Nicotine Replacement Therapies: Cardiovascular Implications

C. Delles. *University of Glasgow, Glasgow, United Kingdom.* Sponsor: M. Olfert

E-cigarettes have overtaken nicotine replacement therapies to become the preferred nicotine replacement product to support quit attempts. Despite the potential harm reduction associated with e-cigarettes, their role as a smoking cessation aide remains controversial and has raised global debate. Research into the cardiovascular and other adverse effects of e-cigarettes is challenging for a number of reasons. First, there is a paucity of well-designed human physiology studies into biomarkers and intermediate cardiovascular phenotypes, and robust long-term outcome data are not (yet) available to truly estimate the risk of e-cigarettes at the population level. Second, although preclinical studies can be useful, the choice of model depends on the expected adverse effects, and no model is able to truly reflect all aspects of human cardiovascular pathophysiology. Third, while e-liquids only contain a limited number of apparently safe ingredients, the process of heating and vaporizing produces hundreds or thousands of intermediate compounds with unknown safety profile. To complicate matters, the effects of nicotine (e.g., on the renin-angiotensin-aldosterone and sympathetic nervous systems) have to be separated from effects of other components of the inhaled product. Fourth, the technology advances quickly whereas research and legislation lag behind, making it difficult to compare studies or draw conclusions from data on "old" technology to "new" technology. These challenges translate into uncertainty among health care professionals regarding the risks and benefits of e-cigarettes, although there are good reasons to believe that e-cigarettes have a more favorable risk profile than tobacco cigarettes. This presentation also will highlight examples of research into the cardiovascular effects of e-cigarettes from a clinician's perspective, focusing on (1) the association between e-cigarettes and global cardiovascular risk, (2) immediate and intermediate effects of e-cigarettes on vascular function and structure, and (3) cardiac effects of e-cigarettes, including risk of myocardial infarction. Regulatory constraints surrounding research into smoking in smoke-free clinical research environments will be discussed.

1769 Environmental Exposure and Health Effects of Organophosphate Esters

D. Volz. *University of California Riverside, Riverside, CA.*

Organophosphate esters (OPEs) are high-production volume chemicals used worldwide within a number of products, including but not limited to electrical and electronic equipment, furniture, building materials, and vehicle parts. OPEs are additive flame retardants (FRs) and plasticizers that have the potential to migrate from end-use products into the ambient environment. As such, OPEs are ubiquitous in the environment and elevated within various sources of human exposure. As the extent and magnitude of exposure are likely associated with human population densities, this has raised concerns about the potential health risk to humans and the environment within densely populated regions around the world. However, OPE-specific toxicity data and epidemiological studies are relatively limited, although numerous studies have demonstrated that chronic human exposure is common within countries relying on OPE-containing materials. Therefore, the objective of this timely and globally relevant Symposium is to bring together several leading investigators that are actively conducting research on OPE exposure and effects within a range of environmental media and model systems. After a brief introduction of the Symposium and each of the speakers, the first speaker will provide an overview of OPE-specific uses, market trends, and regulatory challenges; the second and third speakers will focus on OPE exposure within the natural and built environment; and the last two speakers will focus on OPE effects on early and later life stages of vertebrate development.

1770 OPE-Specific Uses, Market Trends, and Regulatory Challenges

J. Tenney. *Israeli Chemicals LTD Industrial Products Group, Tarrytown, NY.* Sponsor: D. Volz

OPEs are an important class of FRs. The market growth for these chemistries is estimated to be around 5% annually. A major driver of this demand is fire safety standards in electronics, building and construction, and transportation applications. Market demand also is stimulated by continued interest in alternatives to brominated or chlorinated FRs. This presentation will review FR market trends, OPE functionality as an FR choice, major OPE uses/innovation, and regulatory challenges impacting FR selections.

1771 OPEs in the Biotic Exposome and the Influence of Environmental Processes on Fate and Biological Effects

R. J. Letcher. *Environment and Climate Change Canada, Ottawa, ON, Canada.*

OPEs have a variety of uses, including as FRs, plasticizers, pesticides, and additives to engine oils. Halogenated OPEs have been used as FRs as far back as the 1960s, and the phase-out of the polybrominated diphenyl ether (PBDE) FRs resulted in the substantial increase in the last 15 years in the production volumes and usage of an increasing array of OPEs. OPEs have a wide range of physical and chemical properties, ranging from very polar to very hydrophobic. Long-range transport of some OPEs has been shown based on concentrations reported in air (particle) samples. Atmospheric OPEs can be found at concentrations that are orders of magnitude higher than those of FRs such as PBDEs. Relative to abiotic environments, there is a growing body of evidence reporting much lower and mainly nondetectable OPE concentrations in biota. Degradation and transformation processes (including metabolism) and protein binding are proving to be major factors affecting OPE behavior in the environment and biological effects *in vitro* and *in vivo* in exposed organisms. This presentation will examine the current knowledge of OPE environmental and physiological behaviors in biota and biological effect outcomes, and the influence of chemical properties and degradation processes, which are relevant in comparisons with humans.

1772 Human Exposure to OPEs: Exposure Pathways, Predictors, and Health Concerns

H. M. Stapleton. *Duke University, Durham, NC.*

OPEs are commonly used in building materials and consumer products as FRs and plasticizers. The application of these chemical additives in textiles and polymers in particular has grown considerably over the last two decades, particularly following the phase-out of brominated FRs, and raising concerns about exposure among the general population and risk for adverse health outcomes. Our research group has conducted several studies among various populations (pregnant women, children, and adults) to characterize exposure among the general public and evaluate variables influencing exposure. This presentation will highlight our findings on exposure levels, demographic variables related to exposure, and associations with health outcomes. Specifically, we will discuss (1) the various OPEs identified in building materials (e.g., insulation) and consumer products (e.g., furniture, electronics); (2) measurement of exposure biomarkers in the general population, highlighting the higher concentrations observed in infants relative with adults, and in pregnant women compared with nonpregnant women; (3) the influence of age, BMI, and parity on exposure measurements; and (4) associations between exposure to OPEs during pregnancy and birth outcomes. This research is critical to conducting thorough and sound risk assessments for human health.

1773 Leveraging Zebrafish to Unravel Mechanisms of OPE-Induced Developmental Toxicity

D. C. Volz. *University of California Riverside, Riverside, CA.*

A better understanding of the potential effects of prenatal exposure of OPEs is needed. Based on our research over the last decade, this talk will highlight how our studies within zebrafish have enabled us to begin uncovering the mechanism of developmental toxicity for two high-production volume OPEs—tris(1,3-dichloro-2-propyl) phosphate (TDCIPP, a chlorinated phosphate ester) and triphenyl phosphate (TPHP, an unsubstituted aryl phosphate ester)—that exhibit unique modes of action during embryogenesis. Specifically, our more recent data show that (1) TDCIPP exposure at the beginning of cleavage (0.75 hours post-fertilization, hpf) results in delayed epiboly progression and disruption of dorsoventral patterning, phenotypes that may be due to alterations in epigenetic reprogramming within the first few hours of development; and (2) TPHP exposure from 5-72 hpf interferes with cardiac looping and heart chamber development, a phenotype that may be due to direct or indirect disruption of retinoic acid signaling pathways during organogenesis. Overall, our findings and ongoing studies within zebrafish (1) provide a foundation for understanding the impacts of TDCIPP and TPHP exposure on embryonic development, and (2) help formulate mechanistic-based hypotheses for studies within human cell-based models and prenatal developmental toxicity studies within mammalian models.

1774 Sex Differences in the Placental Accumulation and Activity of OPEs: A Novel Route of Neurodevelopmental Toxicity

H. B. Patisaul. *North Carolina State University, Raleigh, NC.*

The placenta is a critical source of hormones and neurotransmitters for the developing brain, particularly in early embryonic and fetal development. Thus, it may be an underappreciated but important target to consider in the context of developmental neurotoxicity. The commercial mixture Firemaster 550 contains two brominated compounds, bis (2-ethylhexyl)-2,3,4,5-tetrabromophthalate (TBPH, also known as BEH-TEBP) and 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (TBB, also known as EH-TBB), and two OPEs including triphenyl phosphate (TPHP, also known as TPP) and a mixture of isopropylated triarylphosphate isomers (ITPs). Prior work by us and others has shown that gestational exposure can produce sex-specific effects on anxiety and exploratory-related behaviors. However, the mechanism of action remains unclear. Using Wistar rats, we showed that TBB, TBPH, and TPHP dose-dependently accumulate in placenta, with higher levels of TBPH and TPHP in male-associated placentas. Using a mixture of hypothesis generating (RNA sequencing and untargeted metabolomics) and targeted (qRT-PCR and targeted neurotransmitter analysis) approaches to examine fetal Wistar rat brain and placenta, we found that FM 550 likely impacts neurodevelopment by multiple mechanisms, including disruption of neurotransmitter, endocrine, and inflammatory pathways. Ongoing work with an OPE mixture is continuing to reveal how toxicity at the level of the placenta can alter neurodevelopment.

1775 Quantitative and Translational Systems Toxicology: Improving Drug Safety from Preclinical to Clinical Outcomes

J. Stevens. *Universiteit Leiden, Leiden, Netherlands.*

Before market approval, all new medicines require extensive preclinical and clinical safety testing. Molecules deemed safe in preclinical studies are generally safe during clinical trials, yet safety signals and adverse events do occur in human subjects. Catastrophic outcomes, although rare, do occur, and recent high-profile failures illustrate the potential for significant morbidity and mortality. Thus, predicting when preclinical results indicate increased clinical risk remains challenging and highlights the need for more quantitative and translational safety approaches. Systems approaches can be useful in estimating when biological response in one species is preserved in another. Various modeling approaches, including modular and network models, have been used to determine conservation of biology across scales of evolution. These systems models provide opportunities to place safety prediction on a more quantitative basis, especially if they are combined with PBPK models to link exposure to pathogenesis in a multi-scale quantitative systems toxicology (QST) framework. Multi-scale QST models incorporate data across vast scales of complexity, from cells to intact organisms, and may include data from the genome to the proteome and metabolome. For example, transcriptomic data can inform global metabolic models and provide measures of cellular stress response that are linked to metabolism and disposition of a novel drug candidate within an adverse outcome pathway that spans molecular responses to pathogenesis *in vivo*. Presentations in this Symposium will tackle various aspects of QST modeling. The session opens by addressing challenges in merging systems models with traditional PBPK models into complex multi-scale and multi-dimensional QST models. After this introduction, the presenters will focus on case studies illustrating the potential to improve translation of nonclinical to clinical safety for common organ targets, including liver, kidney, gut, and heart. The speakers will summarize progress in the field, illustrate new concepts that are nearing application, and highlight the opportunities and challenges in achieving more quantitative estimates of human safety.

1776 Challenges and Opportunities for Multi-Scale and Multi-Dimensional Models

C. Fisher. *Certara UK Limited, Sheffield, United Kingdom.*

Fundamental to any QST model is an understanding of the linkages between exposure and critical biological response parameters underlying safety and pharmacology. Physiologically based pharmacokinetic (PBPK) models integrate population-specific data (systems parameters) and compound-specific parameters to predict the absorption, distribution, metabolism, and elimination of compounds in the body, and subsequently enable the translation of these processes across populations and preclinical species. Such models represent a branch of quantitative systems pharmacology (QSP) and can act as a hub for the integration of models encompassing biological resolution ranging from the physiology to tissue and transcript levels. PBPK simulation of tissue/tissue substructure exposure profiles can provide the operating con-

centrations for tissue/cellular-level QSP models capturing mechanisms underlying cellular division, differentiation, death, repair, and core metabolism. These models can be further informed based on data from 'omics datasets (e.g., transcriptomics, proteomics, and metabolomics), and integrated models can range from the qualitative to the quantitative in their encoding and output. The ultimate aim is a multi-scale modeling framework spanning levels of biological organization and mechanistic resolution integrating multiple data sources. This will enable an iterative workflow of hypothesis formulation, model-based prediction, testing, and model refinement operating in parallel to, and simultaneously informing, the discovery and development pipeline, from target identification through to market. Using experiences and expertise from the IMI-TransQST project consortium, this talk will introduce the potential of such an approach and summarize the current state of the art and remaining challenges ahead.

1777 Modeling Stress Responses across Scales of Complexity: From High Content Imaging in Cells to Modeling Co-expression Networks

B. van de Water. *Universiteit Leiden, Leiden, Netherlands.*

Drug safety testing often begins in cell-based models before progressing to clinical and nonclinical studies. Drug-induced liver injury (DILI) and drug-induced kidney injury (DIKI), subsequent to cellular injury, remain an important concern in drug development and an area of high need for QST modeling and translational safety. Cellular stress response pathways are critical for adaptation to cell injury and can signal progression to adverse cellular and tissue outcomes. This presentation focuses on modeling drug-induced cellular stress response pathways across different scales of complexity. First, high content single live cell confocal imaging of GFP-tagged protein captures the dynamics of stress-responsive transcription factors (e.g., Nrf2, Xbp1, p53, and NF-kB) and corresponding downstream target proteins, allowing detailed quantification of cellular stress-responsive and inflammatory pathways after drug treatments. The detailed temporal- and concentration-dependent dynamics of stress pathways are used to develop computational models of the stress responses linking drug treatment to liver and kidney toxicity. Secondly, *in vitro* stress responses are linked to *in vivo* stress response pathways by building gene co-expression networks for both liver and kidney. Activation levels of the various stress gene networks by the cellular stress-responsive transcription factors noted here are assessed systematically and quantitatively for both DILI and DIKI compounds. We have further assessed the association of the various cellular stress-response network perturbations with adverse pathological outcomes in liver and kidney. Ultimately, mapping cellular stress-response network activation and the preservation of networks across species will enable quantitative translational risk assessment as new drugs enter clinical trials.

1778 Modeling Cardiovascular Safety Using a Quantitative Systems Pharmacology Approach

D. Leishman. *Lilly Research Laboratories, Indianapolis, IN.*

Cardiac function and frank injury to the myocardium itself are among the primary causes of attrition in both clinical and nonclinical studies. Computational models of cardiac electrophysiology and hemodynamics have been around since the '60s and '70s, respectively. This presentation will describe the use of these mature models and their further refinement to address critical questions relevant to changes in cardiac function during drug development. The presentation also will illustrate how these can be combined with PBPK models to move beyond pharmacological properties and in to patient-dependent intrinsic and extrinsic factors. The format of the presentation will follow an introductory overview of the models with case study vignettes addressing key questions drug development teams face. The case studies will involve examples related to cardiac electrophysiology, cardiac contractility, blood pressure, and heart rate. The talk will illustrate how the use of PBPK and functional models are integrated in asking the questions, Will my molecule delay cardiac repolarization (QTc)? and Will my molecule be proarrhythmic? In addition, examples will demonstrate how hemodynamic modeling can be used to address the question, What is the mechanism for the blood pressure change I observe with my molecule? Finally, the talk will illustrate a modeling approach to addressing whether or not a compound will be associated with cardiac hypertrophy. Overall examples will address cardiac electrophysiology, cardiovascular function, and structural toxicity.

1779 Multi-Scale Modeling Approaches to Describe Drug-Induced Gut Toxicity

C. Pin. *AstraZeneca, Cambridge, United Kingdom.* Sponsor: J. Stevens

The gut not only is a primary route of drug absorption but also is a well-known target for anti-proliferative compounds and can be dose limiting in clinical studies if the relationship between exposure and disruption of gut homeostasis is poorly understood. The dynamic nature of gut biology, including rapid cell turnover and unique immune functions, makes it a complex tissue with unique challenges. Multi-scale models enable the prediction of toxicity and recovery at multiple spatial and temporal scales. They are instrumental to quantify how target organs respond to toxicological challenges as a whole and at each structural level. This presentation will discuss modeling approaches able to describe the propagation of drug toxicity across scales in the gastrointestinal (GI) epithelium and how these approaches may enable quantitative predictions of GI clinical adverse effects based on the compound mechanism of action. As an example, data and models generated within the TransQST project wil be introduced to demonstrate how multiscale quantitative approaches can integrate the spatiotemporal cell dynamics of the GI epithelium with the dynamics of relevant proteins that regulate the cell cycle. The use of a computational model to simulate the impact of transcriptional changes, driven by clinically relevant PBPK models of cytotoxic drugs, on the cell cycle and the subsequent cascade of events spanning from single cell stress and/or apoptosis to the perturbation of cell migration across the crypt-villus axis with altered cell turnover and ultimately loss of epithelial integrity will be demonstrated. In summary, the application of QST multi-scale models to connect the molecular level with the clinic and predict emergent properties with impact on the discovery of new pharmacological properties and prevention of on-target GI toxicity will be demonstrated.

1780 Human-Relevant Carcinogenicity Testing: Tools for Cancer Assessment in 2020 and Beyond

N. Kleinstreuer. *NIEHS/NICEATM, Research Triangle Park, NC.*

For decades, risk assessors have relied on the rodent cancer bioassay to collect apical endpoints that are used to identify potential human carcinogens. The rat and mouse bioassays are currently required by most regulatory authorities for carcinogenicity assessment of industrial and agro-chemicals, food additives, pharmaceuticals, and environmental pollutants. However, five decades of cancer research have raised concerns about the utility of the rodent cancer bioassays to accurately identify potential human carcinogens. Timely discussions have reached a tipping point due to known limitations of the bioassay, including that it is expensive and time-consuming, uses hundreds of animals per test, and has questionable human relevance. As a result, experts are working to develop novel, human-relevant tools and approaches to assess potential carcinogenic effects. Steps are now being taken to modernize carcinogenicity testing through the use of mechanistic approaches that reduce testing on animals and may provide more human health-protective information. In this session, cross-sector experts will deliver presentations and participate in a panel discussion, providing insight into current challenges and opportunities in designing human-relevant chemical carcinogenicity assessment strategies. A representative from the National Toxicology Program will discuss their ongoing Health Effects Innovation Initiative that is working toward modernizing their carcinogenicity testing program. An investigator from the US Environmental Protection Agency will give a presentation highlighting the use of gene expression endpoints in short-term animal tests to predict liver tumorigens. Methods developers will discuss *in silico* expert-driven systems to develop testable biological hypotheses, small model organisms providing mechanistic insights, and complex organotypic model tumor systems that *rec*Apitulate human cancer. These presentations from a diverse panel of experts will provide a timely and thought-provoking discussion on the opportunities to modernize cancer assessment and will be of interest to a wide range of stakeholders, including regulators, cancer toxicologists, systems modelers, and industry scientists.

1781 Modernizing the NTP Carcinogenicity Testing Program

W. Casey. *NIEHS/NTP, Research Triangle Park, NC.*

Since the early 1980s, the US National Toxicology Program has served as a national and world resource for conducting the two-year rodent bioassay to assess the (human) carcinogenic potential of industrial and agricultural chemicals, food additives, environmental pollutants, and other exposures of public health concern. However, the acknowledged limitations of the rodent bioassay include high cost, extensive time to conduct and report, and limited

translational relevance. In building on its history of innovation, excellence, and impact, the National Toxicology Program is now leading the development of a new framework for assessing human cancer risk from environmental exposures. This talk will discuss the approaches being developed to better understand and interrogate the initiation/promotion and progression processes of human carcinogenesis as well as the etiology of a set of human cancers potentially associated with environmental exposures. The rationale for selecting these specific cancer targets and progress made on developing the associated adverse outcome pathways will be discussed. Other topics covered will include a description of ongoing efforts to develop a suite of *in vivo*, *in vitro*, and *in silico* approaches to screen and prioritize substances, utilization of longitudinal human cancer data, and opportunities for future engagement with stakeholders.

W 1782 Toward Patient-Specific Organotypic Models of Cancer

D. Beebe. *University of Wisconsin–Madison, Madison, WI.* Sponsor: N. Kleinstreuer

A critical piece of cancer assessment for chemical safety is the development of human-relevant models that can be used to more reliably predict human clinical outcomes and can in turn be applied to understanding environmental chemical contributions to carcinogenesis. Micro-scale organotypic tumor models hold promise because they use smaller numbers of cells, thus enabling the construction of patient-specific models from biopsy samples. In addition, the model can incorporate multiple cell types (e.g., cancer, stromal, and vascular) in more relevant context (e.g., ductal structures). We have developed organotypic tumor models across a range of patients in both breast and kidney cancer. These models exhibit more *in vivo*-like characteristics (e.g., reduced proliferation rates as compared with 2D culture) as well as increased sensitivity to xenobiotics. The development of these human organotypic tumor models will aid in mechanistic understanding of human cancer outcomes as well as provide enhanced testing approaches for the assessment of potential human carcinogens.

W 1783 Development of an Adverse Outcome Pathway Network to Support an Integrated Approach to Testing and Assessment of Carcinogenic Risk

S. Stalford. *Lhasa Limited, Leeds, United Kingdom.* Sponsor: N. Kleinstreuer

The prediction of human carcinogenicity and related toxicity endpoints has always been a principal area of concern during chemical safety assessments. Historically, the two-year rodent bioassay has been used as the ultimate method of assessing human carcinogenic risk. However, this type of assay is expensive and time-consuming and is not always accurate in extrapolating to humans. More recently, alternative methods have been developed to predict carcinogenic risk, including both *in vitro* and *in silico* techniques. However, while there is some guidance on how to integrate specific pieces of evidence in well-defined use cases, a unified approach to combination has yet to emerge, and new techniques are developed all the time. One approach to creating a framework in which this evidence could be combined in different ways would be to utilize the concept of adverse outcome pathways (AOPs). Using information already contained within Derek Nexus (DX), an expert rule-based SAR system with a well-developed knowledge base for carcinogenicity-related endpoints, and literature review, a carcinogenicity AOP network has been developed and expanded upon using evidence from the literature to create a network containing 27 molecular initiating events that link to the adverse outcome of carcinogenicity via more than 400 pathways. This network can be used in combination with Derek Nexus alerts as a rudimentary profiling tool for carcinogenicity mode of action prediction. Presenting more detailed information on potential pathways by making predictions in this way allows for integration of existing and emerging *in vitro* and *in vivo* test results at the protein level with predictions to support an overall conclusion on carcinogenic potential. This approach to knowledge presentation also allows for easier interpretation of the evidence available relating to a given prediction.

W 1784 Toward Replacing the Two-Year Bioassay with Short-Term Assays: Gene Expression Thresholds Can Predict Rat Liver Tumorigens

C. Corton. *US EPA, Research Triangle Park, NC.*

Traditional data sources for cancer hazard assessment are resource intensive, retrospective, and not feasible for the vast majority of environmental chemicals. Incorporation of quantitative genomic data from short-term rodent studies may adequately define protective thresholds for potential tumorigens as a bridge to move from current testing to greater reliance on *in vitro* assays. We hypothesized that gene expression biomarkers that measure the activation of the major molecular initiating events (MIEs) in rodent liver cancer adverse outcome pathways exhibit chemical-independent thresholds beyond which cancer occurs and the thresholds could be used to predict liver cancer. The hypothesis was tested by defining thresholds of gene expression biomarkers of liver cancer MIEs using training sets from the 77 and 86 chemicals in the TG-GATES and DrugMatrix datasets, respectively, and testing them in a number of contexts. The biomarkers tested, consisting of 7-113 genes, included those that predict genotoxicity, cytotoxicity, and activation of AhR, CAR, ER, or PPARa. Thresholds were calculated as the maximum values derived from exposures that do not lead to liver cancer. In all cases, clear threshold values could be identified that were consistent across training and test sets. Thresholds derived from the TG-GATES study were not very predictive of liver tumorigens in the DrugMatrix study (77%-81%). In contrast, thresholds derived from the DrugMatrix study were predictive in the TG-GATES study (84%-100%). The DrugMatrix-derived thresholds were most predictive when applied to test sets of 7d and 14d treatments (100% and 99%, respectively). In addition, thresholds derived from just 12 genes (two/biomarker) exhibited high predictive accuracy (up to 94%). These findings support the idea that early genomic changes can be used to establish threshold estimates or "molecular tipping points" that are predictive of later-life outcomes. *This abstract does not reflect US EPA policy.*

W 1785 Using Preclinical Models to Understand Metastasis

K. Tanner. *National Cancer Institute, Bethesda, MD.* Sponsor: N. Kleinstreuer

Much of our knowledge on tumor progression and metastasis has been obtained using murine models, where dissecting the role of the physical microenvironment in regulating organotropism remains technically challenging. The zebrafish is rapidly becoming a model for studying tumor behavior at different stages of the metastatic cascade.[1,2] Moreover, organs that are frequent sites of metastasis in human patients are well conserved between mammals and zebrafish. Our previous work has quantified tissue mechanics and architecture of diverse organs to assess direct comparisons between zebrafish and mammalian systems. We recently developed a zebrafish model of human tumor metastasis and human macrophage migration and demonstrated that it recapitulates patterns of metastasis of human tumors in mouse models. We discovered that human breast cancer cells that home to specific organs in mice also show nonrandom extravasation in an organ-specific manner within zebrafish. Specifically, cells that home to the murine brain also home to the zebrafish brain, whereas cells that home to the murine bone marrow also home to the embryonic bone marrow niche in larval fish. Extravasation was mediated by ß1 integrin, where knockdown of ß1 integrin reduced extravasation for both clones in the CVP but did not affect extravasation of brain-tropic clones in the brain. In contrast, silencing unconventional myosin 1b redirected brain tropic clones from the brain to the CVP. *References: 1. Follain, G., et al. "Hemodynamic Forces Tune the Arrest, Adhesion, and Extravasation of Circulating Tumor Cells."* Dev Cell *45, 33-52 e12, doi:10.1016/j.devcel.2018.02.015 (2018). 2. White, R., Rose, K., and Zon, L. W 1786 Using Human Genetics to Aid in Safety Assessment of Therapeutics

J. Yuan. *Amgen Inc., Cambridge, MA.*

Preclinical safety evaluation of pharmaceuticals relies mainly on studies in animal models. While the use of animals has made significant contributions to safety assessment, there remains uncertainty in the extrapolation of risk from animals to humans. This is particularly true for novel therapeutics that do not cross-react to animal orthologs and lack pharmacological activity in species used for toxicology studies. Therefore, development of human-centric approaches to predict drug safety in humans is essential. Research in human genetics has discovered hundreds of gene variants associated with complex and rare disease. Both studies of Mendelian syndromes and genome-wide associ-

ation studies (GWAS) have resulted in the discovery of new therapeutic targets and have provided therapeutic support for existing drugs. Retrospective analyses of clinical studies have demonstrated that drugs whose targets are validated by human genetics are more likely to reach approval. While the application of human genetics has been discussed primarily as a method to discover and validate the efficacy of novel targets, there is increasing appreciation for the use of genetic data to predict safety liabilities. Human genetic variants can represent a model for lifelong modulation of a therapeutic target and can be used to inform the potential for on-target toxicity as well as the effects of drug off-target interactions. In addition, human genetics may help to identify genetic risk factors contributing to rare adverse drug reactions. The overall objective of this Workshop is to showcase the use and potential of human genetics to inform safety signals of therapeutics. The session will cover the following topics: (1) an overview of human genetic association studies including GWAS and PheWAS, with the aim of providing a basic understanding of the methodologies and applications to the drug development process; (2) case examples that illustrate the applications of human genetics in target validation and to inform on- and off-target safety—the impact on drug safety evaluation and clinical utility will be discussed; (3) the utility of human genetics in identifying genetic risk factors contributing to adverse drug reactions from a large volume of health records as well as knowledge accumulated from drug development; and (4) discussion on the challenges of and future perspectives on translating human genetic information to predict drug effects in preclinical and clinical development. This session will be of interest to toxicologists engaged in preclinical and clinical safety evaluation during drug development and to human geneticists interested in preclinical applications and clinical translation.

W 1787 Genetics for Target Validation and Case Studies

D. Diogo. *Merck Research Laboratories, Boston, MA.* Sponsor: J. Yuan

Human genetics serves as an "experiment of nature" to help inform drug discovery. Naturally occurring mutations ("perturbation") may affect the function of a gene ("target") and lead to reproducible effects on clinically relevant phenotypes ("clinical indication" and/or "adverse drug event" [ADEs]). These genetic instruments thus mimic the effect of therapeutic modulation of the target and can help to predict dose-response curves at early stages of target validation. Human genetic data linking the target gene to the clinical indication (predicting drug efficacy) have been demonstrated to increase the success rate of drugs in clinical trials. Examples of approved or failed drugs also illustrate the potential of human genetics to retrospectively predict ADEs, both on-target and off-target. In this section, we will discuss how Mendelian genetics (disease-causing mutations implicated in Mendelian syndromes) and population genetics (rare-to-common genetic variants found in the general population and associated with disease predisposition) can be leveraged to predict efficacy and safety. We will introduce the concepts of genome-wide association study (GWAS), phenome-wide association study (PheWAS), and Mendelian Randomization, and will illustrate, through selected retrospective examples, how these methods can be applied to inform efficacy, identify potential alternative indication, and predict potential on-target or off-target ADEs. We also will discuss the potential of rapidly growing biobank initiatives, linking genome-wide genetic data with extensive health information in large cohorts of participants, to accelerate efficacy and safety predictions. We will conclude by discussing some challenges and limitations of human genetics to inform drug discovery and development.

W 1788 Using Genetics to Select Safer Targets and Drugs

P. Nioi. *Alnylam Pharmaceuticals, Cambridge, MA.* Sponsor: J. Yuan

In drug development, early-stage genetic validation often focuses more on efficacy than safety. Here, we present the results of systematic analyses that support two ways in which human genetics can be used, even preclinically, to improve safety: anticipating target-mediated side effects and prioritizing off-target screening of drug candidates. In a retrospective analysis, we found a correlation between the organ systems affected by genetic variation in drug targets and the organ systems in which side effects were observed during clinical trials. This result suggests that human genetic data can be used to help predict target-driven drug safety issues and should be integrated into safety assessments. A key consideration for drug safety is not only the biology of the intended target, but also the effects on secondary "off-targets." Based on an analysis of marketed drugs, we recommend that genetics be used to guide counter screening during drug development. We anticipate that integrating genetics into on- and off-target safety assessment will help to reduce safety-related drug failures.

W 1789 Observational Data for Pharmacogenomics Discovery

N. P. Tatonetti. *Columbia University, New York, NY.* Sponsor: J. Yuan

Observation is the starting point of discovery. Based on observations, scientists form hypotheses that are then tested. In the information, trillions of observations are being made and recorded every day—from online social interactions to the emergency room visit. With so much data available, generating hypotheses using a single scientist's mind is no longer sufficient. Data mining is about training algorithms to recognize patterns in enormous sets of data and automatically identify new hypotheses. This presentation will discuss how we use data mining algorithms to characterize drug response in ancestrally diverse patient populations (NYC EHR data) and use large repositories of genetic data (both local and the UK Biobank) to identify genetic risk factors of adverse drug reactions. The presentation will demonstrate that statistical machine learning can produce patient phenotypes even when primary diagnosis data are unavailable. This allows us to use noisy databases, like the electronic health records, for genetics and pharmacogenomics studies.

W 1790 The Role of Genetics and Genomics in Predicting Drug-Induced Liver Injury

W. Tong. *US FDA/NCTR, Jefferson, AR.*

Drug-induced liver injury (DILI) is a serious safety concern, with >1,000 drugs being reported to possess the potential to cause liver injury. However, most DILI occurs at low frequency (idiosyncratic) and some are genetically driven. Despite the vigorous and extensive safety testing during the drug development process, DILI remains an enigma. We have been developing the Liver Toxicity Knowledge Base (LTKB) for an enhanced assessment of DILI with emerging methodologies, including genomics and genetic methodologies. In addition to drugs' innate properties, mechanistically relevant cellular endpoints from *in vitro* assays, and histopathology findings, LTKB utilizes the pharmacogenomics information and patients' phenotypic responses to drug treatment to understand the underlying genetic mechanisms for DILI. The goal of LTKB is to develop a content-rich resource to improve understanding of liver toxicity and ultimately for the US Food and Drug Administration to utilize and reference when liver toxicity issues arise during various stages of the regulatory review process. This presentation will provide an overview of the LTKB, with a specific emphasis on applications of the genetic and genomic data to assess and predict DILI.

W 1791 Integrating Genetic Evidence into Drug Safety Research: From Target Discovery through Pharmacovigilance

M. Nelson. *Deerfield, New York, NY.* Sponsor: J. Yuan

Our session presenters will share the latest advances in our understanding of the capabilities and limitations to use genetic insights to reduce risks of developing new therapies that have safety hazards through understanding who is at increased risk of experiencing adverse events and using genetic information to reduce them. In this synopsis, we will summarize the state-of-the-science to reaffirm the opportunities to impact drug discovery, development, and post-marketing pharmacovigilance, as well as to highlight the gaps in understanding and practice for these insights to benefit patients.

PL 1792 Does Variability in Ontogenetic Maturation Trajectories Explain the Variability in Drug Pharmacokinetics for Preterm and Term Birth Neonates?

J. Fisher[1], D. Mehta[1], and J. Troutman[2]. [1]*US FDA/NCTR, Jefferson, AR; and* [2]*Procter & Gamble, Mason, OH.*

In 2016 the FDA reported a lack of PBPK model performance in describing the pharmacokinetics of drugs in pediatrics. A deep-dive into model parameter assumptions for a neonate PBPK model was accomplished, which included creating longitudinally based growth curves and data-derived estimates for model parameter variability. A preterm and term neonate model was constructed to predict plasma concentrations for a combination drug Piperacillin (PIP) and Tazobactam (TAZ) in 31 neonates. To evaluate the model performance, model predicted and observed plasma concentrations of PIP and TAZ were compared without any adjustment of model parameters. Armed with predicted 90 percentile distribution intervals for PIP and TAZ plasma concentrations, the PBPK model failed to predict the observed plasma PIP

levels in only 12% of the neonates for PIP and 17% for TAZ. For the remaining preterm and term neonates nearly 50% of the neonates were deemed acceptable and the remaining neonates were categorized as mixed, with 2 or more plasma concentrations outside 90 percentile distribution intervals for each drug. The model performance outcomes were very promising given that the PBPK model was not calibrated by adjusting model parameters. The variability in the drug plasma concentrations was greater than the predicted variability based on distribution assumptions for maturation of body weight, organ volumes, blood flows, cardiac output, plasma protein binding, GFR, and tubular secretion. Future efforts to improve performance includes the characterization of neonatal illness, refined descriptions for model parameters, and expanding the number of drugs for simulation purposes.

1793 Enhancing Stem Cell-Based Toxicity Assays by Engineering the Culture Niche in a High-Throughput Assay-Agnostic Manner

N. A. Geisse. *NanoSurface Biomedical Inc., Seattle, WA.* Sponsor: N. Geisse, American Society for Pharmacology and Experimental Therapeutics

Human induced pluripotent stem cells (hiPSC) hold great promise for detecting adverse events *in vitro*, but there are limits to their ability to accurately model human physiology. For example, hiPSC-Cardiomyocytes (CMs) misclassify several compounds of known cardiotoxicity. Cell maturity is a major contributor to this; most hiPSC-CMs express fetal phenotypes, leading to inaccurate or difficult-to-translate results. Extracellular matrix (ECM) engineering improves both structural and functional phenotypes, but is challenging to perform on industry-standard assays and instrumentation platforms. Engineering increasingly intricate artificial culture environments often drives decisions to trade off biological complexity with experimental throughput. Here, we developed biomimetic patterns that mimic the shape and structure of the ECM on transparent polymers which direct focal adhesion assembly mechanisms in individual iPSC-CMs and drive higher-ordered tissue architecture. These 2D cardiac syncytia are formed in industry-standard microplate formats compatible with light microscopy. The method is also extended to micro-electrode arrays (MEA) in a manner that maintains both the quality of MEA recordings and baseline electrophysiological properties. iPSC-CMs grown this way show adult-like structural and biochemical phenotypes like protein isoform expression, myofibril alignment, and sarcomere dimensions. We show that biomimetic cues enhance the electrophysiological response of cardiomyocytes to various drugs of known effect. Since ECM structuring recapitulates the polarized nature of gap junctions, we used the connexin blocker carbenoxolone for validation. Our data show that structured tissues enable differential conduction block measurements across longitudinal and transverse directions and that patterned tissues have increased sensitivity to the drug (IC50s of 14.71 vs. 398.1 nM, respectively) and compare favorably to clinically relevant unbound concentrations. Our approach is instrument- and assay agnostic, effective on a variety of cell types and lines (including neuronal cells), and compatible with high-throughput approaches. We conclude that bioengineering techniques can enhance the predictivity and maturity of iPSC-CMs in culture.

1794 Optimization of UGT Inhibition Assays: Evaluation of Substrate and Inhibitor Selectivities

J. Reinen, M. Smit, and M. Wenker. *Charles River, 's-Hertogenbosch, Netherlands.* Sponsor: H. Emmen

Glucuronidation is the major Phase II drug metabolizing pathway which is catalyzed by UDP-glucuronosyltransferases (UGTs). A significant number of drugs are known to be metabolized by UGTs, either directly or following Phase I metabolism. Inhibition of UGTs by xenobiotics may alter the pharmacokinetics of drugs that are eliminated primarily via glucuronidation. It is therefore very important to evaluate the potential UGT inhibition for new chemical entities (NCEs) during drug development. In human liver, seven major UGT enzymes (1A1, 1A3, 1A4, 1A6, 1A9, 2B7 and 2B15) are present and assays to determine the inhibition of these enzymes have been developed. In the current study, we have evaluated the use of different substrates and inhibitors in order to implement assays to study the inhibition of the seven major UGT isoforms. Based on literature research, β-estradiol (E2) and SN-38 (both 1A1), CDCA (1A3), trifluoperazine (1A4), serotonine (1A6), propofol (1A9), zidovudine (2B7), oxazepam (2B15) and the general UGT substrates 4-methylumbelliferone and 7-hydroxycoumarine were selected as substrates. Analytical methods (UPLC-PDA-MS) were developed and implemented for each substrate and the corresponding glucuronide metabolite and incubations with human liver microsomes were performed to evaluate the selectivities of the selected substrates. Specificity for the intended UGT was confirmed for SN-38, CDCA, trifluoperazine, serotonine, propofol, zidovudine and oxazepam (S-oxazepam-glucuronide formation only) whereas E2 was found to be metabolized by multiple UGTs. Subsequently, protein- and time-dependent experiments were performed to optimize the reaction conditions for the UGT-specific substrates to ensure that reactions followed first-order kinetics and that substrate depletion was below 30%. The optimized reaction conditions were used to evaluate the inhibition potential of a selection of known inhibitors (erlotinib, troglitazone, hecogenin, niflumic acid, diclofenac and ketoconazole) for each of the seven UGTs. The current study gives an overview of assays that can be used to study UGT inhibition and therefore is of added value for risk evaluation of UGT-mediated drug-drug interactions (DDIs).

1795 New Statistical Modeling Strategy to Dissect the Effects of Drug Properties and Host Factors on Toxicity Using Postmarket Surveillance Data

D. Wang, K. K. Khadka, and M. Chen. *US FDA/NCTR, Jefferson, AR.*

Due to the well-known limitations for current animal testing based approaches to drug toxicity, there is heightened interest in both high throughput *in vitro* assays and epidemiological data. Epidemiological data sets are especially important for dissecting the effects of drug properties, host factors, and their interactions in effecting drug toxicity. But comprehensive data sets fit for this purpose are very difficult to obtain. Postmarket surveillance databases such as the FDA Adverse Event Reporting System (FAERS) database represent a rich but underutilized data source for data mining and model development in this area. Current applications using FAERS data commonly focus on detecting drug-adverse event (AE) combinations with unusually high relative reporting rates while using FAERS data for model development and validation regarding drug properties or host factors is relatively rare. This is partly due to the lack of well-developed statistical methodology. In this paper, we developed a novel statistical approach that incorporates drug properties and host factors in the modeling of relative reporting rates using large postmarket surveillance databases like FAERS. It is a natural extension of current data mining approaches for detecting drug-AE combinations with unusually high relative reporting rates like multi-item Gamma Poisson Shrinker and likelihood ratio tests. By incorporating covariates in a Poisson regression framework, the effects of drug properties or host factors on toxicity can be estimated and tested. In one case study, we demonstrated that a predictor that we constructed in a previous study with AOP networks and *in vitro* assays is very significantly associated with a drug's relative reporting rates ($p<10^{-6}$), thus collaborating the model using high throughput assays. We also demonstrated the proposed model can be used to identify drug-AE combinations with significant sex disparity in relative reporting frequency. With further development, this method has potential to enable extensive studies regarding the interplay between drug properties and host factors for drug toxicity using publicly available postmarket surveillance databases.

1796 Revisiting the hERG Safety Margin after 20 Years of Routine hERG Screening

D. Leishman, M. A. Abernathy, and E. B. Wang. *Eli Lilly and Company, Indianapolis, IN.* Sponsor: L. Buckley

It has been two decades since screening new molecules and potential clinical drug candidates against the hERG potassium channel became a routine part of safety pharmacology. The earliest heuristic for what was an adequate safety margin to separate molecules with a liability to cause the arrhythmia torsade de pointes (TdP) from those with no such liability emerged in 2002 and was determined to be 30-fold the therapeutic free plasma Cmax (Webster et al., 2002). In the intervening years nonclinical and clinical ICH guidances have been introduced and intense scrutiny has been applied to the QT interval of the electrocardiogram in animals and man. Has the 30-fold heuristic stood the test of time? The hERG margin between the IC_{50} value and the therapeutic unbound plasma concentrations were examined for 351 compounds. These margins were compared against the categories used by www.CredibleMeds.com to classify a drug's TdP risk. A subset of 320 of these drugs were compared against their US product labels with respect to black box warnings on QTc prolongation or TdP, warnings and precautions on QTc or TdP and QTc language in the clinical pharmacology section. Against the CredibleMeds Classification the modes of the distributions of margins for Known, Possible, Conditional Risk of TdP, and Not Listed (presumably no TdP liability) were 5, 17, 56 and 468, respectively. Against the US label language the modes of the distributions of margins for black boxes and warnings were 5 and 10, respectively. The margins associated with, positive QTc outcome, negative QTc outcome and no QTc language were 8, 355 and 52, respectively. The 30-fold heuristic would still appear to hold with respect to the US label language falling between the margins for negative QTc outcome or no QTc language and positive QTc outcome, warnings or black boxes. Similarly, the

30-fold mark separates drugs with a known or possible TdP risk from those where it is at best conditional and certainly from the 231 drugs not listed on www.CredibleMeds.com. The fact that the margins in each category form distributions is not surprising but a more consistent manner of assessing hERG potency and evaluating relevant exposures would likely reduce the spread in these distributions making margins even more useful as a decision-making data point.

1797 Assessing the Poly-Pharmacology of Kinase Inhibitors by Transcription Factor Activity Profiling

S. S. Makarov[1], L. Medvedeva[1], E. Martsen[1], K. Gorman[1], B. Lin[1], W. Zuercher[2], D. Drewry[2], L. M. Graves[2], S. Makarov Jr.[1], and A. Medvedev[1]. *[1]Attagene Inc., Research Triangle Park, NC; and [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Protein kinases are promising drug targets for multiple diseases. The challenge in developing therapeutic PK inhibitors (PKI) stems from the fact that most PKIs interact with multiple kinases and non-kinase targets (PKI polypharmacology). Existing evaluation approaches afford kinome-wide profiling of PKI activity but do not consider the biological effects of PKIs and their interactions with non-kinase targets. Here, we describe an effect-based methodology to biological evaluation of PKIs. Under this approach, we assess cell response by profiling the activity of multiple transcription factors (TFs), proteins connecting signaling pathways with regulated genes. Previously, we demonstrated that TF activity profiles (TFAPs) provided robust quantitative signatures of compounds, permitting straightforward identification of perturbed biological processes[1]. Using a multiplexed reporter assay[2] (the FACTORIAL™) in human hepatocytic HepG2 cells, we evaluated TFAP signatures for a panel of over 120 PKIs in a broad range of concentrations. (1) We found that inhibitors for the same kinase shared an identical TFAP signature, regardless of structural dissimilarities and MOA (ATPase vs. allosteric inhibitors); furthermore, kinase-dead cDNA mutants produced the same signature. Therefore, this invariant signature is a bona fide marker for inhibited kinase; (2) we found distinct invariant signatures for multiple kinases (Raf, Mek, Erk, mTOR, Akt, and Aurora); (3) the invariant signatures for kinases of the same vertical pathway (Raf/Mek/Erk; mTOR/Akt) had a high-degree similarity, suggesting a straightforward approach to mapping kinases within the signaling network; (4) the TFAP signatures of most PKI changed with concentration; by querying those TFAPs against the invariant signatures for inhibited kinases and landmark perturbagens, we determined the concentration windows wherein the dominant effect of a PKI was an inhibition of a particular kinase or a perturbation of a non-kinase processes (e.g., mitochondrial malfunction, DNA damage, proteotoxicity). Our methodology is a powerful addition to existing techniques, illuminating biology that is invisible to target-based screening. The TFAP signatures provide quantitative metrics for assessing PKI polypharmacology by revealing the dominant effects on kinases and non-kinase targets. This approach also suggests a new methodology to map the human kinases in the context of vertical pathways and to deorphanize the dark kinases. *References: 1. Medvedev, A.* et al. Sci. Adv. *4, eaar4666 (2018). 2. Romanov, S.* et al. Nat. Methods *5, 253-60 (2008).*

1798 Investigative Safety Strategies to Reduce Risk of Drug-Induced Cholestasis and Hepatobiliary Toxicity in Drug Discovery and Development at Bristol-Myers Squibb Company

M. W. Gill, H. Shen, X. Zhuo, L. Sivaraman, M. Sinz, B. Johnson, K. Chadwick, and M. Davis. *Bristol-Myers Squibb Company, Princeton, NJ.*

Drug induced liver injury (DILI) is a major cause of drug attrition in the pharmaceutical industry and altered bile acid homeostasis has been hypothesized to cause cholestasis and liver injury. BMS has withdrawn drug candidates from development due to clinical evidence of hepatobiliary toxicity. One such candidate was the LPA_1 receptor antagonist BMS-986020. Data with structurally distinct LPA_1 antagonists indicated that the toxicity from BMS-986020 was compound- rather than LPA_1-mechanism-based. Retrospective studies with BMS-986020 to assess the mechanism for hepatobiliary toxicity demonstrated inhibition of key hepatic canalicular and sinusoidal bile acid transporters (i.e., BSEP, MRP3, MRP4) by BMS-986020 at relevant clinical drug exposures. BMS-986020 also inhibited taurocholate efflux from human hepatocytes into bile and blood, and inhibited the efflux of phospholipids from human hepatocytes into bile mediated by MDR3. In agreement, BMS-986020 increased plasma bile acid levels in rats and humans. Moreover, BMS-986020 altered mitochondrial function in human hepatocytes and cholangiocytes, and caused hepatobiliary toxicity in monkeys. Based on these data, data for other BMS compounds, and literature reports, an investigative preclinical testing strategy was developed for BMS compounds that inhibit BSEP, the primary hepatic bile acid efflux transporter. This testing strategy progresses sequentially through tiers from early discovery to early development. Tier 0 considers *in vitro* high throughput inhibition data for BSEP. Tier 1 compares projected clinical plasma drug concentrations to the BSEP inhibition data, and Tier 2 incorporates data for risk enhancers (noncompetitive BSEP inhibition, inhibition of additional bile acid efflux transporters and MDR3, hepatic drug accumulation, and increased bile acids *in vivo*) and risk reducers (inhibition of hepatic bile acid uptake transporters NTCP and OATP). In Tier 3, additional DILI liabilities (altered mitochondrial function, oxidative stress, reactive metabolites) and *in vivo* nonclinical evidence of hepatobiliary toxicity are considered for an integrated DILI risk assessment. Taken together, this study presents the data to support an investigative strategy of drug-induced perturbations of bile acid homeostasis, cholestasis, and hepatotoxicity for preclinical and clinical programs.

1799 Understanding the Applicability of *In Silico* and *In Vitro* Safety Models to Improve the Risk Assessment of Drug Candidates

T. Takai, and R. Naven. *Takeda California, San Diego, CA.*

Many *in silico* and *in vitro* safety models are used during lead optimization to identify safety-related liabilities. Most are validated using diverse sets of compounds in an attempt to understand a model's predictive potential. However, most of these models are not perfect in terms of their performance against the training set and it is essential to understand under what situations a model is or is not predictive. For example, through an assessment of an *in silico* model of *in vitro* 3T3 phototoxicity, the use of the HOMO-LUMO gap descriptor was shown to be most important factor towards the prediction of 3T3 activity. A deeper analysis, however, showed that this descriptor was only useful for describing the phototoxic potential of compounds without a fused-ring system and not those with fused-ring systems, highlighting a predictivity gap within the model. With respect to *in vitro* systems, we assessed the applicability of several cytotoxicity assays in terms of their ability to predict toxicity in preclinical *in vivo* safety studies. Cytotoxicity assays using HepG2 and HUVEC showed good performance for predicting toxicity findings below the total Cmax level of 10 uM (AUCs by ROC curve analysis were 0.679 and 0.696, respectively) but this was not the same for human primary hepatocytes (ROC AUC = 0.574). The *in vivo* toxicity profile of those compounds that were cytotoxic only towards primary hepatocytes was diverse and not restricted to the liver. This suggests that it is challenging to interpret the cytotoxic activity of a candidate drug in human primary hepatocytes. A further analysis, however, indicated that they may be useful for the determination of toxicity mechanisms, particularly with respect to metabolism. For example, a compound that was only active in human primary hepatocytes showed metabolite-related toxicity in the kidney, indicating that primary liver cells can identify the risk of metabolite-related toxicity in various organs, not only in liver. Several case studies within Takeda will be presented to show the importance of understanding the value of *in silico* and *in vitro* models through structural and mechanistic investigation of the training set. Knowledge learnt from these analyses cannot only identify predictive knowledge gaps, but also uncover toxicological knowledge that can be used to build more effective safety screening paradigms.

1800 De-Risking Biotherapeutic Lead Selection: How Specific Is Your Antibody?

R. Fong, D. Harmon, T. Sullivan, J. Rucker, and B. Doranz. *Integral Molecular, Philadelphia, PA.* Sponsor: J. Rucker, American Association for the Advancement of Science

Poor specificity frequently derails drug discovery and over half of preclinical safety failures are caused by off-target binding. We developed the Membrane Proteome Array (MPA) platform to de-risk lead selection by testing biotherapeutics for specificity and off-target binding. This platform tests specificity across 6,000 human membrane proteins, each expressed in live cells. In contrast to commonly used Tissue Microarrays (TMAs), proteins in the MPA exist in their native conformations and are not altered by fixation. Binding interactions are assayed by high-throughput flow cytometry allowing for high sensitivity detection and rapid analysis. In the process of testing hundreds of antibodies, we found that up to 20% of antibodies exhibit detectable off-target binding. In many cases, off-target interactions occurred with unrelated proteins and could not be predicted by protein sequence homology. We used our high-resolution Shotgun Mutagenesis epitope mapping platform to elucidate these unintended interactions and better understand the nature of unpredicted off-target binding.

1801 Iodoacetic Acid Affects Estrous Cyclicity, Ovarian Gene Expression, and Hormone Levels in Mice

A. Gonsioroski[1], D. D. Meling[1], L. Gao[1], M. J. Plewa[1,2], and J. A. Flaws[1]. [1]*University of Illinois at Urbana-Champaign, Urbana, IL; and* [2]*Safe Global Water Institute, Champaign, IL.*

The disinfection of drinking water was a major public health achievement of the 20th century. However, the reaction between disinfectants and organic matter in water generates water disinfection by-products (DBPs). Iodoacetic acid (IAA) is one DBP that has been shown to be an ovarian toxicant *in vitro*, but its effects on the ovaries *in vivo* are not well known. This study determined whether IAA exposure affects estrous cyclicity, ovarian expression of genes that regulate apoptosis, the cell cycle, steroidogenic factors, estrogen receptors, and the levels of reproductive hormones in mice. Adult CD-1 mice were dosed with IAA (0, 0.5, 10, 100, and 500 mg/L) in the drinking water for 35 days and estrous cyclicity was monitored for 14 days. After 35 days, ovaries were collected for analysis of expression of apoptosis regulators (*Bax, Bok, Aimf1, Bcl2* and *Bcl2l10*), cell cycle regulators (*Ccna2*, *Ccne1*, *Ccnb1*, *Ccnd2*, *Cdk4,* and *Cdkn1a*), steroidogenesis factors (*Star*, *Cyp11a1, Cyp17a1, Cyp19a1, Hsd17b1,* and *Hsd3b1*), and estrogen receptors (*Esr1* and *Esr2*). In addition, sera were collected to measure pregnenolone, androstenedione, testosterone, estradiol, inhibin-B, and follicle stimulating hormone (FSH) levels. IAA exposure decreased the time that the mice spent in proestrus compared to control. Further, IAA exposure decreased expression of the pro-apoptotic factor *Bok* (100 and 500 mg/L), the cell cycle regulator *Ccnd2* (500 mg/L), and borderline decreased expression of the anti-apoptotic factor *Bcl2l10* (10 mg/L), the pro-apoptotic factor *Aimf1* (0.5 mg/L), and the steroidogenic factor *Cyp19a1* (10 and 500 mg/L) compared to control. In contrast, IAA exposure increased expression of the pro-apoptotic factors *Bax* and *Aimf1* (500 mg/L), the anti-apoptotic factor *Bcl2l10* (500 mg/L), the cell cycle regulators *Ccna2*, *Ccnb1*, *Ccne1*, and *Cdk4* (500 mg/L), and the estrogen receptor *Esr1* (500 mg/L) compared to control. IAA exposure did not affect expression of *Star*, *Cyp11a1, Cyp17a1, Hsd17b1, Hsd3b1,* and *Esr2.* Further, IAA exposure decreased estradiol levels (500 mg/L), but did not alter pregnenolone, androstenedione, testosterone, inhibin-B, and FSH levels. Collectively, these data show that IAA exposure alters estrous cyclicity, ovarian gene expression, and estradiol levels in mice. *Supported by NIH R21 ES028963 and NIH T32 ES007326.*

1802 Earlier Puberty and Ovarian Germ Cell Depletion in Female Mice Exposed *In Utero* to Benzo[a]pyrene during Either Germ Cell Mitosis or Meiosis Onset Developmental Windows

K. Malott, M. Lee, L. Ortiz, and U. Luderer. *University of California Irvine, Irvine, CA.*

Polycyclic aromatic hydrocarbons (PAHs), such as benzo(a)pyrene (BaP), are products of incomplete combustion of organic materials. It has been shown that exposure to PAHs during ovarian development causes premature ovarian failure in rodents. Primordial germ cells (PGCs), embryonic precursors of oocytes, arise in the mouse yolk sac at 7.25 days postcoitum (dpc). PGCs proliferate before and after arriving at the gonadal ridge 10.5 dpc and begin entering meiosis at 13.5 dpc. Now oocytes, they arrest in the first meiotic prophase beginning at 17.5 dpc. This finite oocyte pool is the primary determinant of female fertility and reproductive lifespan. We have shown that *in utero* exposure of female mice to 2 or 10 mg/kg/day BaP during a dosing window that spans the mitotic and meiotic stages of PGC development results in depleted follicle numbers postnatally. We hypothesized that PGCs are more sensitive to BaP exposure during rapid proliferation, starting at 6.5 dpc prior to entry into meiosis at 13.5 dpc. We exposed timed-pregnant female mice to 0 or 2 mg/kg/day of BaP in oil, by oral pipetting, from 6.5-11.5 dpc or 12.5-17.5 dpc corresponding to germ cell mitosis and meiosis, respectively. Female offspring were examined daily for vaginal opening. Then vaginal cytology was conducted until first estrus to assess puberty onset. One female from each litter was euthanized for ovarian follicle counts on the morning of first estrus. The females exposed to BaP *in utero* displayed a 2-day earlier first estrus (P=0.005) compared to unexposed females, regardless of exposure window. Females exposed to BaP, regardless of timing, were sensitive to germ cell depletion. We observed statistically significant decreases in primordial, primary, and secondary follicle counts with BaP dose (P<0.02, 2-way ANOVA, N=5-8/oil, 9-11/BP), but no statistically significant effects of dosing window or the interaction between BaP dose and window (P>0.48). We observed little change in number of antral follicles for both dosing windows. These results support that germ cells are equally sensitive to BaP-induced cell death during mitosis and meiosis developmental windows and demonstrate that prenatal exposure to BaP depletes the finite ovarian reserve and hastens the onset of puberty. *This research was supported by NIH R01ES020454.*

1803 Prenatal Exposure to an Environmentally Relevant Phthalate Mixture Accelerates Reproductive Aging in Multiple Generations of Female Mice

E. Brehm, C. Zhou, L. Gao, and J. A. Flaws. *University of Illinois at Urbana-Champaign, Urbana, IL.*

Phthalates are found ubiquitously in products including plastics and personal care products, resulting in daily human exposure. Phthalates are known endocrine disrupting chemicals that have been shown to negatively affect female reproduction. Previously, our laboratory found that prenatal exposure to a relevant phthalate mixture composed of 35% diethyl phthalate, 21% di(2-ethylhexyl) phthalate, 15% dibutyl phthalate, 15% diisononyl phthalate, 8% diisobutyl phthalate, and 5% benzylbutyl phthalate disrupted female reproduction in multiple generations of mice. However, it is not known if prenatal exposure to a mixture of phthalates affects reproductive aging and if these effects are accelerated compared to control. Reproductive aging in females is characterized by a decrease in the follicle pool, a lack of normal cyclicity, an increase in the occurrence of cystic ovaries, and a dysregulation of the hypothalamic-pituitary-gonadal axis, leading to decreased fertility. This dysregulation is defined as a decrease in sex steroid and peptide hormone levels and an increase in gonadotropin hormone levels. Thus, we tested the hypothesis that prenatal exposure to a mixture of phthalates accelerates reproductive aging in multiple generations of female mice. Pregnant CD-1 dams were orally dosed with control or a phthalate mixture (20 µg/kg/day-500 mg/kg/day) daily from gestational day 10 to birth. Adult F1 females born to these dams were used to generate the F2 generation by mating them with unexposed males and F2 females were used to generate the F3 generation. At 13 months, estrous cyclicity was monitored for 14 days and ovaries and sera were collected for analysis. Prenatal exposure to the phthalate mixture (200 µg/kg/day) decreased primordial follicle numbers and increased the occurrence of cystic ovaries in the F1 generation. The mixture (20 and 200 µg/kg/day, 500 mg/kg/day) increased time spent in metestrus/diestrus in the F3 generation. Further, the mixture decreased levels of progesterone (F2), testosterone (F1, F2), and inhibin B (F1), but increased levels of follicle-stimulating hormone (F1) and luteinizing hormone (F1, F3) in multiple generations of aging mice. These data suggest that prenatal exposure to a relevant phthalate mixture accelerates reproductive aging in a multi- and transgenerational manner in female mice. *Supported by NIH P01 ES022848 and EPA RD-83459301.*

1804 A Subcompartmental Analysis of Oxidative Stress in Ovarian Reproductive Aging

W. S. Parkes[1], S. Numata[1], F. Amargant[2], F. E. Duncan[2], and M. T. Pritchard[1]. [1]*University of Kansas Medical Center, Kansas City, KS; and* [2]*Northwestern University, Chicago, IL.*

Environmental toxicants cause tissue damage, in part through reactive oxygen species (ROS) formation. ROS also contributes to aging. Previous work from our group revealed an increase in ovarian fibrosis in old mice compared to young mice and this is associated with a significant decrease in total ovarian hyaluronan (p<0.05). Hyaluronan (HA) is a large (> 2 MDa) extracellular matrix (ECM) glycosaminoglycan that helps maintain tissue homeostasis and is abundantly expressed in the ovary. In extra-ovarian tissues, HA depolymerization to low molecular weight fragments (<250 kDa) by hyaluronidases and ROS can aid in tissue repair or, if persistent, can promote inflammation and fibrosis, both of which are hallmarks of ovarian aging. We hypothesized that ovarian ROS would be associated with HA loss in an age-specific and compartmental specific manner. To test this hypothesis, oxidative stress and antioxidant gene expression in whole ovaries or isolated ovarian stromal husks from reproductively young (6-12 weeks) and old (14-17 months) mice were analyzed using a pathway targeted QPCR array, followed by QPCR-based gene expression validation. 4-hydroxynonenal (4-HNE) immunohistochemistry was used to detect ROS-mediated ovarian macromolecule damage. HA was localized in ovaries from young and old mice followed by subcompartment quantification of HA-positive staining. The stromal compartment had a significant increase in the oxidant production-related genes Ncf1 and Ncf2 in old vs young mice (p<0.05). The antioxidant genes Txn1 and Hmox1 were significantly increased, while Gpx6 was decreased in old stroma vs young stroma (p<0.05). 4-HNE adducts were localized to the stroma, follicles, corpora lutea, and theca cells in both young and old mice; only theca-associated 4-HNE was greater in old mice (p<0.05). This was fascinating since we also observed a significant decrease (p<0.05) of HA in the theca layer in old mice vs young mice. Collectively, these data suggest that increased theca cell oxidant stress could contribute to HA loss in this ovarian subcompartment, but not in the non-theca stromal cell compartment, with advanced reproductive age. In conclusion, our findings indicate that ROS could be a potential mechanism by which HA is degraded in ovarian reproductive aging.

1805 Testing the Response of Pharmaceutical Compounds on Female Reproductive System Using Tissue Engineering and Microfluidic Culture Technologies

J. Xu[1], H. Rogers[2], Y. Wang[1], Y. Zhang[2], J. Zhu[2], K. Fabre[3], K. Maratea[4], Q. Zhang[5], T. K. Woodruff[2], and S. Xiao[1]. *[1]University of South Carolina, Columbia, SC; [2]Northwestern University, Chicago, IL; [3]Baylor College of Medicine, Houston, TX; [4]AstraZeneca, Waltham, MA; and [5]Emory University, Atlanta, GA.*

The lack of optimal *in vitro* models for testing the safety of pharmaceutical compounds on female reproductive system makes the current gold standard dependent on *in vivo* animal studies. To aid in the rapid assessment of likely compound toxicity prior costly animal studies and to ultimately reduce or replace the use of animals in biomedical research, we have developed *in vitro* systems that are being tested against standard static well-based assessment modalities. To date, newly tested tissue engineered mimics and 3D microfluidic culture have produced more physiologically relevant environment *in vitro* and also allow the integration of multiple organ systems. Our next step is to determine if they provide an efficient and reliable pre-clinical tool for screening the response of pharmaceutical compounds on female reproductive system and functions. In this work, we used a combination of encapsulated *in vitro* follicle growth model (eIVFG) and a microfluidic culture model to screen for the impact of compounds under pharmaceutical development at AstraZeneca (AZ) that were stopped for safety concerns. Multilayered secondary ovarian follicles were isolated from 16-day-old CD-1 female mice and encapsulated within 0.5% alginate hydrogel. Follicles were then cultured using traditional static 3D culture, treated with various compounds at concentrations of 0, 0.1, 1.0, 10, or 100 μM for 24h, and then cultured for a total of 8 days. Using this approach, it was identified that while some compounds had no effect on follicle growth and survival, other compounds exhibited adverse impact at high-doses or in a dose-dependent manner. Additionally, ovarian explants were cultured using microphysiological systems (MPS), treated with concentrations of 0, 10 or 100 μM for 24h, and then cultured for 8 days. In microfluidic culture, compounds showed similar results to that in the static culture. These results illustrate the potential application of tissue engineering and microfluidic technologies in the investigation of reproductive safety of pharmaceutical compounds of interest.

1806 Integrated Genomic, Epigenomic, and Exposomic Analysis of Placentas from Preeclamptic Patients Identifies Links to Acetaminophen and Placental Cellular Damage Signaling

C. K. Carberry[1], J. Szilagyi[1], A. Chao[2], J. Grossman[3], K. Lu[1], E. Martin[1], K. Boggess[1], J. Sobus[4], R. Fry[1], and J. Rager[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; [3]Agilent Technologies Inc., Santa Clara, CA; and [4]US EPA, Research Triangle Park, NC.*

Preeclampsia is a serious pregnancy disorder that results from the dysregulation of placental function that can be detrimental to both the mother and developing fetus. Preeclampsia impacts up to 8% of all pregnancies worldwide, yet the factors contributing to the development of this disease remain largely unknown. This study set out to test the hypothesis that understudied xenobiotic chemicals are capable of reaching the human placenta and disrupting critical pathways relevant to placental cell health and preeclampsia. Placentas from a previously established cohort of patients with normotensive (N=17) and preeclamptic (N=18) pregnancies were analyzed using non-targeted approaches based on high-resolution quadrupole time-of-flight mass spectrometry to identify unknown molecular features. Features were matched against multiple chemical inventories, including the Agilent MS/MS fragmentation database and the US Environmental Protection Agency computational toxicology database. Feature concentrations were statistically associated with preeclampsia disease status, as well as genomic and epigenomic signatures from the same placental samples. A total of 172 molecular features were identified with significantly increased levels in tissues from preeclamptic patients. One of the identified features showing the largest increase in concentration was acetaminophen. Concentrations of acetaminophen were found to be associated with altered expression of 26 genes and 57 miRNAs and altered methylation status of 18 genes relevant to preeclampsia. Acetaminophen-associated genes showed enrichment for cell death / damage signaling, which were further characterized through *in vitro* testing with immortalized trophoblasts. This research provides novel evidence towards characterizing the placental exposome and identified acetaminophen as one of the most significantly associated compounds related to preeclampsia. Mechanistic findings showed changes in signaling relevant to placental cell damage that may be relevant to preeclampsia etiology and support the need for further investigation. This study serves as an important foundation to further elucidate relationships between potential chemical exposures and placental health in pregnant women.

1807 Transcriptional Profiling of the Trichloroethylene Metabolite *S*-(1,2-Dichlorovinyl)-L-Cysteine Revealed Activation of the EIF2α/ATF4- Integrated Stress Response in the HTR-8/SVneo Trophoblast Cell Line

E. R. Elkin[1], K. M. Bakulski[1], J. A. Colacino[1], D. Bridges[1], D. R. Armant[2], D. Ruden[2], and R. Loch-Caruso[1]. *[1]University of Michigan, Ann Arbor, MI; and [2]Wayne State University, Detroit, MI.*

Exposure to trichloroethylene (TCE) in pregnancy has been associated with reduced birth weight in humansand rats. Due to environmental contamination and continued usage, TCE exposure is an ongoing risk. The TCE metabolite *S*-(1,2-dichlorovinyl)-L-cysteine exhibits toxicity in a placental cell line. Thus far, investigations into the mechanisms of DCVC-induced cytotoxicity have been limited to narrowly-defined methods evaluating single molecular signaling pathways and biological responses. In the current study, genome-wide transcriptomics and gene set enrichment analyses were used to identify novel biological processes and molecular signaling pathways altered by human exposure-relevant DCVC concentrations in HTR-8/SVneo cells. Transcriptomics revealed 123 significantly up-regulated and 225 down-regulated genes with exposure to 20 μM DCVC for 12 h (FDR<0.05 and fold-change < -1.5 or >1.5). Gene set enrichment analyses demonstrated that the most substantially altered molecular signaling pathway was the EIF2α/ATF4 Integrated Stress Response (ISR), with the most abundantly altered Gene Ontology Biological Processes including amino acid transport, metabolism and biosynthesis, transcription and translation, and regulation of tissue development. Western blotting confirmed the involvement of the ISR. Our results provided insight into functional consequences in the cells. For example, decreased global protein synthesis was measured in agreement with ISR signaling. However, no changes in cell cycle progression or proliferation were detected, suggesting that a generally successful adaptive process occurred after 12 h of 20 μM DCVC treatment. This study provides further insights into the mechanism of DCVC-induced cytotoxicity by revealing the involvement of a specific stress signaling pathway.

1808 A Modified Parachute Assay for Accurate Assessment of Gap Junction Intercellular Communication in Placental Trophoblast Cells

J. Gingrich, Y. Pu, and A. Veiga-Lopez. *Michigan State University, East Lansing, MI.*

Gap junction intercellular communication (GJIC) can be assessed with a parachute assay, where fluorescent dye-loaded donor cells are seeded onto acceptors and dye diffuses to adjacent cells with active gap junctions. GJIC is expressed as the percent dye positive cells. Since cells remain in co-culture for up to 4 h, donor cells can attach, but the assay does not allow distinction between donors and acceptors, which is a major limitation. Updates to this method use DiI dye, but DiI can be effluxed by donors over time resulting in false positives. We aimed to develop a parachute assay with distinguishable populations and hypothesized that it will assess GJIC comparable to current methods such as the scrape load/dye transfer assay (SL/DT) and is more accurate than methods lacking donor detection. Since intercellular communication is required during placental development, we used the trophoblast cell line HTR8-SVneo as the acceptor and HTR8-SVneo expressing red-fluorescent protein (RFP) as the donor. The assay was optimized under positive-control conditions using PKA activator, CW008. We have previously shown that gestational exposure to bisphenol S (BPS) reduces binucleate trophoblast cell number in sheep by disrupting fusogenic cell signaling. Since GJIC is one of the first steps in cell fusion, we also tested if BPS alters trophoblast cell GJIC. Donors and acceptors were exposed for 24 h to DMSO (0.1%), CW008 (1 μM), BPS (200 ng/mL), 12-O-tetradecanoylphorbol 13-acetate (TPA; 10 nM; negative control), or combinations of the three. Donors loaded with calcein AM (10 μM) were then added at 10,000 cells/well onto acceptors. Cells remained in co-culture for 3 h then fixed, DAPI stained, and imaged. Transfer events were calculated as: Σcalcein positive cells minus ΣRFP positive cells over total cells; normalized to the control. BPS enhanced GJIC in HTR8-SVneo cells, like CW008. TPA significantly attenuated both chemical-induced enhanced GJIC. As predicted, exclusion of donors during quantification resulted prevented false positives. This is the first report of a parachute assay for measuring GJIC in placental cells. Like the SL/DT assay, this novel parachute method reliably

detects both enhanced and suppressed GJIC. The ease and accuracy of quantification over current methods make this new assay optimal for automation and a useful tool for *in vitro* toxicological placental testing. *Supported by NIEHS R01ES027863 to AVL. JG was supported by NICHD T32HD087166.*

1809 Per- and Polyfluoroalkyl Substances (PFAS) Inhibit Trophoblast Migration and the Expression of Inflammation-Related Genes

J. T. Szilagyi, J. T. Bangma, A. N. Freedman, and R. C. Fry. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Per- and polyfluoroalkyl substances (PFAS) are used as industrial surfactants and chemical coatings for household goods such as Teflon. Despite regulatory efforts to phase out historical PFAS perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), PFAS are detectable in drinking water throughout the United States. This is due to the stability of PFOS and PFOA and the continued use of replacement compounds, such as GenX. PFAS have also been detected in placenta and cord blood. Of concern for pregnant women, PFAS have been associated with low birthweight and increased preeclampsia risk in humans. Preeclampsia is a leading cause of maternal morbidity and mortality worldwide and is driven by insufficient trophoblast migration into the maternal endometrium, resulting in poor placental blood flow. PFAS alter migration of other cell types, but their impact on trophoblast migration is not understood. Allowing for mechanistic research, trophoblast migration can be assessed *in vitro*. We assessed the effects of PFAS on trophoblast gene expression and function *in vitro*. Trophoblast migration was assessed using a traditional *in vitro* scratch assay. The results showed that exposure to 1000 ng/mL PFOS, PFOA, and GenX was associated with decreased trophoblast migration over 24 h, with each PFAS having a similar effect. Treatment with PFOS, PFOA, and GenX also decreased trophoblast expression of chemokines (e.g. *CCL2, CCL7*), chemokine receptors (e.g. *CCR4, CCR7*), and inflammatory enzymes (e.g. *ALOX15, NOS2*) involved in migration. Prior reports have shown that PFAS alter migration and inflammation in other cell types through a peroxisome proliferator-activated receptor (PPAR)-dependent mechanism. We therefore tested the interaction of PFOS, PFOA, and GenX with PPARs using reporter cell lines. We determined that all 3 PFAS can both activate and inhibit (in the presence of a known ligand) one or more PPAR isoforms. Taken together, these data indicate that PFAS potentially decrease trophoblast migration. Moreover, by understanding the mechanisms involved, it may be possible to identify risk factors for and preventative measures against disease associated with failed trophoblast migration such as preeclampsia.

1810 Association of Maternal-Fetal Polybrominated Diphenyl Ether (PBDE) Levels with Biomarkers of Placental Development and Disease During Mid-Gestation

J. R. Varshavsky[1], J. F. Robinson[1], Y. Zhou[1], K. A. Puckett[1], E. Kwan[1], S. Buarpung[1], R. Aburajab[1], S. L. Gaw[1], S. Sen[2], J. Park[3], S. C. Smith[3], S. J. Fisher[1], and T. J. Woodruff[1]. *[1]University of California San Francisco, San Francisco, CA; [2]University of Tennessee Health Science Center, Memphis, TN; and [3]California EPA, Berkeley, CA.*

While the mechanisms and periods of sensitivity remain undefined, *in utero* exposures to polybrominated diphenyl ethers (PBDEs) may be linked with placenta-mediated fetal and maternal health complications. To define the relationship between exposure to PBDEs and human placental development during mid-gestation, we performed a two-part analysis: 1) an evaluation of PBDE exposures in matched samples of maternal serum, placenta, and the fetal liver collected from healthy pregnant women undergoing elective termination procedures during mid-gestation (n=180; 2014-16); and 2) a semi-qualitative characterization of biomarkers of human placental development in relation to placental PBDE levels (n=62). All study protocols were approved by the University of California, San Francisco (UCSF) institutional review board prior to recruitment; written and verbal consent were obtained from each study participant at the time of enrollment. We used censored Kendall's tau correlation and maximum likelihood regression to compare PBDE levels between maternal-fetal tissues and examine their associations with biomarkers of placental development and disease. Specifically, we profiled placental cytotrophoblast (CTB) expression of integrin alpha 1 (ITGA1) and vascular endothelial-cadherin (CDH5) and metalloproteinase 1 (MMP1). In addition, we evaluated morphological features: leukocyte recruitment (basal plate), fibrinoid deposition (villous, basal plate), and CTB endovascular invasion. PBDEs were detected in all biomatrices. Prior to lipid adjustment, wet-weight levels of PBDE congeners were highest in the fetal liver compared to other compartments ($p<0.001$). In contrast, after lipid adjustment, PBDE levels were significantly higher in maternal serum compared to the fetal liver and placenta ($p<0.001$). We also observed significant associations between placental PBDE levels and endovascular CTB immunoreactivity of ITGA1 (inverse) and interstitial CTB immunoreactivity of CDH5 (positive), suggesting these markers of CTB invasion and development may be sensitive placental biomarkers of PBDE exposure. In summary, our work suggests that PBDEs are widely detected and differentially distributed in maternal-fetal compartments. Furthermore, we propose specific biomarkers of placental development as potential barometers of PBDE exposure during mid-gestation. This paradigm could be extended to other environmental chemicals and placental stage-specific antigens. *This work was supported by the US EPA (No. RD-83543301) and NIEHS (P01ES022841, R00ES023846).*

1811 Integrated Approaches to Testing and Assessment of Chemical Respiratory Sensitizers: A Weight-of-Evidence Assessment of Available Information to Derive a List of Reference Chemicals

K. Sullivan[1], N. Baker[2], S. Cochrane[3], J. Ezendam[4], G. Patlewicz[5], R. Rajagopal[3], E. Roggen[6], R. Settivari[7], and K. Sewald[8]. *[1]Physicians Committee for Responsible Medicine, Washington, DC; [2]Leidos, Research Triangle Park, NC; [3]Unilever Safety and Environmental Assurance Centre, Sharnbrook, United Kingdom; [4]Rijksinstituut voor Volksgezondheid en Milieu (RIVM), Bilthoven, Netherlands; [5]US EPA, Research Triangle Park, NC; [6]3RsMC ApS, Lyngby, Denmark; [7]Corteva Agriscience, Newark, DE; and [8]Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany.*

An Adverse Outcome Pathway leading to chemical respiratory sensitization has been outlined and, despite progress made in developing hazard identification approaches to assess chemicals for this endpoint as well as high regulatory need, there remains a lack of internationally harmonized approaches to identify chemical respiratory allergens. In order to assess potential *in vitro* and *in silico* approaches, a reference list of ~120 putative chemical respiratory sensitizers was generated based on structural alerts; a weight of evidence-based approach was undertaken to validate the reference list based on human clinical, *in vivo* non-human, and *in vitro* data. Well-defined criteria and a scoring matrix were used to curate the human data, taking into consideration the variability in tests performed by asthma clinics and laboratories alike, as well as uncertainties embedded in these analyses and reporting. To allow for a weight of evidence analysis, we are collecting all data but qualifying the data to reflect methodological quality. We are also making use of the Abstract Sifter literature review tool to identify additional potential respiratory sensitizers. Briefly, a set of PubMed MeSH terms describing adverse effects (AEs) for 92 known sensitizers was used to query a large database of chemicals and AEs, yielding over 7000 chemicals of potential interest. Work is ongoing to identify query terms which yield the most relevant papers. The resulting chemical list, which will be shared with regulatory agencies and the public, is an important step towards the assessment of potential test methods and the creation of internationally harmonized integrated approaches for the detection of chemical respiratory allergens. *Does not necessarily represent US EPA policy*.

1812 Maternal Arsenic Exposure Modulates Microglial Activation, Proliferation, and Phenotypic Transition in Developing Mouse Brain

J. A. Ansari[1,2], S. Kushwaha[1,2], S. K. Mishra[1], and D. Ghosh[1,2]. *[1]CSIR-Indian Institute of Toxicology Research, Lucknow, India; and [2]AcSIR, Ghaziabad, India.* Sponsor: K. Ansari

Arsenic (As) is a famous environmental toxicant and more than 200 million people worldwide are exposed to As. As is a known human carcinogen and its carcinogenic and systemic toxicity have been extensively studied. As can easily pass through blood-placenta and blood-brain barrier. As exposure alters cognitive function, particularly learning and memory during Childhood. However effects of As on microglia in developing brain have not been studied. Microglia originates from embryonic yolk sac in early embryonic days and colonizes neuroepithilium. In early postnatal development microglia has amoeboid morphology which is mitotically very active. During third postnatal week microglia attain the desired number, their proliferation reduces and transform into ramified morphology. In case of chronic maternal immune activation they cannot transformed into ramified shape. Runx1 is a key regulator of myeloid cell proliferation and differentiation in the postnatal brain. It inhibits microglia proliferation and promotes progression to ramified state. In this study we investigated the effect of arsenic on proliferation and phenotypic transition of microglia in developing brain upon maternal As expo-

sure. Female Balb/c mice were exposed 0.38 mg/kg sodium arsenite ($NaAsO_2$ from GD5 to PND22) through oral gavage. RTqPCR and western-blot were performed to detect expression of microglia phenotypic marker. Maternal As exposure induced the expression of amoeboid phenotype marker (CD86) in primary microglia as well as maternally-exposed developing brain. We have also found that maternal As exposure increased the level of secretary molecule like ROS and NO. As also altered the level of Chemokine, (RANTES, MIPα, MIP1β) and cytokines (IL1α, IL6 and TNF α) secretion determined by multiplex assay. RTqPCR, Western-blot and Immunoflorescence analysis showed that As induces the microglia activation (CD68), proliferation (CSF1R) and also induces the expression of RUNX1 in developing brain. These findings suggest that chronic maternal exposure to As altered microglial activation, proliferation and phenotypic transition that may lead to neurodevelopmental disorder.

1813 Comparative Effects of Exposure to Whole Cigarette Smoke and Tobacco Heated Vapor in Jurkat T Cells

P. Scharf, G. H. Rocha, S. Sandri, C. S. Heluany, and S. H. Farsky.
Universidade de São Paulo, São Paulo, Brazil. Sponsor: S. Barros

Cigarette smoking is a challenge for public health systems and government agencies, linked to high mortality rates worldwide. Cigarette toxicity is due to its combustion, which releases chemical compounds capable of damaging human physiology and leading to homeostasis imbalance. Among other toxic effects, conventional cigarette smoking is known to impair immune responses and the biological functions of cellular components, such as T lymphocytes, which are a major subset of immune cells responsible for mediating adaptive immunity. The effects of cigarette smoking on T cells are linked to either development or aggravation of diseases such as rheumatoid arthritis, ulcerative colitis and chronic obstructive pulmonary disease. Thus, non-combustible cigarettes ("heat-not-burn") have been developed aiming at reducing the toxic effects due to use of tobacco products, but data in scientific literature on their immunotoxic effects are still scarce. In the present work, we investigated the effects of exposure to cigarette smoke and tobacco heated vapor on T lymphocytes. For such, Jurkat cells were exposed to either cigarette smoke or heated tobacco vapor in an *in vitro* system composed of an air-liquid interface; in a exposure chamber coupled to peristaltic pumps, the cells were exposed to either smoke or vapor for 30 minutes in cycles of 2 second followed by 58 seconds of airflow. Cells were also co-stimulated with phorbol myristate acetate (PMA) to determine whether exposure to smoke or tobacco vapor could exacerbate the parameters evaluated in an inflammatory context. The viability of cells when exposed to cigarette smoke, stimulated or not with PMA, decreased significantly when compared to cells exposed to heated tobacco vapor or to airflow. Oxidative (reactive oxygen species and nitric oxide) and inflammatory (tumor necrosis factor alpha, interleukin 8, and interferon gamma) mediators were elevated in the cigarette-exposed groups compared to the heated tobacco vapor and airflow groups. Therefore, exposure to heated tobacco vapor caused less cytotoxic effects on Jurkat cells in comparison to conventional cigarette smoke.

1814 P,p'dde Exposure Modulates Nitric Oxide Production and Arginase Activity in Bone Marrow-Derived Macrophage from Mouse

V. Cortés-Montoya, C. D. Ortíz-Robles, and E. S. Calderón-Aranda.
Cinestav, Mexico City, Mexico. Sponsor: I. Hernández-Ochoa

The Stockholm Agreement (2013) and the World Health Organization (WHO) allow using restricted for the DDT for disease vector control purposes. The Mexican population remains exposed to this compound and its metabolites, such as p,p'-DDE, the most persistent due to its lipophilicity. The DDT produces adverse effects on the endocrine, nervous, and immune systems, and it has been classified as a possible carcinogen by the IARC. Exposure to p,p'-DDE high levels are associated with systemic Lupus erythematosus, and in exposed individuals, elevated levels of IL-4 and Th2 cytokines, and decrement f Th1 cytokines have been observed in plasma, as well as increased lower respiratory tract infections. In macrophages of mouse cell lines, p,p'-DDE inhibits the ability to limit intracellular growth of *Mycobacterium microti* and yeast while increases the number of macrophages in adipose tissue. The objective of this study was to evaluate the effect of p,p'-DDE on macrophage's polarization to M1 and M2 phenotypes. The bone-marrow-derived macrophage (BMDM) was exposed to 0.125, 1.25, and 2.5 micrograms p,p'-DDE /mL and activated with cytokines: IFN-gamma /LPS (to M1) or IL-4/IL-13 (to M2). The p,p'-DDE exposure starts 12 h before the activation, and it remains until the end of the assays. Cell viability was assayed by MTT. Effects on the macrophages functionality were determined through a) the inflammatory phenotype was by the nitric oxide (NO) production, and b) by Arginase enzyme activity as a marker of the tissue repair. In macrophages activated with IFN-gamma /LPS, the p,p'-DDE does not affect the cell viability, significantly decreases the NO production, and does not affect the arginase activity at 72 h. In macrophages activated with 1L-4/IL-13, the p,p'-DDE does not affect the cell viability, neither the NO production, but significantly augments the arginase activity at 72 h. The effect of the p,p'DDE on other markers of macrophage M1 and M2 and the potential mechanisms by which the p,p'-DDE modulated this polarization of macrophages, is currently evaluated. *The study is funded by the Mexican Council for Science and Technology (Conacyt 32913).*

1815 Altered Immune Cell Migration Kinetics Contribute to Sex-Dependent Influenza Pathology in Arsenic-Exposed Adult Mice

S. E. Attreed[1], C. M. Kashiwagi[2], K. A. Rychlik[1], E. J. Illingworth[1], T. Howard[1], S. L. Klein[1], C. D. Heaney[1], and F. C. Sille[1]. [1]*Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; and* [2]*Stanford Medicine, Stanford, CA.*

Inorganic arsenic (iAs) is a common drinking water contaminant and immunotoxicant associated with increased risk of infection. Respiratory infections like influenza A virus (IAV) remain among the top ten causes of death worldwide. We previously demonstrated increased IAV susceptibility in iAs-exposed mice, with females suffering greater morbidity and mortality than males. Females exposed to iAs exhibit a cytokine storm in the lungs at 3 days post challenge (DPC), but maintain higher lung viral titers by 9 DPC compared to control females and dose-matched males. However, it is still unknown how iAs exposure modulates immune cell infiltration and kinetics in both the mediastinal lymph nodes and lungs during infection and how this contributes to sex-specific pathology. We hypothesize that exposure to iAs skews the immune response in a sex-specific manner, contributing to the increased pathology and mortality observed in females. After 5-wks of 0 or 10 ppb iAs (sodium meta-arsenite) drinking water exposure, C57BL/6 mice were intranasally infected with a mildly lethal dose of mouse-adapted A/California/04/2009 [ma2009]. Results demonstrate that exposure to iAs causes significant changes in immune infiltration kinetics by 3 DPC. Cell counts reveal fewer cells in both the mediastinal lymph nodes (p=0.077) as well as the lungs (p<0.05) of males compared to control females. In both males and females exposed to 10 ppb iAs, CD4:CD8 T cell ratios in the lungs are non-significantly reduced at 3 DPC (p<0.10). Additionally, the median fluorescence intensity (MFI) of CD86 is significantly increased in the cells of *ex vivo* stimulated MHCII+ and MHCII- endothelial cells from the lungs of 10 ppb iAs-exposed females compared to control females and dose-matched males (p<0.05). This effect is also true of control females when compared to control males in the same cell populations (p<0.001). We are currently investigating how iAs exposure modulates B cell and innate immune cell populations at 3 DPC and how all of these populations continue to shift by 9 DPC. Our data suggest that sex-dependent immunomodulatory effects of iAs drive influenza infection pathology. These results help elucidate the increased respiratory pathology seen in epidemiological studies of individuals heavily exposed to drinking water iAs. *Funding: 5T32HL007534-37 (SEA).*

1816 The Interplay between Dietary Indole-3-carbinol, Th17 Cells, and the Microbiota in the Gut Influences T1D Development

H. M. Kahalehili[1], J. M. Pennington[2], N. I. Kerkvliet[2], and A. K. Ehrlich[1]. [1]*University of California Davis, Davis, CA; and* [2]*Oregon State University, Corvallis, OR.*

For nearly the past two decades, there has been a steady increase in the incidence of type 1 diabetes (T1D), an autoimmune disease that causes the destruction of insulin-producing beta cells. Susceptibility to T1D has been attributed to both genetic and environmental factors; however genetic predisposition alone cannot explain this rise. Understanding how environmental factors impact the immune response in individuals who are genetically susceptible to T1D can help in developing prevention methods. Primary interactions between the environment and the host immune system occur at mucosal sites, where both the diet and the microbiome have been identified as potential risk factors for T1D. One connection between the diet and the microbiome is the aryl hydrocarbon receptor (AhR), a ligand activated transcription factor that modulates the expression of metabolizing enzymes (e.g. Cyp1a1) as well as immune genes. To better understand the extent by which a dietary AhR ligand can modify T1D development, we fed NOD mice a synthetic diet supplemented with 2000 ppm indole-3-carbinol (I3C; equivalent to 250 mg/kg/day). I3C is found in cruciferous vegetables such as broccoli, kale, and brussels sprouts. I3C highly activated AhR in the small intestine, as measured by Cyp1a1. AhR was also induced systemically, although to a much lower extent. Critically, after 5 weeks of supplementation, I3C increased

the degree of insulitis. To identify the mechanisms by which I3C may modulate the development of insulitis, we isolated the spleen, pancreatic draining lymph nodes, Peyer's patches, small intestine intraepithelial lymphocytes, and small intestine lamina propria lymphocytes and analyzed T-cell subsets (Th1, Th17, Foxp3+Tregs and Tr1). Dietary I3C did not alter these populations in the spleen, pancreatic draining lymph nodes, or intraepithelial lymphocytes. CD4+RORγt+Foxp3- (Th17 cells), however, were increased in both the lamina propria and Peyer's patches. Th17 cells significantly and positively correlated with the severity of insulitis in mice treated with dietary I3C. A follow-up study confirmed that the increase in CD4+RORγt+Foxp3- also corresponded with an increase in IL-17-producing T-cells in the lamina propria. Stool samples were taken prior to treatment and throughout the study for 16s rRNA sequencing. Data are currently being analyzed to predict networks connecting bacteria, intestinal Th17 cells, and insulitis.

PS 1817 Propylene Glycol/Vegetable Glycerin and Menthol-Flavored E-cigarette Aerosol Induced Strain and Sex-Dependent Immune Toxicity in Mice

T. M. Muthumalage, I. K. Sundar, and I. Rahman. *University of Rochester, Rochester, NY.*

Flavored e-cigarettes (e-cig) have become popular among teenagers in recent years. Due to flavor bans, the regulatory agencies are not sure about including menthol flavors among the other e-cig flavors that need to be banned. We have previously shown that menthol flavor induces reactive oxygen species and inflammation *in vitro* in human lung cells. In this study, we hypothesized that menthol-flavored e-cigarettes differentially affect the immune-inflammatory response in a strain and sex-dependent manner. C57BL/6J and BALB/cJ strains (male and female; n=4/group) were exposed to e-cig aerosols containing PG/VG (50:50) or menthol (Ecto 0 mg/ml and 24 mg/ml nicotine) for two hours/day for 3 days using the Scireq inExpose exposure system [Puff profile: 2 puffs/min, 70 ml puff volume]. Similarly, mice were also exposed to tobacco flavored e-cig aerosols for comparison with menthol-flavored e-cigs. Differential cell counts and inflammatory mediators were measured in bronchoalveolar lavage (BAL) fluid. Acute exposure to e-cig aerosol containing PG/VG, menthol without nicotine, and menthol with nicotine increased the total cell counts in the BAL fluid in male and female of both mouse strains. PG/VG exposure caused the highest infiltration of total cell counts in the BAL fluid. Neutrophil counts were increased in both PG/VG and menthol (0 or 24 mg/ml) exposed both male and female BALB/cJ mice. $CD4^+$ T-lymphocyte counts were altered in PG/VG and menthol with and without nicotine exposed BALB/cJ mice. Most significant changes in the differential BALF cell counts were observed in male BALB/cJ compared to C57BL/6J (male and female) mice. E-cig aerosol containing PG/VG and menthol (0 and 24 mg/ml) differentially affect inflammatory cytokines, such as MCP-1, IFNγ, KC, TNFα, RANTES, and Eotaxin in both the mouse strains compared to air group control. Further, we compared the effects of tobacco vs. menthol-flavored e-cig aerosols with and without nicotine to determine the difference in their respiratory toxicity. E-cig exposure containing PG/VG alone and menthol without nicotine induced chemotaxis such as neutrophilia and inflammatory response that may be predominantly Th1 driven. Nicotine differentially affects chemotaxis, inflammatory mediators, and increased susceptibility to immune-toxicity in menthol exposed male compared to female mice. *This study was supported by NIH R01HL135613 and U54CA228110.*

PS 1818 Lead Exposure Modulates TNF-alpha Secretion and Arginase Activity in Macrophage J774A.1

C. D. Ortiz-Robles, and E. S. Calderón-Aranda. *Cinestav, Mexico City, Mexico.* Sponsor: I. Hernández-Ochoa

Lead is a potent toxic metal naturally present in the earth's crust. The extensive and continual use of lead has resulted in high pollution. The exposition to lead induces significant public health problems, alteration in the organ functioning, including dangerous effects on the immune system. The macrophages are targeted by lead, resulting in increased susceptibility to infections. The macrophages have a crucial role in immunity against intracellular pathogens and are responsible for leading the beginning (M1 phenotype), regulation and resolution of the inflammatory process and tissues reparation (M2 phenotype). The goal of this study was to evaluate the effect of lead on the macrophage's polarization to M1 and M2 phenotypes. The murine J774A.1 macrophage was exposed to 0.01, 0.05, 0.1, 0.25, 5, and 10 µg/dl lead acetate and activated with cytokines: INF γ/LPS (to M1) or IL-4/IL-13 (to M2). Lead exposure starts 24 h before the activation, and it remains present until the end of assays. Cell viability was assayed by MTT. Effects on the macrophages functionality were determined through a) the production of nitric oxide ($NO^•$) and secretion of TNF-alpha (markers of inflammation), b) the secretion of IL-10, and by arginase enzyme activity, needed to the synthesis of collagen precursors (markers of the tissue repair). At any lead concentration, was detected cytotoxic effects. On cells activated with INFγ/LPS, the lead did not alter $NO^•$ production, significantly decreased TNF-alpha secretion, whereas IL-10 levels and arginase activity were not modified. In cells activated with IL-4/IL-13, the lead did not alter levels of $NO^•$; however, it significantly increases arginase activity. Currently, the lead effect on TNF-alpha and IL-10 is being evaluated in this experimental condition. Overall, data suggest that lead partly decrease the inflammatory function of macrophages, causing a harmful modulation of the TNF-alpha secretion, while in response to the tissue repair stimulus, it increases the arginase activity and, consequently, the proline production. The mechanisms by which lead modulated the polarization of macrophages phenotypes should be further evaluated. *This study was partially funded by a grant from the Mexican Council for Science and Technology (Conacyt 152491).*

PS 1819 Assessment of the Impact of Aerosol from Heated Tobacco Compared with Cigarette Smoke on Experimental Rheumatoid Arthritis

C. S. Heluany[1], P. Scharf[1], A. H. Schneider[2], P. B. Donate[2], F. Q. Cunha[2], and S. H. Farsky[1]. *[1]Universidade de São Paulo, São Paulo, Brazil; and [2]Universidade de São Paulo, Ribeirão Preto, Brazil.* Sponsor: S. Barros

Cigarette smoke (CS) is the leading environmental risk factor for many diseases and promotes the initiation as well as the aggravation of rheumatoid arthritis (RA), a chronic autoimmune disease. Alternative modified-risk tobacco products are being developed to provide substitute products for smokers who are unable or unwilling to quit. Among then, heat-not-burn tobacco products generate reduced yields of toxicants compared with cigarettes and hold great potential for reducing the harms associated with cigarette use. Here we aimed to investigate and compare the effects of CS exposure and the aerosol from heated tobacco on an experimental RA model. Male adults C57BL/6 mice were exposed to synthetic air (control), heated tobacco (heatstick HEETS, PMI) or commercial cigarettes (Marlboro, PMI) in a smoking chamber (6 animals/chamber) for 1 hour, 2 times/day, during the developmental phase of antigen-induced arthritis, between days 14 to 20. Mice were exposed to 24 cigarettes or 48 HEETS per day. Mice were injected s.c. on day 0 with 500 µg of mBSA with CFA, and boosted on day 7 and 14 with mBSA in IFA. On day 21, mice were challenged by i.a. injection of mBSA (10 µg) into the knee joint and after 24 h, inflammation was assessed by measuring edema, neutrophil migration to the joints, mechanical articular hyperalgesia, and changes in the frequencies of cells from draining lymph nodes (DLNs), spleen, plasma and bone marrow. We found that heatstick aerosol, compared with CS, demonstrated lower impact on the disease onset, observed by reduced joint swelling, mechanical articular hyperalgesia and neutrophil infiltration to the joints. Moreover, heatstick exposure did not alter the frequencies of cells in the plasma, bone marrow and spleen in comparison to the control group. However, heatstick aerosol increased the number of eosinophils in the plasma, and similar to observed from CS exposure, heatstick exposure reduced the number of cells from DLNs and the number of blasts in the bone marrow. In conclusion our data confirm the harmful effects of cigarette smoke on the RA progression and aggravation and provides novel evidence surrounding the heated tobacco products as a possible alternative to reduce the smoking-related health risks, mainly in chronic diseases.

PS 1820 The Kinetic Direct Peptide Reactivity Assay (kDPRA): An *In Chemico* Method to Characterize the Skin Sensitization Potency of Chemicals

B. Wareing[1], A. Natsch[2], S. Kolle[1], B. Birk[1], N. Alepee[3], T. Haupt[2], R. Kathawala[4], P. Kern[5], L. Nardelli[3], H. Raabe[4], M. Rucki[6], C. Ryan[7], S. Verkaart[8], W. Westerink[8], and R. Landsiedel[1]. *[1]BASF SE, Ludwigshafen am Rhein, Germany; [2]Givaudan Schweiz AG, Dübendorf, Switzerland; [3]L´Oréal Research and Innovation, Paris, France; [4]Institute for In Vitro Sciences Inc., Gaithersburg, MD; [5]Procter & Gamble, Brussels, Belgium; [6]National Institute of Public Health, Prague, Czech Republic; [7]Procter & Gamble, Cincinnati, OH; and [8]Charles River, Den Bosch, Netherlands.*

While the skin sensitization hazard of substances can readily be identified using non-animal methods, the classification of potency into UN GHS sub-categories 1A and 1B remains challenging. The kinetic direct peptide reactivity assay (kDPRA) is a modification of the DPRA (OECD TG 442C) wherein the reaction kinetics of a test substance towards a synthetic cysteine-containing peptide is evaluated. For this purpose, several concentrations of the test substance are incubated with the synthetic peptide for several incubation times at 25°C. After the respective incubation time, the reaction is stopped by ad-

dition of the fluorescent dye monobromobimane (mBrB). The highly reactive and non-fluorescent mBrB rapidly reacts with unbound cysteine moieties of the model peptide to form a fluorescent complex. The remaining non-depleted peptide concentration is determined thereafter by fluorescence measurement at defined time points. Kinetic rates of peptide depletion are then used to distinguish between two levels of skin sensitization potency, i.e. to discriminate between UN GHS sub-categories 1A and 1B. In this study, we present a ring trial study of the kDPRA 24 blind-coded chemicals in seven labs. The intra- and inter-laboratory reproducibilites were 96% and 88%, respectively (both differentiating UN GHS Cat 1A sensitizers from UN GHS Cat 1B/ not classified). The extension of the kDPRA database substances to further assess the predictive capacity of the assay resulted in 88% sensitivity and 87% specificity to identify UN GHS Cat 1A sensitizers in comparison to LLNA data (167 substances) and 63% and 88% in comparison to human data (85 substances), respectively. Besides UN GHS Cat 1A identification, the kDPRA can be used as a part of defined approach(es) with a quantitative data integration procedure for skin sensitization potency assessment.

1821 Sparstolonin B, a TLR4 Antagonist is a Prime Candidate to Combat Systemic Inflammation and Restore Gut Health in GWI Mouse Models

D. Bose[1], D. Kimono[1], S. Sarkar[1], P. Saha[1], M. Albadrani[1], A. Mondal[1], R. Seth[1], K. Sullivan[2], P. Janulewicz[2], M. Nagarkatti[1], P. Nagarkatti[1], R. Horner[1], N. Klimas[3], and S. Chatterjee[1]. *[1]University of South Carolina, Columbia, SC; [2]Boston University School of Public Health, Boston, MA; and [3]Nova Southeastern University, Fort Lauderdale, FL.*

Gulf War Illness is a group of medically unexplained symptoms that was found to affect the veterans of the Persian Gulf War in 1991, due to exposure to toxic chemicals like Pyridostigmine bromide, Permethrin during the war theater. We have shown in our previous studies that administration of Gulf War (GW) chemicals in mouse model has resulted in gut leaching which causes portal endotoxemia that leads to upregulation of toll like receptor 4 (TLR4) receptors in small intestine. We have also found that Sparstolonin B (SsnB), a compound isolated from Chinese herb *Sparanganium stoloniferum* to be a potent TLR4 antagonist. In this study, we wanted to test in murine models whether administration of GW chemicals leads to TLR4 mediated inflammasome activation and to investigate the potential of SsnB in decreasing the inflammasome activation and restoring systemic inflammation through immunofluorescence and western blot. We found that the expression and recruitment of TLR4 in lipid rafts of intestinal epithelium was higher in GW chemical treated group which was decreased when treated in combination with SsnB. Increased expression of NLRP3/ASC and NLRP3/Caspase1 and IL-1β was observed in GW treated group which clearly indicated the activation of inflammasome and upregulation of proinflammatory cytokine suggesting inflammation. This inflammasome activation and expression of proinflammatory cytokine was significantly decreased in groups treated with SsnB and GW chemicals. We further tested our hypothesis in intestinal epithelial cells (IEC-6) the results for which corroborated with our *in vivo* results. Interestingly, we found that IEC-6 cells treated with LPS and acetylated SsnB, a pseudo inactivated drug showed results similar to LPS treated cells which provide the proof of concept that SsnB indeed was causing the effect. In conclusion, SsnB can be proposed as a therapeutic candidate against GW chemical induced intestinal inflammation and to restore gut health. *Supported by DoD Grant W81XWH1810374 and VA Merit Award I01CX001923-01 to S.C.*

1822 Effects of *In Vitro* and *In Vivo* Inorganic Arsenic Exposure on Murine Bone Marrow-Derived Macrophages

E. Illingworth, K. Rychlik, H. Zhang, and F. Sillé. *Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.*

In many parts of the world, including the United States, inorganic arsenic (iAs) contaminates groundwater used for drinking, food production, and irrigation. The World Health Organization set a 10 µg/L safety limit for arsenic in drinking water, yet still as many as 140 million people worldwide are exposed to drinking water with arsenic contamination at levels above this threshold. Eliciting a broad range of adverse health effects, arsenic is a confirmed carcinogen by the IARC and also causes increased susceptibility to infectious diseases, indicating that arsenic affects the immune system. The purpose of this study is to elucidate the effects of arsenic on the innate immune system with *in vitro* and *in vivo* exposure models. Briefly, bone marrow-derived macrophages (BMDMs) were harvested from 8-12 week old adult C57/BL6 mice. These M0-BMDMs were dosed *in vitro* with different levels of iAs (0.0001 - 1 µM) during macrophage differentiation and stimulated with LPS and IFN-γ (for "M1" macrophage activation) or IL-4 and IL-13 (for "M2" macrophage activation). Supernatant was analyzed for nitric oxide (NO) production, as well as cytokine and lipid secretion. 50-plex cytokine analysis revealed differences between iAs-exposed and nonexposed macrophages, with and without stimulation. We saw decreases in TNF with increasing iAs doses applied to M1-BMDM cultures, indicating that iAs may skew macrophages to an immunosuppressive phenotype. Exposure to iAs *in vitro* alters M1-BMDM NO production, and targeted nonpolar lipid analysis of mouse M0-BMDMs exposed to iAs had increased expression of pro-oncogenic lipids that skew macrophages to the M2 phenotype. Preliminary data shows similarly suppressed cytokine profiles replicated in an *in vivo* model where adult C57/BL6 mice were chronically exposed to 1000ppb iAs for 6-8 weeks. These data collectively suggest that iAs affects macrophage polarization, and dysregulated macrophage polarization could lead to increased susceptibility to infectious agents and cancer. Further mechanistic investigation and pathway analysis will elucidate how iAs affects macrophage function and determine whether iAs exposure makes macrophages more tumorigenic. Research such as this contributes to our understanding of the full spectrum of adverse health effects of iAs exposure and may aid in the development of therapeutics for iAs-induced diseases like cancer. *Supported by NIEHS R00ES024808 (FS) and T32ES07141 (EI, KR).*

1823 Sex Differences in Trichloroethylene-Induced CD4 T Cell Subset Differentiation in Non-Autoimmune-Prone Mice after Developmental Exposure

S. J. Blossom. *University of Arkansas for Medical Sciences, Little Rock, AR.*

Autoimmune diseases are increasing as our society has become more industrialized. While genetic predisposition is important, most autoimmune diseases are driven by environmental factors such as trichloroethylene (TCE). TCE is a halocarbon known for its use as an industrial solvent and metal degreaser. TCE has contaminated water systems, is an occupational hazard, and has been linked to several autoimmune diseases and T cell hypersensitivity disorders in humans. Developmental exposure of TCE in the drinking water increased the generation of effector/memory IFN-γ- and IL-17-secreting $CD4^+$ T cells commensurate with autoimmune hepatitis in autoimmune-prone female MRL mice relative to untreated controls. The immune enhancing effects of TCE on non-autoimmune-prone mice (e.g., C57/BL6) have not been thoroughly examined. Because TCE can also promote autoimmunity and hypersensitivity reactions in men, we also sought to determine whether developmental TCE exposure *in vivo* promoted the differentiation of pathogenic effector Th1 and Th17 and/or the suppression of non-pathogenic iTregs in both sexes of C57 mice. Naïve CD4 cells were isolated from male or female C57/Bl6 mice and incubated for 5 days to induce Th cell subsets [e.g., Th1, Th2, Th17, and inducible regulatory T cells (iTregs)]. The results demonstrated that TCE skewed Th1, iTreg, and Th17 CD4 subset differentiation in a sex-dependent manner. Specifically, IFN-γ and its major transcription factor, T-bet, were more robustly modified by TCE exposure in female mice relative to males. However, autoimmune disease pathology was not observed in any of the mice, regardless of sex. These results show that CD4s from mice that are not genetically predisposed towards developing autoimmune disease are sensitive to TCE's effects. However, the development of immune pathology likely involves other mechanisms. Further study on how TCE alters epigenetic regulation of $CD4^+$T cells during differentiation will provide meaningful mechanistic data.

1824 The 2-Hydroxyiminostilbene Metabolite of Carbamazepine or the Supernatant from Incubation of Hepatocytes with Carbamazepine Activates Inflammasomes

R. Kato[1], Y. Ijiri[1], T. Hayashi[1], and J. Uetrecht[2]. *[1]Osaka University, Osaka, Japan; and [2]University of Toronto, Toronto, ON, Canada.*

Although the pathophysiology of carbamazepine-induced idiosyncratic or hypersensitivity reactions is unclear, they are presumed to be immune mediated and involve a complex interplay between drug metabolism and activation of the immune system. Reactive metabolites can cause cell damage with the release of damage-associated molecular patterns (DAMPs), which is thought to be involved in immune activation. Presumably the reason that the liver is a common target of idiosyncratic drug reactions is because it is the major site of drug metabolism and reactive metabolite formation. Inflammasomes can be activated by DAMPs, and this may be a common mechanism by which DAMPs initiate an immune response. In this study, we tested the ability of carbamazepine to induce the release of DAMPs that activate inflammasomes. Human hepatocarcinoma functional liver cell-4 (FLC-4) cells were used for bioactivation of carbamazepine. For detection of inflammasome activation we used the human macrophage cell line, THP-1 cells. We found that the supernatant from the incubation of carbamazepine with FLC-4 cells for 7 days led to increased caspase-1 activity and production of IL-1ß by THP-1 cells. In the supernatant of FLC-4 cells with carbamazepine, the heat shock protein (HSP) 60 was signifi-

cantly increased. In addition, 2-hydroxyiminostilbene, which is the metabolite of carbamazepine, activated inflammasomes of THP-1 cells. THP-1 cells whose inflammasome is activated increase high mobility group box 1 protein. These results support the hypothesis that the reactive iminoquinone metabolite can directly activate inflammasomes or it can cause the release of DAMPs from hepatocytes, which in turn, can activate inflammasomes. Inflammasome activation may be an important step in the activation of the immune system by carbamazepine, which in some patients can lead to hypersensitivity reactions.

1825 Potential Therapeutic Effects of Andrographolide in Attenuating Gut-Brain Inflammatory Surge in a Mouse Model of Gulf-War Illness

P. Saha[1], D. Bose[1], D. Kimono[1], A. Mondal[1], S. Sarkar[1], R. Seth[1], K. Sullivan[2], P. Janulewicz[2], M. Nagarkatti[1], P. Nagarkatti[1], R. Horner[1], N. Klimas[3], and S. Chatterjee[1]. *[1]University of South Carolina, Columbia, SC; [2]Boston University School of Public Health, Boston, MA; and [3]Nova Southeastern University, Fort Lauderdale, FL.*

Gulf war illness (GWI) is a chronic multisymptomatic disorder, which includes metabolic syndrome, gastrointestinal (GI) disturbances and neuroinflammation, that persists till date in affected veterans. Previously we reported that butyrate administration in mice with GWI decreased metabolic abnormalities and other GWI-associated symptoms. Most recently we found that a broad-spectrum antiviral drug has potent anti-inflammatory effects on GWI pathology. Andrographolide (AG), a labdane diterpenoid produced by the plant *Andrographis paniculata*, have a broad range of anti-inflammatory properties in various cell types. Currently, our lab studies the role of AG in combating gut and brain inflammation in GWI murine models. AG was selected based on its various beneficial effects which are crucial to overcome some of the toxicity associated with prolonged use of antiviral drugs. Adult C57BL/6J mice were exposed to GWI chemicals Pyridostigmine bromide and Permethrin for a week (GWT group) and treated with AG and Ribavirin (RB). Our results showed decreased expression of tight junction proteins Zona Occludin 1 (ZO1), Occludin, which significantly decreased in mice treated with AG alone or together with RB. Also, increased expression of Claudin-2 was observed, which is a signature of "leaky gut" in GWT models. Pro-inflammatory cytokine MCP1 expression was markedly decreased with RB, AG and combination of both in small intestine. These results indicate that AG alone or together with RB can provide increased protection from gut leaching in GWI mice model. Furthermore, our results showed that AG either individually or with RB significantly decreased the levels of CD11b, while increasing the levels of BDNF and blood brain barrier tight junction protein Claudin-5. This result clearly indicates that AG either singly or in combination had a significant impact in decreasing gut-associated inflammation and neurotoxicity and can be proposed as a potential therapeutic agent in GWI patients. *This study was supported by DoD Grant W81XWH1810374 and VA Merit Award I01CX001923-01 to S.C.*

1826 Single Cell Transcriptomics Reveals TCDD-Mediated Decrease in Gene Expression Associated with Erythropoiesis and Ribosomal Proteins in Early Phase of Human B Lymphopoiesis

D. M. Isha Olive Khan[1], P. W. Karmaus[2], A. Bach[1], R. B. Crawford[1], and N. E. Kaminski[1]. *[1]Michigan State University, East Lansing, MI; and [2]NIEHS, Durham, NC.*

Persistent aryl hydrocarbon receptor (AHR) activation impairs B cell development by mechanisms not fully understood. Single cell RNA-Sequencing (scRNA-Seq) was employed to study the effect of AHR activation by 1 nM 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) on early stages (7 days of culture) of B lymphocyte development. An *in vitro* culture system supplemented with cytokines that drive B cell development from human cord blood derived $CD34^+$ hematopoietic stem and progenitor cells (HSPCs) was used. The objective was to determine how TCDD treatment modulates gene expression in differentiating HSPCs and to identify cellular transcriptomic heterogeneity. Using machine learning algorithms, we identified distinct cellular clusters in the scRNA-Seq dataset characterized by unique gene expression patterns, defined in part by expression of the AHR transcriptional target *CYP1B1*. *CYP1B1* induction was 2-fold higher in TCDD treated vs vehicle (VH; 0.02% DMSO) group, but not all TCDD treated cells expressed *CYP1B1*, indicating cellular transcriptional heterogeneity. Interestingly, *CYP1B1* expression was observed in 30% of the cells in VH group, suggesting endogenous AHR activation. Cells with higher *CYP1B1* expression in both treatment groups were associated with higher (>3.5 fold) expression of *CD14*, suggesting CD14 as a surface marker for high *CYP1B1* expression. In total, 90 genes were differentially regulated (log fold change difference > 0.25, p value < 0.01) by TCDD treatment. TCDD downregulated ribosomal protein encoding genes (11) and genes associated with erythropoiesis including drastic reductions in *HBD*, *HBB* and *HBG2*. Irrespective of treatment, most cells expressing genes associated with erythropoiesis and ribosomal proteins expressed 4-fold lower *CYP1B1* induction, suggesting that AHR activity is antagonistic to expression of these genes. This study demonstrates the presence of AHR activity in differentiating HSPCs, allows characterization of cells that are heterogeneous in AHR activity, and shows that genes associated with erythropoiesis and ribosome formation are suppressed by AHR activation early during B cell development. Further time course studies using scRNA-Seq will elucidate TCDD's effect on the cellular developmental trajectory from HSPCs to B cells.

1827 Alterations in the Mouse Skin and Gut Microbiome and Skin Integrity following Dermal Exposure to the Antimicrobial Chemical Triclosan

R. Baur, N. B. Marshall, E. Lukomska, L. M. Weatherly, H. L. Shane, and S. E. Anderson. *CDC/NIOSH, Morgantown, WV.*

It is increasingly being recognized that the microbiome plays an important role in human health. Dysbiosis of the microbiome has been shown to alter immune responses and has been associated with increased risk of allergic disease. Triclosan is an antimicrobial chemical used in the healthcare field as a high level disinfectant. In humans, triclosan exposure has been associated with an increase in food and aeroallergy and asthma exacerbation. Although not directly sensitizing, dermal exposure to triclosan has been shown to augment allergic responses to experimental allergens in mouse models. However, the impact of dermal exposure to antimicrobials, such as triclosan, on the microbiome and skin integrity is unknown. This study investigated the impact of dermal exposure to triclosan on the skin and gut microbiome and on the skin integrity in mice. Mice were dermally exposed to 2% or 3% triclosan or acetone vehicle control once daily for either 7 or 28 consecutive days. Swabs were used to collect skin commensal bacteria prior to exposure and over the course of the exposure period. Following the final triclosan exposure, skin was collected to assess expression of skin integrity genes and fecal pellets were collected to assess gut commensal bacteria. Following bacterial DNA extraction from skin swabs and fecal pellets, composition of the skin and gut microbiota was determined by 16S rRNA gene sequencing. Triclosan exposure decreased the relative abundance of Proteobacteria and increased the abundance of Firmicutes, specifically the families Lachnospiraceae and Ruminococcaceae, on the skin. Triclosan exposure also led to increased abundance of Lactobacillaceae in the gut. Seven days of triclosan exposure altered the expression of two skin integrity genes, filaggrin 2 and keratin 14, in the skin. Taken together, dermal exposure to triclosan altered the composition of commensal bacteria in both the skin and gut of mice and altered the expression of skin integrity genes, suggesting that triclosan can both induce dysbiosis of the microbiome and alter skin integrity and that this may contribute to the observed alternations in immune function.

1828 Effects of THC and CBD Treatment on IL-1β Secretion in TLR7- and TLR8-Stimulated Monocytes from HIV-Negative and HIV-Positive Subjects

S. Sermet, M. D. Rizzo, A. Bach, J. R. Marty, R. B. Crawford, P. G. Gulick, and N. E. Kaminski. *Michigan State University, East Lansing, MI.*

Δ^9-tetrahydrocannabinol (THC) and cannabidiol (CBD) are two immune modulating cannabinoids present in *Cannabis sativa*. THC is the primary psychotropic constituent, acting on CB1 receptors in the central nervous system and CB1 and CB2 receptors on immune cells. CBD, is non-psychotropic and possesses low affinity for both CB1 and CB2 receptors. The primary molecular target by which CBD mediates biological activity has yet to be identified. Cannabis is commonly used by human immunodeficiency virus (HIV)-infected individuals, with a prevalence of about half of those afflicted. Previous research has shown that THC and CBD can have immunosuppressive and anti-inflammatory properties. Here we report on the immune modulating activity of THC and CBD in activated monocytes, when stimulated through various toll-like receptor (TLR) pathways. The objective of this study was to determine the effects of THC and CBD on monocyte IL-1β secretion in HIV- and HIV+ individuals when activated through TLR7 and TLR8 pathways. When activated through TLR7 by R837, monocytes isolated from HIV- and HIV+ donors showed similar IL-1β secretion profiles. THC treatment in combination with R837 resulted in a concentration-dependent decrease in monocyte IL-1β secretion, while CBD augmented secretion. Stimulation through TLR8 by ssRNA40, also showed a concentration-dependent decrease in IL-1β secretion from monocytes isolated from both HIV- and HIV+ donors. Interestingly, CBD

had no effect on IL-1β secretion in ssRNA40 activated HIV- monocytes, while modestly decreasing secretion in HIV+ monocytes. In summary, CBD exhibited differential effects on monocyte-derived IL-1β depending on whether the monocytes were activated via TLR7 or TLR8, where as THC suppressed IL-1β responses to both TLR7 or TLR8 activation. *Supported by NIH R01-DA047180.*

1829 Regulation of STAT3 but Not STAT1 Signaling in Human Naïve B Cells by TCDD-Mediated Alteration of the SHP-1/PP2a Signaling Axis

L. K. Blevins, R. B. Crawford, and N. E. Kaminski. *Michigan State University, East Lansing, MI.*

2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD) is a persistent environmental contaminant formed as a by-product of organic synthesis and incineration of organic materials. TCDD has potent immunotoxic effects in B lymphocytes resulting in decreased cellular activation and suppressed IgM secretion following activation with CD40 ligand. Previous work from our lab demonstrated that TCDD treatment of naïve human B cells resulted in significant increases in the levels of the tyrosine phosphatase SHP-1 which, corresponded with suppression of IgM secretion. STAT proteins are critical mediators of immune cell activation and effector function via their phospho-regulation. STAT3 is critical for B cell activation and secretion of immunoglobulins (Ig). STAT3 can form homodimers or heterodimers with STAT1, another critical mediator of interferon mediated immune cell signaling and translocate to the nucleus following phosphorylation as a result of cytokine receptor signaling. We hypothesized that TCDD-mediated increases in SHP-1 could result in decreased STAT3 tyrosine phosphorylation. While we found no alteration of STAT3 or STAT1 tyrosine phosphorylation, there were significant reductions in levels of STAT3 but not STAT1 serine phosphorylation as early as 12 hours following activation. These results corresponded to decreased STAT3-mediated gene transcription and increased PP2a activity, a serine specific phosphatase, which is known to be regulated by SHP-1. Lastly, pharmacological inhibition of SHP-1 phosphatase activity restored IgM secretion and STAT3 serine phosphorylation in TCDD-treated B cells while decreasing PP2a activation. Together, these data highlight a potential mechanism for TCDD suppression of Ig secretion and demonstrate the potential of inhibition of SHP-1 phosphatase activity as a means to reverse this effect in primary human B lymphocytes. *Support in part by R01ES002520.*

1830 Thirty-Day Toxicological Assessment of Perfluoroether Acids (PFEAs)

T. L. Woodlief, S. A. Vance, Q. Hu, and J. C. DeWitt. *East Carolina University, Greenville, NC.*

Perfluoro-2-methoxyacetic acid (PFMOAA), perfluoro-2-methoxypropanoic acid (PFMOPrA), and perfluoro-4-methoxybutanioc acid (PFMOBA) are per- and polyfluoroalkyl substances (PFAS) structurally considered perfluoroether acids (PFEAs) as they contain an oxygen in between the carbon chains. Some PFEAs have replaced the longer carbon chain compounds perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). Recently, these compounds have been identified in surface waters used as drinking water sources for several communities within the state of North Carolina. While the toxicity of PFOA and PFOS have been well characterized in animal models and epidemiological studies of humans, to our knowledge, no toxicological data exist in the publicly available literature for PFMOAA, PFMOPrA, and PFMOBA. Therefore, the present studies sought to describe signs of toxicity following 30 days of exposure to various oral doses of these compounds. Adult male and female C57BL/6 mice (6-8 weeks old) were exposed by gavage once/day for 30-days to PFMOAA at 0mg/kg, 0.00025mg/kg, 0.025mg/kg, or 2.5 mg/kg, or to PFMOPrA or PFMOBA at 0 mg/kg, 0.5 mg/kg, 5 mg/kg, or 50 mg/kg. Endpoints collected included in-life observations, organ weights, immunophenotype of lymphoid organs, and liver peroxisome proliferation. At doses administered, no differences were detected in terminal body weight, liver, spleen or thymus weights. Some shifts in immune cell populations were observed within male and female spleen and thymus in response to PFMOAA and within female thymus in response to PFMOBA. Male spleen B and NK cells were increased by ~83% and ~97%, respectively in response to PFMOAA at 2.5 mg/kg. PFMOBA induced a ~50% increase in peroxisome proliferation in the females at 50 mg/kg, while PFMOAA induced a ~25% increase in peroxisome proliferation in females exposed to 2.5 mg/kg. Exposure to PFMOPrA did not affect any of the measured parameters at any of the administered doses. These results indicate that these "understudied" PFAS discovered in North Carolina have toxicological potential that require additional investigation. Ongoing studies are evaluating the ability of these compounds to affect immune function, a sensitive endpoint associated with exposure to PFAS.

1831 Difference in Cellular Immune Functions between Broiler Chicken Husbandry and Grape Orchard Workers

Y. Heo[1], A. Maharjan[1], J. Jo[1], C. Kim[1], S. Yang[1], M. Acharya[1], R. Gautam[1], S. Sin[2], M. Ahn[2], and H. Kim[3]. *[1]Daegu Catholic University, Gyeongsan, Korea, Republic of; [2]National Institute of Agricultural Sciences, Wanju, Korea, Republic of; and [3]Catholic University of Korea, Seoul, Korea, Republic of.*

Exposure to organic dust, especially in animal husbandry environment, is recognized to affect farmer's health associated with respiratory illness. Orchard farm workers are exposed to various toxic substances including organic dust, agrochemicals, or physical hazards such as ultraviolet irradiation, but little is known about the immune modulation to orchard farmers. This study aimed to compare the general immunity of orchard farmers with broiler chicken farmers. Blood taken from the chicken or grape orchard workers was subjected to plasma IgE and IgG subclass measurements. Isolated blood mononuclear cells (PBMC) were stimulated and cytokine production was measured. Respirable dust levels were determined at each indoor (chicken farms) or outdoor workplace (grape orchards). Fifteen male and 4 female orchard workers (age: 65±8) and 11 male and 6 female chicken husbandry workers (age: 59±12) participated. Respirable dust level was higher in the chicken confinement buildings (mean 119 μg/m^3) than the grape orchard workplace (61 μg/m^3). Regarding the skewedness toward type-2 helper T cell immune reactivity, interleukin (IL)-4:interferon (IFN)-γ and IL-13:IFN γ ratios were significantly higher to the orchard workers than the chicken farmers. Level of IgE, frequently cited as a humoral allergic marker, was significantly higher to the orchard farmers than the chicken farmers. Proportions of $CD8^+$ cytotoxic T cell, $CD3^-CD16^+CD56^+$ natural killer cell, and $CD19^+$ B cell were lower to the orchard workers than the chicken husbandry workers. Considering the differences in the immune parameters, and no significant difference in age and gender composition, immune homeostasis are apparently disturbed in the orchard farmers compared to the chicken farmers. Further investigation with enough number of study subjects is needed for generalization of those findings. *Supported by Rural Administration Agency PJ014269022017.*

1832 Effects of IL-4 Administration or Zinc Supplementation on Thymic Fat in Zinc Deficient Rats

T. Kido, E. Hachisuka, M. Suka, M. Tsunoda, and H. Yanagisawa. *Jikei University School of Medicine, Tokyo, Japan.*

Nutritional zinc deficiency induces immune dysfunctions including inflammatory diseases. We previously demonstrated that the inflammation induced by zinc deficiency can be inhibited by IL-4 administration or recovered by zinc supplementation. Furthermore, the inhibition of this inflammation was also associated with reduced thymus atrophy. In the current study, we explored the involvement of PPAR-γ expression in thymus atrophy (thymic fat) in zinc-deficient rats. In addition, we examined whether the factors related to T cell maturation were affected by zinc deficiency. Five-week-old male rats were fed a standard diet (17 g/day), and two groups were fed a zinc-deficient diet (n = 7 each). Each group was also injected with saline or IL-4. Another group of rats were fed a zinc-deficient diet for 6 weeks and returned to the standard diet for 4 weeks thereafter. After the dietary manipulation, qRT-PCR was performed to estimate *PPAR-γ, IL-7, SCF*, and *TSLP* mRNA expression levels. Immunohistochemical staining for *PPAR-γ* was carried out on thymus tissue sections utilizing antibodies. The thymus was also pathologically examined by oil red O stain. Positive cells and areas were quantitated by image analysis. The number of PPAR-γ positive cells, PPAR-γ mRNA expression, and the oil red O positive area in the thymus was significantly higher in the zinc-deficient group compared to the others. mRNA expression of IL-7 in the thymus was significantly lower in the zinc-deficient group than in the other groups. However, mRNA expression levels of SCF and TSLP in the thymus was comparable among all groups. The number of PPAR-γ positive cells, PPAR-γ mRNA expression and thymic fat in zinc-deficient rats were increased. Therefore, the PPAR-γ appear to relate to thymic fat. Among factors involved in T cell maturation, IL-7 expression in the thymus of zinc-deficient rats was decreased. The decrease in IL-7 mRNA expression may be due to thymic fat. Also, the IL-4 administration or zinc supplementation did not increased the PPAR-γ expression, and thymic fat was not caused. It suggested that IL-4 administration or zinc supplementation inhibits thymic fat in zinc-deficiency.

1833 The Effects of Graphene and Other 2D Nanomaterials on Immune Toxicity

H. Lin, D. Ji, M. Lucherelli, and A. Bianco. *Université de Strasbourg, Strasbourg, France.*

Few-layer-graphene and other 2D-nanomaterials such as molybdenum disulphide have been gaining popularity in various biochemical and industrial uses as demand for such versatile and ground-breaking materials increases. It is therefore pertinent to investigate the toxicological impact of such materials on immune cells, which are the body's main line of defence. We focus on human peripheral blood monocyte-derived macrophages cultivated using both GM-CSF and M-CSF to better understand the effect of these materials, and have found minimal detriment to cell viability and macrophage surface marker expression, as well as an increase in autophagic flux using LC3-II western blotting. We also observed heterogeneity in material uptake using phase-contrast microscopy, which could augur patient-to-patient variability in cumulative exposure. With the results of our research, we hope to better shape the design of future graphene- and 2D-based nanomaterials for improved immune compatibility.

1834 Metabolic Syndrome Enhances Nanoparticle-Induced mTOR Signaling via Alterations in the Biocorona

L. Xia[1], S. Adamson[2], S. Alqahtani[1], L. Kobos[1], and J. Shannahan[1]. *[1]Purdue University, West Lafayette, IN; and [2]Procter & Gamble, Cincinnati, OH.*

Nanoparticles (NPs) interact with biomolecules forming a biocorona (BC) in biological environments. The BC impacts biological responses affecting NP biomedical applications. Metabolic syndrome (MetS) is a prevalent condition and results in the formation of unique BCs. In this study, we examined differential cell signaling that may occur in MetS by using the BC. Rodent cell lines (rat endothelial cells and mouse macrophages) and human relevant Fe3O4 NPs without or with BCs were utilized. NPs were incubated in water, 10% normal rat serum, or 10% MetS rat serum to form BCs. Endothelial cells were exposed to NPs for 3, 12, or 24 h and differential cell signaling was discovered using a RNA-Seq approach. Functional enrichment of the differentially expressed genes identified differential activation of pathways including DNA damage repair, oxidative stress, inflammation, and mTOR signaling. Examination of mTOR signaling demonstrated MetS BC enhanced phosphorylation of AKT and elevations in total and phosphorylated mTOR. Markers of apoptosis (cleavage of caspase-3 and cytochrome c levels) were increased only in cells exposed to NPs with a MetS BC. mTOR signaling induces apoptosis via inhibition of autophagy. Macrophages demonstrated decreased gene expression of LC3, a marker of autophagy, only in cells exposed to NPs with a MetS BC. Treatment with rapamycin, an inhibitor of mTOR, inhibited changes in LC3 expression. To understand up-stream regulation of mTOR, we utilized pharmacological inhibitors of scavenger receptors. CD36 was determined to be the primary facilitator of NP internalization and is increasingly expressed due to MetS. A CD36-specific ligand enhanced mTOR gene expression similarly to NPs with a MetS BC. A number of processes down-stream of mTOR (insulin sensitivity and lipogenesis) were uniquely altered by the MetS BC. Together these findings demonstrate that the formation of a BC within MetS may result in enhanced mTOR signaling due to increased scavenger receptor interactions leading to exacerbated responses and progression of MetS-associated diseases.

1835 miRNAs and Dendritic Cell Activation in Allergic Contact Dermatitis

V. Galbiati, A. Maddalon, M. Marinovich, and E. Corsini. *Università degli Studi di Milano, Milan, Italy.*

Allergic contact dermatitis (ACD) is an immunological mediated inflammatory disease and is one of the most common occupational disease in industrialized countries. Chemical allergy is of considerable importance to the toxicologist, who has the responsibility of identifying and characterizing the allergenic potential of chemicals and estimating the risk they pose to human health. While incredible progresses have been made in the development of non-animal tests, currently it is not possible to estimate the sensitizing potency of chemical allergens. The main aim of this project was to investigate if contact allergens of different potency are able to differently modulate miRNA expression, using only *in vitro* methods. Recent findings indicate that miRNAs may determine reprogramming of gene expression in target cells. Although ACD has been studied extensively, there are few studies conducted to investigate miRNA expression. Based on our preliminary results, and the working hypothesis that allergens of different potency induce different cellular activation, two contact allergens of different potency were selected: 2,4-dinitrochlorobenzene (DNCB - extreme) and imidazolidinyl urea (IMZ - weak), respectively extreme and weak contact allergens. THP-1 and subsequently, differentiated THP-1 (mature dendiritc cells - mDCs) cells were used as cellular lines. Additional experiments have been done with the microvesicles (MVs) released from THP-1 cells, always after exposure to extreme and weak contact allergens. Specific Array Panels for miRNAs screening were performed to evaluate the up and down regulation of these after cells treatment. Target genes and protein have been finally identified and confirmed. Results obtained shown a different miRNAs regulation induced by contact allergens of different potency in THP-1 cell. In particular, results obtained evaluating 6 selected miRNAs, based on literature research and miRNAs target databases, suggest an important role played by miR-27a-3p and miR-223-3p. From analysis of data obtained after differentiation and maturation of THP-1 cells, it is interesting to notice that immature dendritic cells (iDCs) exposed to the extreme contact allergen DNCB were able to induce a modulation of miRNA similar to mature dendritic cells (mDCs) obtained starting from THP-1 with the addition of a cocktail of maturation factors (with the exception for only one miRNA - 27a-3p). These results support previous data obtained in our laboratory that demonstrate that extreme contact allergens lead to a full maturation of iDCs.

1836 Tcdd-Mediated Upregulation of FasL on B Cells Triggers Apoptosis in T Cells in EAE

E. Rushing, A. McDonald, A. Nicaise, A. Bell, E. Kummari, and B. Kaplan. *Mississippi State University, Mississippi State, MS.*

Previous results from our laboratory showed that TCDD can suppress the autoimmune disease experimental autoimmune encephalomyelitis (EAE). Specifically, TCDD suppressed T cell immune function in the spleen, which correlated with decreased neuroinflammation and clinical scores. The goal of this project is to determine if TCDD-treated B cells contribute to decreased T cell function. Our hypothesis is that TCDD will induce Fas ligand (FasL) regulatory B cells in EAE, which could induce apoptosis in Fas-expressing cells, such as T cells. We developed the JC-1 assay, which measures mitochondrial membrane potential as an indicator of cell viability. Optimization was done *in vitro* using FCCP as a positive control. We then conducted studies using TCDD-treated lymphocytes, B cells or IgM-depleted B cells mixed with target T cells that were prestained with CD4. The rationale for depleting IgM for some B cell preparations is that TCDD upregulates FasL to a greater degree on follicular B cells, which express more IgD than IgM. We first used lymphocytes isolated from spinal cord following an 18-day EAE disease course with 30 µg/kg TCDD given i.p. on day 1 but did not detect apoptosis in CD4+ T cells in the presence of EAE plus TCDD-treated spinal cord lymphocytes. We then used cells isolated from spleen following an 18-day disease course with 30 µg/kg TCDD given orally over 12 days at 2.5 µg/kg/day. We mixed EAE plus TCDD-treated splenocytes, purified B cells or IgM-depleted B cells with CD4+ T cells. In two separate replicates of the experiment, mitochondrial membrane potential in the CD4+ T cells was lower in the presence of TCDD-treated cells as compared to corn oil vehicle-treated cells. The decrease in mitochondrial membrane potential in CD4+ T cells was highest in the presence of EAE plus TCDD-treated IgM-depleted B cells (7-33% decrease ratio of JC-1 aggregates to monomers). Together these results demonstrate that the mechanism by which TCDD suppresses T cell function involves its ability to induce FasL on B cells, which triggers apoptosis in T cells. *Supported by NIH R15ES027650.*

1837 Effect of TCDD on Antibody Production in Various Anatomic Locations in Experimental Autoimmune Encephalomyelitis

A. McDonald, E. Rushing, A. Nicaise, A. Bell, E. Kummari, and B. Kaplan. *Mississippi State University, Mississippi State, MS.*

The prototypical AhR ligand, TCDD, has been well characterized to be immunosuppressive. It has been determined that TCDD robustly attenuates the autoimmune disease experimental autoimmune encephalomyelitis (EAE), a mouse model to study multiple sclerosis. The purpose of this study was to evaluate IgG production in different anatomic locations including spleen, lymph node, bone marrow, spinal cord, and blood. In each location, specific B cell populations, including CD19, B220, and CD5, were analyzed in mice induced with EAE disease and treated with TCDD. CD19 and B220, an isoform of CD45, are B cell markers expressed at all stages of B cell development but lost upon plasma cell differentiation. CD5 is an indicator of one population of innate B cells. To evaluate antibody production in the B cell populations of TCDD-treated mice, disease was induced and 2.5 µg/kg/day of TCDD was orally administered for 12 days, for a total of 30 µg of TCDD. It was hypothesized that TCDD would downregulate IgG production in all anatomic locations. TCDD was very effective in suppressing MOG-specific IgG in serum. Overall, IgG was suppressed by TCDD in splenocytes. Interestingly, IgG was most affected by TCDD in CD19-, B220-, and CD5-negative populations. TCDD

did not affect IgG production in bone marrow- or lymph node-derived B cells, but TCDD did suppress IgG production in B cell populations in the spinal cord. In conclusion, these data show that TCDD's target tissues at end-stage disease are spleen and spinal cord. These results provide valuable insight into the mechanism of immunotoxicity of TCDD. In addition, the findings contribute to the understanding of how AhR ligands affect EAE and may help us develop a less toxic treatment for autoimmune disease. *Supported by NIH R15ES027650.*

1838 $OANO_2$ Increases the Likelihood of Survival and Resolution Signaling in Response to Bleomycin-Mediated Lung Injury

M. L. Wilkinson, E. Abramova, C. Guo, and A. J. Gow. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Nitro-oleic fatty acid ($OANO_2$), a potent electrophile, is endogenously found in humans and modifies cysteine residues via Michael addition to alter protein function. It reduces inflammatory activation in the cardiovascular system, and potentially the lung. Intratracheal bleomycin (ITB) is a model of pulmonary inflammation, resolution, and fibrosis. Earlier work showed a loss of resident alveolar macrophages (AMs) and activation of interstitial macrophages (IMs) in the early phase of the response to ITB (7 days) that was abrogated by $OANO_2$. Here, we examined the effect of $OANO_2$ on the resolution phase of the ITB response. ITB (3 U/kg) was administered to animals while $OANO_2$ was delivered via osmotic pump (1 nmole/g/hr). Bronchoalveolar lavage (BAL) and lung tissue were collected at 17 days post ITB. Our prior studies have shown that $OANO_2$ alters macrophage activation at 7 days post ITB. Therefore, we examined both BAL and tissue macrophage phenotypes in response to ITB with and without $OANO_2$ treatment. In the BAL, resident AMs (CD45+, SiglecF+, F4/80+, CD11c+) were lost 7 days post ITB (95 ± 3.9% vs 49 ± 3.9%*) but recovered by 17 days (68 ± 3.5%*). $OANO_2$ preserved resident AMs at 7 days (69 ± 3.9%*) and increased recovery at 17 days (73 ± 3.8%*). IMs show a similar pattern of activation and resolution. ITB increases the proportion of mature IMs (CD11c+) expressing both Ly6C (43 ± 3.7% vs 13 ± 3.4%*) and mannose receptor (MR) (28 ± 3.6% vs 5 ± 3.4%*) at 7 days; returning closer to control at 17 days (Ly6C+ 16 ± 2.4%; and MR+ 9 ± 1.2%). $OANO_2$ reduces activation at 7 days post ITB (Ly6C+ 27 ± 2.4%#; and MR+ 13 ± 3.9%#), but perpetuates activation at 17 days (Ly6C+ 28 ± 5.1%#; and MR+ 10 ± 2.3%). These observations are consistent with $OANO_2$ driving an increased level of resolution. This is confirmed within mesenchymal stem cells (CD45-, CD31-, Sca1+), where ITB increases fibrotic signaling (CD44+) at 7 days (70 ± 4.7% vs 26 ± 4.5%*); while the addition of $OANO_2$ reduces the early expression of CD44 (58 ± 4.3%#) but potentiates activation at 17 days (CD44+ 69 ± 5.3%#; and CD90+ 23 ± 1.7%#). Mice administered ITB lost a significant amount of bodyweight compared to controls; $OANO_2$ mitigated this loss at 7 days (-4.0 ± 0.3% vs 0 ± 0.5%#); and this weight loss continued to 10 days post ITB. At this time point mice either stabilized in weight or did not survive. Importantly survival rates were higher in $OANO_2$ treated animals (80% vs 35% #) at 17 days post ITB. Histological findings in animals sacrificed revealed signs of inflammation, epithelial destruction, and proteinaceous deposits. These findings suggest that $OANO_2$ administration increases the likelihood of resolution and survival (* $p<0.05$ vs control; # $p<0.5$ vs ITB).

1839 Role of Arsenic in Modulating Ligand-Induced Microglial Neuroinflammatory Response

S. Kushwaha, J. A. Ansari, and D. Ghosh. *CSIR-Indian Institute of Toxicology Research, Lucknow, India.*

Microglia plays an important role in various neuroinflammatory diseases, where it gets activated and secrets proinflammatory cytokines, leading to neuronal damage. Microglial activation status can be modulated by various environmental factors like arsenic, known to induce immunosuppression. Lipopolysaccharides (LPS) is a ligand for TLR-4 involved in NF-kB signaling. It can induce microglial activation where Poly (ADP Ribose) Polymerase PARP1 is involved. PARP1 is a zinc finger protein containing C3H1 motif and arsenic has been reported to selectively bind to zinc finger motifs especially C3H1 and C4. We investigated the effect of arsenic on ligand-induced neuroinflammation and the involvement of PARP1 in this event. Male Balb/c mice were exposed to 0.38 mg/kg bd. wt. sodium arsenite ($NaAsO_2$) for 30 days following intraperitoneal 0.33 mg/kg LPS exposure for 24 hours. *Ex vivo* microglia isolation was done to check the level of proinflammatory cytokines through multiplexing. With it, microglia cell line (N9) was also exposed with 500nM $NaAsO_2$ and 1.2 µM $ZnCl_2$ for 24 hours followed by 100 ng/mL LPS for 6 hours and multiplexing was performed to check the levels of pro-inflammatory cytokines. Arsenic exposure decreases LPS-induced microglia inflammation as well as LPS induced Poly ADP Ribosylation by inhibiting PARP1. This inhibition of PARP1 activity by binding with arsenic suppresses p65 phosphorylation and blocks microglia activation. Supplementation of Zinc in microglia cells neutralizes the arsenic-mediated reduction in LPS-induced proinflammatory cytokines production that confirms the involvement of PARP1 in this event. Additionally, *in silico* analysis reveals that ATR and Chk1 can be involved in the p65 phosphorylation pathway. Thus, pre-treatment of ATR/Chk1 inhibitor reduces p65 phosphorylation following LPS stimulation, confirms the involvement of these two molecules in ligand-induced neuroinflammation. Therefore, our study will help in the development of new therapeutic strategies for neuroinflammatory diseases and unveil the mechanism of arsenic mediated suppression of ligand-induced neuroinflammation by finding the missing link between PARP1 and NF-kB signaling and raise the possibility of using arsenic for its therapeutic effect at lower doses.

1840 Inhibition of the Respiratory Burst by Six Per- and Polyfluoroalkyl Substances (PFASs)

D. W. Phelps, J. Driggers, A. Palekar, and J. A. Yoder. *North Carolina State University, Raleigh, NC.*

Per- and polyfluoroalkyl substances (PFASs) are a class of almost 5,000 anthropogenic compounds used in the production of non-stick coatings, food wrappers, water- and stain-resistant fabrics, and fire-fighting foams. Due to their ubiquity, persistence, and mobility in the environment, between 95% of 99% of all Americans have detectable levels of PFASs in their blood. Exposure to PFASs has been linked to cancer, thyroid disease, and impaired adaptive immune system responses. However, the impact of PFASs on the innate immune system remains unknown; should the innate immune system be impaired, the host may be susceptible to infectious or neoplastic disease. In order to investigate this, larval zebrafish and human neutrophil-like cell lines were exposed individually to six PFASs that have been detected in the water and air in Fayetteville, North Carolina: PFOA, PFOS, PFHxA, PFHxS, GenX, and fluoroether E1. Initially, we performed range-finding studies to determine doses that were non-teratogenic to zebrafish and non-cytotoxic to human cells. Doses for which no teratogenicity or cytotoxicity were observed served as the highest doses tested in subsequent assays. We then measured the respiratory burst as a functional readout of innate immune function. The respiratory burst is the process by which phagocytes, such as macrophages and neutrophils, produce microbicidal reactive oxygen species to fight infections. Range-finding studies for developmental toxicity and cytotoxicity identified PFOA and PFOS as developmentally toxic to larval zebrafish, but none of the tested PFASs were cytotoxic. In the respiratory burst assay, PFOS, PFHxA, and E1 suppressed the respiratory burst *in vivo*. However, *in vitro*, all of the PFASs that were tested suppressed the respiratory burst. This may indicate that, while PFASs are able to directly impair innate immune function *in vitro*, certain PFASs may target other organ systems *in vivo*, resulting in no observable immune dysfunction. Future studies plan to explore this hypothesis, whether PFAS-induced immunotoxicity is differentially influenced by chronic or acute exposure, and whether exposure to PFASs confers susceptibility to infectious disease.

1841 Effects of Two Food Additives, 3-HT and BHT, on OVA-Elicited Food Allergy in Mice

Y. Jin, K. E. Guzman, A. P. Boss, V. Gangur, and C. E. Rockwell. *Michigan State University, East Lansing, MI.*

There has been a steady rise in the prevalence of food allergy for the past couple of decades, however the underlying cause has not been identified. Many factors contribute to food allergies, including environmental chemical exposure, genetics, microbiota, etc. Recent findings show that there could be a link between a common food additive, tBHQ, and food allergies, which suggests the need to test other food additives. In our study, we investigated if butylated hydroxytoluene (BHT) and 3-hydroxytyrosol (3-HT), play a similar role as tBHQ in an OVA-sensitized mouse model. Female BALB/c mice (4 weeks old) were given a control, BHT (0.0014%), or 3-HT (0.0014%) diet and exposed to OVA transdermally once per week for four weeks during the sensitization phase. Sensitization to OVA was assessed by the rise in OVA-specific IgE and IgG1 by ELISA. Whereas BHT and 3-HT decreased the IgE response to OVA, IgG1 levels were similar between all the diets during the sensitization phase. Upon oral challenge, mice were monitored for systemic anaphylaxis, hypothermia shock response (HSR) and mast cell protease (mMCP)-1 response. Systemic anaphylaxis clinical symptoms were quantified. Mice on the 3-HT and BHT diets had less severe clinical signs of anaphylaxis. BHT and 3-HT diminished the decrease in body temperature with a more rapid return to normal temperature as compared to control diet. Mouse mast cell protease-1 (mMCP-1) levels from BHT, 3-HT and control group were determined through ELISA, indicating decreased mast cell degranulation in the BHT and 3-HT groups. In addition, flow cytometry showed T helper 2 (Th2) cells (CD4+ IL-4+) population in splenocytes from the 3-HT-treated group were decreased

significantly compared to control. Taken together, BHT and 3-HT may have a protective effect in regard to the OVA-elicited food allergy mouse model, in contrast to tBHQ. These results could potentially help industry decision makers reconsider which food additives to use as preservatives and will be important to mitigate the rise in food allergy.

1842 Pathway Analysis for Immunotoxicity Assessment by Co-culture of THP-1 Cells and NHEK

Y. Sawada[1], H. Kobayashi[1], M. Kono[2], H. Ikeda[2], H. Itagaki[3], and K. Iijima[1]. *[1]Yokohama National University, Yokohama, Kanagawa, Japan; [2]Mandom Corp., Osaka, Japan; and [3]ITACS Consulting, Sagamihara, Kanagawa, Japan.*

To establish a skin sensitization assessment method including cell-cell interactions and chemical metabolic reactions, we integrated human monocytic leukemia cell line (THP-1 cells) into a skin model using differentiated normal human epidermal keratinocytes (NHEK). However, previous studies have shown that medium composition and the secretion from NHEK affected the expression of THP-1 cells surface marker, which is an index for assessing skin sensitization. In this study, gene expression profiling using microarray was performed to explore new indicators in the co-culture system. Human epidermis model was developed on the cell culture insert according to the protocol of EPI-KIT (J-TEC). These culture inserts transferred into well of 24-well plate which were seeded with THP-1 cells at density of 1×10^6 cells/well. As the medium for co-culture, THP-1 cells culture medium and the mixture of THP-1 cells culture medium and keratinization induction medium at the ratio based on seeding number of each cells (the mixed medium) was used. 2,4-Dinitrochlorobenzene (DNCB) as a test substance was exposed to THP-1 cells through a human epidermis model, and total RNA was isolated from both cells after exposure for 18 hours and analyzed transcriptome changes using with Clariom™ S Human Array (Thermo Fisher Scientific). The pathway analysis tool, Wiki Pathways, was used to examine the immune response of THP-1 cells by DNCB treatment after clarifying the effects of medium composition and secretion from NHEK. Several pathways were activated by changing from THP-1 culture medium to the mixed medium however there were no pathways significantly induced by co-culture with NHEK. Regardless of medium composition and culture condition (co-culture or pure culture), DNCB treatment activated MAPK signaling pathway which mediate CD40/CD54/CD86 expression[1], and VEGFA-VEGFR2 signaling pathway which regulate ICAM-1 protein expression via TNF-α[2]. Our results ware suggested that skin sensitization evaluation using the gene expression as an index is possible in co-culture system. *References: 1) Miyazawa, M., Ito, Y., Kosaka, N., Nukada, Y., Sakaguchi, H., Suzuki, H., & Nishiyama, N. Sci., 33 (1), 51-59. 2) Peeradech, T., Steven, J,H., Kanokpan, W., & David, O,B. (2014). TNF-α-induced ICAM-1 expression and monocyte adhesion in human RPE cells is mediated in part through autocrine VEGF stimulation. Mol. Vis., 20, 781-789.*

1843 Regulation of Ubiquitin Specific Peptidase 2 by Farnesoid X Receptor in Glioblastoma NCI-60 Cell Lines

C. A. Nadolny[1], J. Chambers[1], G. Guo[2], and J. R. Richardson[1]. *[1]Florida International University, Miami, FL; and [2]Rutgers, The State University of New Jersey, Piscataway, NJ.*

Glioblastoma multiforme is the most common primary brain tumor in adults. It is extremely aggressive and one of the least treatable types of cancers. Although treatment options include surgery, chemotherapy, and radiotherapy, the median survival is 14-15 months after diagnosis. With no obvious cause and little progress in development of new therapies, there is a clear need to identify new potential targets. Farnesoid X Receptor (FXR) is a nuclear receptor predominantly expressed in the liver and intestine, where it is has been reported to be critical in maintaining bile acid homeostasis and suppress hepatocellular carcinoma through anti-inflammatory activity and repair of liver injury. Our laboratory has previously found FXR expressed in the brain. Specifically, in mouse and human astrocytes FXR regulates the inflammatory response to pro-inflammatory cytokines. Additionally, we evaluated the expression of FXR in six NCI-60 glioblastoma cell lines, one immortalized glioblastoma cell line (ATCC U118), and primary human astrocytes. Basal levels of FXR were measured by qPCR and immunofluorescent staining, indicating the presence of this gene product and protein in glioblastoma and human astrocyte cells. When these cells were treated with an FXR agonist (10μM WAY 362450), significant induction of the validated downstream target gene small heterodimer partner (SHP) occurred. Further, Ubiquitin Specific Peptidase 2 (USP2), a deubiquitinating enzyme with a complex role in tumorigenesis, was increased following FXR agonist treatment in the glioblastoma and primary human astrocyte cell lines. qPCR and immunofluorescent staining revealed a significant increase in USP2 mRNA (~1.5-2.1 fold) and protein (~1.2-2.0). These data further solidify the presence of functional FXR in human astrocytes and glioblastoma, identifying it as a desirable target for further research.

1844 Metallothionein, a Small Stress Response Protein, Serves as a Co-Stimulatory Molecule for Lymphocyte Activation

K. E. Dostie, and M. Lynes. *University of Connecticut, Storrs, CT.*

Metallothioneins (MTs) are stress response proteins that are highly inducible by various agents including glucocorticoids, divalent heavy metals, reactive oxygen species, and acute phase cytokines. 33 mol% of MT's amino acid composition are cysteines that provide sulfhydryl groups responsible for metal binding and scavenging reactive oxygen species. Due to its rapid induction in response to acute phase cytokines, MT has been suggested to have potential role(s) in inflammatory microenvironments. Although the intracellular roles of metal homeostasis and free-radical scavenging are typically cytoprotective in inflamed tissues, MT that is released into the extracellular environment may exacerbate local inflammatory activities as a consequence of its chemotactic activities. We have shown that MT also has a modest proliferative effect on B cells and can increase the pool of proliferating cells up to 4-fold when co-administered with bacterial lipopolysaccharide (LPS). This suggests MT may be a costimulatory signal that enhances the vigor of responses to other pro-inflammatory stimuli. Biotin-labeled MT can be detected on the surface of murine lymphocytes by fluorophore-conjugated streptavidin, suggesting MT may provide a costimulatory signal for proliferation by interacting with membrane receptor(s). These interactions may include interactions with chemokine receptors, as shown by downstream signaling and GPCR-specific screening. The synergistic effect of MT on LPS-induced B cell proliferation is not diminished by administration of MT-specific monoclonal antibody, suggesting the costimulatory effect of MT does not require direct activation of a plasma membrane receptor. The antioxidant activity conferred by the free thiols within MT's structure may serve to manage the local redox environment for redox-sensitive surface molecules. The antioxidant glutathione had no effect on proliferation when administered at a dose representing the same reactive thiol molarity as MT used in these studies, suggesting the costimulatory effect of MT is also not solely due to its ability to provide a reducing extracellular environment. Determining MT's mechanism of action in lymphoproliferation may illuminate the role of endogenous MT in the context of the chronic inflammatory stress that can be associated with autoimmune disease and thus lead to novel therapeutic opportunities.

1845 Spatial Dependence of Cytokine and Phosphoprotein Distributions following Exposure to Localized *Staphylococcus epidermidis*

N. Prince[1], J. Penatzer[1], M. Dietz[2], and J. Boyd[2]. *[1]West Virginia University, Morgantown, WV; and [2]West Virginia University School of Medicine, Morgantown, WV.*

The spatial gradients associated with localized infection are not currently well defined, despite the fact that these infections remain a serious complication in clinic. *Staphylococcus epidermidis* is often implicated in these medical device-related infections, and it can lead to failure rates up to 50%. While current surgical treatments rely on understanding the margins of these localized infections, the tissue-level inflammatory response to *S. epidermidis* has not been well investigated spatially. Defining the spatial inflammatory immune response may aid future efforts to combat these persistent infections. In this study, human inflammatory cytokines and phosphoproteins were profiled in patients undergoing revision knee arthroplasty to investigate the spatial dependence of tissue-level response to infection. Samples were collected from male (N=5) and female (N=5) patients, varying in age (46-76 years) and comorbidities. Tissues were collected at seven locations, varying in proximity to prosthetic knee. Six cytokines (IL-1α, IL-1β, IL-4, IL-6, IL-8, and MIP-1α) and four phosphoproteins (Akt, BAD, p70S6K, and ZAP-70) were able to discriminate aseptic vs. septic tissues via two-way ANOVA followed by Bonferroni's post-test ($p<0.05$). Principal component analysis (PCA) was conducted to better characterize the spatial disparities of these responses. Overall, it suggested that phosphoprotein targets (Akt, BAD, p70S6K, and ZAP-70) may be indicative of aseptic tissues, and cytokine targets (IL-1α, IL-1β, IL-4, IL-6, IL-8, and MIP-1α) may be indicative of septic tissues. The ANOVA and PCA data together indicate that there are observable spatial differences ($p<0.05$) in inflammatory tissue response at the levels of cytokines and phosphopro-

teins following localized *S. epidermidis* infection. Through the analysis, it was possible to identify regional variability and offer novel information about tissue-level disparities in localized inflammatory response.

1846 Nimbolide Abrogates Cerulein-Induced Chronic Pancreatitis by Modulating β-Catenin/SMAD in a Sirtuin 1-Dependent Way

S. Bansod. *NIPER Hyderabad, Hyderabad, India.*

Chronic pancreatitis (CP) is characterized by pancreatic inflammation and fibrosis, which leads to impairment of pancreas function. The present study was designed to investigate the possible mechanisms of chronic pancreatitis and the anti-inflammatory, antioxidant and anti-fibrotic effect of nimbolide (NB), active constituent of neem tree *Azadirachta indica* in cerulein-induced CP. Effect of nimbolide was investigated on cerulein 50 $\mu g.kg^{-1}.hr^{-1}$*6 exposures^{-1}day 3 days a week for 3 weeks induced CP model in Swiss albino mice. Nimbolide (0.3 and 1 mg/kg) and sirtuin 1 (Sirt1) inhibitor, nicotinamide (200 mg/kg), were given intraperitoneally daily for 21 days. Pancreatic function was assessed by biochemical evaluation including amylase and lipase levels. The deposition of collagen in pancreatic tissue was measured by using hydroxyproline assay, Picrosirius red and Masson's trichrome staining. The expression of collagen I, α-smooth muscle actin (SMA) and β-catenin in the pancreas tissue was evaluated using immunohistochemistry and immunofluroscence. NB treatment significantly reduced cerulein-induced CP by inhibiting Wnt/β-catenin signaling pathway including β-catenin, MMP7 and GSK3β. NB treatment remarkably decreased α-SMA, TGF-β1, MMP-2, fibronectin, p-smad-2/3 expression and collagen deposition in pancreatic tissue. However, the therapeutic effects of nimbolide against cerulein-induced CP were impaired by nicotinamide treatment. The levels of pro-inflammatory and pro-fibrotic cytokines such as TNF-α, IL-1β, IL-6 and TGFβ1 were elevated by cerulein treatment; further, they were decreased by NB treatment. Additionally, NB was found to increase the expression of Sirt1 protein, which ultimately decreased the expressions of Smad2/3 and β-catenin signalling pathway proteins to attenuate cerulein-induced CP. Nimbolide attenuated cerulein-induced CP by activating Sirt1, which regulates Smad/β-catenin signaling pathways and it could be the novel therapeutic strategy for the treatment of CP associated fibrosis.

1847 Role of Aryl Hydrocarbon Receptor Ligands in Allograft Rejection

B. L. Holloman, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina, Columbia, SC.*

Immune-mediated transplant rejection is a major health problem and use of strong immunosuppressive drugs in patients can lead to susceptibility to infections and cancer. Our studies are aimed at determining whether treatment with AhR ligands could affect transplant rejection. Towards this, the effect of AhR ligands, 6-formylindolo [3,2-b] carbazole (FICZ) and 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) on allogeneic rejection of skin transplants from C3H/HeJ (H-2^k) donors onto C57BL/6 (H-2^b) recipient mice was studied. For this purpose, C57BL/6 recipient mice were treated with 10ug/kg TCDD or 50ug/kg FICZ starting 1 day prior to transplantation every 3 days for 12 days. Our studies demonstrated delayed allograft rejection in TCDD- but not FICZ-treated mice. In addition, increase in CD8+ T cells was observed in vehicle-treated graft recipient mice, which was decreased following treatment with AhR ligands. Furthermore, treatment with the AhR ligands led to decreased expression of Th1 ($CD3^+CD4^+Tbet^+$) cells and increased expression of (CD3+CD4+FoxP3+) Tregs in graft-draining lymph nodes. We next examined the effect of AhR ligands (10nM TCDD or 10uM FICZ) on mixed lymphocyte reaction cultures of spleen cells from C57BL/6 mice as responders when stimulated with mitomycin C-treated splenocytes from C3H/HeJ mice. There was an increase in the CD4+ and CD8+ T cells following treatment with AhR ligands. While there was no change in the induction of T regs *in vitro* following treatment with AhR ligands, FICZ treatment led to an increase in Tr1 (CD3+ CD4+ FoxP3- CD233+ CD49b+) cells. In conclusion, our studies suggest modulating effects of AhR ligands in transplant rejection which may be mediated by dysregulation in CD4+ T regulatory cell subsets. *Supported by NIH grants P01AT003961, P20GM103641, R01ES030144, R01AI129788 and R01AI123947.*

1848 Role of Constitutive Cyp1b1 Expression in Macrophage on Diet-Induced Obesity: Bone Marrow Macrophage Polarization and Peritoneal Macrophage Stimulation by IL-13

A. A. Almeldin[1,2], M. C. Larsen[2], and C. R. Jefcoate[2,3]. *[1]Tanta University Faculty of Medicine, Tanta, Egypt; [2]University of Wisconsin–Madison, Madison, WI; and [3]Molecular and Environmental Toxicology Center, University of Wisconsin–Madison School of Medicine and Public Health, Madison, WI.*
