hyde exposure, *sprtn* knock-down cells have over 400 fold higher BPDE-DNA adducts than wide-type cells in each time point, which was attributed to reduced DNA repair due to increased formaldehyde-induced DPCs. In conclusion, our results demonstrate for the first time that SPRTN plays an important role in the repair of formaldehyde-induced DPCs and formaldehyde-induced DPCs block the repair of BPDE-DNA adducts.

2698 The Role of Genotoxicity in the Carcinogenicity of Acrylamide in the Lungs and Harderian Glands of Mice

Y. Ishii[1], S. Takasu[1], K. Nakamura[1], A. Kijima[1], K. Ogawa[1], and T. Umemura[1,2]. *[1]National Institute of Health Sciences, Kanagawa-ken, Japan; and [2]Yamazaki College of Animal Health Technology, Tokyo, Japan.*

Introduction: Acrylamide (AA) is a contaminant in heated foods and is carcinogenic in multiple organs of rodents. There have been many reports demonstrating AA-induced DNA damages and mutagenicities in *in vivo*. Our previous study showed that exposure to AA at higher dose (400 ppm) for 4 weeks resulted in N7-(2-carbamoyl-2-hydroxyethyl) guanine (N7-GA-Gua) formation and gene mutations in the lungs of *gpt* delta mice. However, in mice treated with AA at a carcinogenic dose (50 ppm), there were no changes in the mutant frequencies (MFs) in the lung in spite of detection of N7-GA-Gua to some extent. We hypothesized that the seemingly incompatible outcome resulted from inadequate duration of the exposure. In the present study, we examined the effects of long-term exposure to AA at the carcinogenic dose on formation of AA-specific DNA adduct and frequency of gene mutations in the carcinogenic target or non-target sites. Method: 6-weeks old B6C3F$_1$ *gpt* delta mice were treated with AA at a dose of 50 ppm in the drinking water for 4, 8 and 16 weeks. After the treatment, lungs and harderian gland as the carcinogenic target sites, and liver as the carcinogenic non-target site, were collected for N7-GA-Gua analysis by liquid chromatography with tandem mass spectrometry (LC-MS/MS) and for reporter gene mutation assay. Results: N7-GA-Gua adducts were detected at the almost similar level among the lungs, harderian glands and livers from 4 weeks. The prolonged duration of the exposure did not affect N7-GA-Gua levels at any sites. *gpt* MFs significantly increased in the lungs and the harderian glands at 16 weeks, but not in the livers, and there were no changes in Spi$^-$ MFs at all organs examined at any points of time. Mutation spectrum analysis of *gpt* mutants revealed increases of G:C-T:A transversion and single base deletion in both lungs and harderian glands of mice at 16 weeks. Discussion: AA at the carcinogenic dose significantly increased *gpt* MFs only at the carcinogenic target site, suggesting that mutagenicity of AA might contribute to tumorigenesis in the lungs and the harderian glands. In addition, N7-GA-Gua formation and subsequent AP site formation might be responsible for mutation spectra characterized by increases in G:C-T:A transversion and deletion mutations. However, in addition to the overall data in the livers observed in the present study, the fact that glycidamide (GA), a causative metabolite of N7-GA-Gua, is a rodent liver carcinogen raises a question of whether the genotoxicity starting from N7-GA-Gua formation is involved in AA-induced carcinogenesis. Thus, the possible epigenetic alterations induced by AA may partly contribute to AA tumorigenesis.

2699 Pyraclostrobin Increases HTT CAG Repeats in Cellular Models of Huntington's Disease

B. H. Baker, S. Park, R. C. Stark, S. M. McLarnan, and B. L. Pearson. *Columbia University, New York, NY.*

Huntington's disease (HD) is a neurological disorder associated with excessive CAG trinucleotide repeats in the coding region of the Huntingtin (*HTT*) gene. Expansion of greater than 36 CAG repeats elicits pathogenic gene products and a late onset, terminal form of neurodegeneration. The length of CAG and other nucleotide repeat sequences throughout the genome is unstable with a high potential to expand. While HD is primarily inherited, a small proportion of cases arise through sporadic CAG repeat expansions. More CAG repeats are associated with earlier onset; approximately 60% of the variance in the onset in HD symptoms is attributable to the number of CAG repeats a person carries. Environmental exposures may cause CAG repeat expansions that could underlie earlier age of onset of HD as well as sporadic cases of the disease. Yet, we do not know which exposures contribute to repeat instability in trinucleotide repeat disorders such as HD. We previously demonstrated that strobilurin fungicides such as pyraclostrobin cause oxidative stress in mouse neurons and elicit gene expression signatures concordant with human HD. Predicted human pyraclostrobin exposure levels are sufficient to impair human mitochondrial function, and thus, potentially contribute to HD through increasing *HTT* CAG repeat expansion. We demonstrated that exposure to pyraclostrobin caused repeat expansion in a CAG-GFP reporter cell line. Repeat expansion was validated with small pool PCR and molecular fragment analysis. To determine if pyraclostrobin increases CAG repeats in HD-relevant target cells and tissues, we prepared primary cortical cells and fibroblasts from neonatal *Htt* CAG knockin mice. We found no evidence of CAG repeat expansion in mutant cortical cultures exposed to pyraclostrobin under the conditions tested. Mutant fibroblasts showed rare or modest expansion upon chemical treatment. Mutant cortical neurons and fibroblasts showed baseline differences in cell viability and mitochondrial superoxide production relative to wild-type controls. These differences may confound the influence of exogenous mitochondrial stressors on CAG repeat status. Further work is necessary to identify the conditions under which chemical exposure is capable of expanding CAG repeats *in vivo*. Our results re-define the role of environmental chemicals as mutagens underlying rare monogenic diseases and provides an experimental framework to identify chemical threats to trinucleotide repeat stability.

2700 Application of Multiple *In Vitro* Genetic Toxicology Endpoints Enables Comprehensive Characterization of Test Compounds' Mode/Mechanism-of-Action

S. M. Bryce, J. C. Bemis, and S. D. Dertinger. *Litron Laboratories, Rochester, NY.*

The development of several automated *in vitro* and *in vivo* genotoxicity assays in our laboratory presents an opportunity for cross-method comparisons. We identified 7 genotoxicants that had been studied across each of 3 *in vivo* assays - blood and liver micronucleus (MN) and blood-based *Pig-a* gene mutation. The chemicals were: benzo[a]pyrene (BP), cisplatin, cyclophosphamide, hydroxyurea (HU), melphalan, temozolomide, and vinblastine (VIN). These agents were selected for further investigation via *in vitro* MultiFlow to provide data on genotoxic mode of action (MoA) and mechanistic information. This approach used human TK6 cells to examine 73 compounds - including the 7 above - with *a priori* genotoxicity information including *in vitro* MN data. MultiFlow dose response data were converted to concentration-normalized area under the curve values for each chemical to enable unsupervised clustering based on MoA. 22/26 clastogens, 13/13 aneugens and 34/34 nongenotoxic agents were identified correctly. The positive compounds were applied to second tier mechanistic assays to identify direct vs indirect DNA-interacting clastogens or aneugens acting via tubulin disruption or Aurora Kinase inhibition. These analyses confirmed *a priori* expectations of the 7 example agents whereby HU grouped with known non-DNA reactive clastogens, VIN grouped with tubulin destabilizers and the remaining compounds clustered with direct DNA-reactive clastogens. Each group was further characterized based on benchmark dose analyses and potency ranking across the various assays. For example, p53 response ranked VIN as the most potent and BP as the least, this relationship was also observed in both *in vitro* and *in vivo* MN assays. These studies demonstrate the utility of a tiered system of assays where *in vitro* methods provide specific mechanistic information on the type of genotoxic hazard present and thus aid in design of subsequent *in vivo* studies. It bears noting that the majority of compounds studies here are pharmaceuticals with specific activities and do not represent the entirety of potential genotoxicants. Additional chemical classes remain to be studied. This strategy for comprehensive assessment of compounds not only provides detail on genotoxic mechanism, but can conceivably benefit *in vitro* to *in vivo* extrapolation and risk assessment.

2701 Determination of the Genotoxic Potential of E-cigarette Aerosols and Reference Cigarette Smoke in the Mechanism-Based ToxTracker Assay

L. Czekala[1], L. Simms[1], E. Trelles Sticken[2], R. Wieczorek[3], G. Hendriks[4], K. Rudd[1], and M. Stevenson[1]. *[1]Imperial Brands, Bristol, United Kingdom; [2]Reemtsma Cigarettenfabriken GmbH, Hamburg, Germany; [3]Reemtsma Cigarettenfabriken GmbH, Bristol, Germany; and [4]Toxys B.V., Leiden, Netherlands.*

The genotoxic assessment of chemicals is a fundamental part of a risk assessment. Studies utilising the *in vitro* micronucleus and Ames assay have shown that *my*blu™ e-cigarette whole aerosol is non-genotoxic under test conditions. In this study we aimed to determine and compare the genotoxic potential of the aerosol/smoke bubbled extracts from the *my*blu™ e-cigarette and 1R6F reference cigarette in the Tox Tracker/ACE assay. ToxTracker is a panel of mammalian stem cell lines that can detect the chemical induction of genotoxicity / cancer pathways through different fluorescent reporters for induction of DNA damage, oxidative stress and protein damage. Smoke/aerosol was generated using an intense smoking regime for 1R6F cigarette (55mL/2s/30s) and the CORESTA Recommended Method N°81 (55mL/3s/30s) for *my*blu™ e-cigarette with 3 different tobacco flavoured liquids (with either

1.6% protonated, non-protonated or 0% nicotine) and unflavoured, based e-liquid without nicotine. Samples were prepared by bubbling through 3 in-line Impingers each containing 10 mL Phosphate Buffered Saline. All samples were tested at a maximum testing concentration of 10%. The differential induction of the green fluorescent protein (GFP) reporters as well as cytotoxicity of the tested compounds was determined using flow cytometry after 24h exposure. In the ToxTracker ACE assay, cell cycle distributions were measured after 4 and 24h. The 1R6F smoke extracts activated both reporters for genotoxicity: Bscl2-GFP, which is activated upon formation of bulky DNA lesions and subsequent DNA replication stress and Rtkn-GFP, which is activated upon induction of DNA double strand breaks, either in absence or presence of S9. Similarly, 1R6F smoke extracts also activated both reporters for oxidative stress, Srxn1-GFP, Blvrb-GFP and the p53 response. Small increases in G2/M phase cells was observed but no increases in aneuploid cells was observed in the ToxTracker ACE assay. None of the aerosols generated with the *my*blu™ e-cigarette were classified as geno- or cytotoxic up to the top testing concentration under the conditions of test. The results obtained highlight the potential utility of this assay for future genotoxicity assessment strategies for tobacco and nicotine-containing products.

PS 2702 Is Endoreduplication an Important Genotoxic Lesion?

L. Gao, L. Wang, J. Jiang, S. Chen, X. Shan, M. Tian, and M. Chen. *WuXi AppTec, Suzhou, China.*

The *in vitro* mammalian cell chromosomal aberration assay is designed to assess structural aberrations and may not be optimal for the assessment of aneuploidy. Since there was no well-validated *in vitro* assay available for the routine screening of aneuploidy, the working group in the first IWGT agreed that many compounds which induced polyploidy also caused aneuploidy *in vitro* and recommended polyploidy (including endoreduplication) should be monitored when observed in the chromosomal aberration assay. Polyploidy induction is used in the chromosomal aberration assay to identify compounds with aneugenic potential as stated in OECD 473 and ICH S2(R1). However, there is a lack of scientific evidence showing that polyploidy is a reliable surrogate for aneuploidy and there are few publications which have included data on spontaneous or induced polyploidy. To better understand the correlation, we retrospectively evaluated the historical data generated in WuXi AppTec for CHO-WBL chromosomal aberration assay. In our laboratory, we recorded the polyploidy and endoreduplication separately and the induced polyploidy or endoreduplication beyond the historical negative control data range was considered positive. In the past two years, 79 CHO-WBL chromosomal aberration studies were conducted. The overall frequencies of positive for polyploidy and endoreduplication were 5% (4/79) and 48% (38/79), respectively. In our studies on pharmaceutical compounds endoreduplication was the lesion most often found, being induced by 27% in short treatment with S9, 39% in short treatment without S9 and 9% of the compounds tested in long treatment without S9. Most of those findings occurred close to the 50% cytotoxicity limit, nearly 86% of positive points are with more than 30% cytotoxicity. Of 38 candidates positive in endoreduplication, two candidates have no *in vivo* data, 4 compounds are positive comprising two with known mechanisms (CDK inhibitor and red cell proliferating agent) and other two kinase inhibitors with no known mechanism, but almost 89% (32/36) of candidates are negative in *in vivo* micronucleus assay, which indicating endoreduplication is clearly over-predicting the frequency of truly aneugenic compounds. Our data showed endoreduplication is seen quite often in *in vitro* CHO-WBL chromosomal aberration assay and not usually indicative of genotoxic (aneugenic) potential as the positive responses are usually not confirmed in *in vivo* micronucleus assay.

PS 2703 Application of High-Throughput CometChip Technology and Quantitative Approaches in Primary Human Hepatocytes

J. Seo, Q. Wu, L. Ren, Q. Shi, N. Mei, and X. Guo. *US FDA/NCTR, Jefferson, AR.*

Primary human hepatocytes (PHHs) are considered as the "gold standard" for evaluating hepatic metabolism and toxicity of xenobiotics. Previously, we evaluated the *in vitro* genotoxicity of a set of genotoxic carcinogens that have different genotoxicity and carcinogenicity modes of action in metabolically competent HepaRG and HepG2 cells. In this study, we used cryopreserved PHHs derived from three individual donors to evaluate the genotoxicity of eleven genotoxic carcinogens requiring metabolic activation (indirect-acting) or not (direct-acting) and five genotoxic non-carcinogens. DNA damage effects of the 16 compounds were determined over a wide range of concentrations using the high-throughput CometChip technology and the resulting dose-responses were quantified using benchmark dose (BMD) modeling. Following a 24-h treatment, nine out of eleven genotoxic carcinogens showed positive responses in PHHs, while negative responses were found in two known aneugens. PHHs gave an overall sensitivity of 100% and 71% for detecting DNA damage of six indirect-acting and five direct-acting genotoxic carcinogens, respectively, which were much higher than did HepG2 and HepaRG cells (i.e., 50-75% and 57% for detecting indirect-acting and direct-acting carcinogens, respectively). In addition, PHHs showed a specificity of 100% for detecting the five genotoxic non-carcinogens. Both BMD_{1SD} and BMD_{10} values were calculated using BMD analysis for the DNA damage dose-responses. HepaRG cells and PHHs showed comparable BMD_{1SD} values among the three types of hepatocytes, whereas similar BMD_{10} values were observed between HepaRG and HepG2 cells. These results suggest that PHHs can be adapted to 96-well CometChip platform for facilitating high-throughput genotoxicity evaluation and that quantitative approaches can be useful in support of developing *in vitro* cell models for genotoxicity testing.

PS 2704 Performance of HepG2 and Metabolically Competent HepaRG Cells in High-Throughput Micronucleus Assay for *In Vitro* Genotoxicity Assessment

X. Guo, J. Seo, V. Tryndyak, and N. Mei. *US FDA/NCTR, Jefferson, AR.*

Micronucleus (MN) test is a core assay for *in vitro* genotoxicity testing. The traditional MN assay is usually conducted in cells lacking metabolic competency or relying on exogenous metabolic activation systems, which is an important drawback of the current *in vitro* systems for genotoxicity assessment. Our previous study demonstrated that compared to HepG2 cells, HepaRG cells expressed a much higher level of CYP450 enzyme activities and detected a greater portion of genotoxic carcinogens requiring metabolic activation (indirect carcinogens) in the high-throughput high-content (HTHC) *in vitro* Comet assay. In this study, we evaluated the performance of HepG2 and HepaRG in HTHC *in vitro* MN assay for genotoxicity evaluation. Both cell lines were treated with wide-ranging concentrations of twelve genotoxic (seven direct and five indirect) carcinogens for 24 h and cultured for additional hours to go through 1.5-2 cell cycles. The results demonstrated that four out of twelve carcinogens showed different responses in these two cell lines. Specifically, three chemicals that require metabolic activation (i.e. 7,12-dimethylbenz[*a*]anthracene, cyclophosphamide, and *N*-nitrosidimethylamine) induced significant increases in MN formation in HepaRG cells when compared to the vehicle control, while no significant MN production was observed in HepG2 cells. Cadmium chloride was positive in HepG2 cells, but negative in HepaRG cells. HepaRG cells showed a much higher sensitivity (80%) than HepG2 cells (20%) in detecting five indirect carcinogens; whereas HepG2 cells showed a higher sensitivity (100%) than HepaRG cells (86%) in measuring seven direct carcinogens. 2,4-Diaminotoluene was negative in both cell lines. These results suggest that HTHC flow cytometry-based MN assay can be adapted to HepaRG cells for genotoxicity assessment, and HepaRG cells are superior than HepG2 cells in detecting carcinogens that require metabolic activation.

PS 2705 Genotoxicity Assessment of DMN and DEN in Cultured Human Peripheral Blood Lymphocytes

S. Roy[1], J. Morales[1], K. Wang[1], A. Szkudlinska[1], V. Johnson-Peltier[1], and J. A. Walker[2]. *[1]MilliporeSigma, Rockville, MD; and [2]Upsher-Smith Laboratories LLC, Maple Grove, MN.*

Dimethyl or diethyl nitrosamine (DMN and DEN) are known liver carcinogen in rats. Various *in vitro* tests have been successfully detected mutagenic potential of these nitrosamines. The *in vitro* tests that has been used mainly involves bacterial system and immortalized mammalian cells originated from rodents. Immortalized mammalian cells are not a true representative of the normal cells of human since some of the important genes are either absent of mutated in cell lines. We investigated the genotoxicity potential of DMN and DEN in cultured human peripheral blood lymphocytes (HPBL) using cytochalasin blocked micronucleus assay (OECD 487). Aroclor-1254-induced rat-liver S9 was used as metabolic system (5% v/v). Current test OECD 487 testing guideline recommend maximum concentration that should be tested is 10 mM or 2 mg/mL, whichever is less. We performed series of experiment using different donors and evaluated micronucleus frequency. DMN and DEN did not induce statistically significant micronucleus frequency up to 10 mM final concentration in culture (DMN =740 µg/mL; DEN = 1021 µg/mL). However, when concentrations were increased to 6000 µg/mL and above, which is equivalent to 8x (DMN) and 6x (DEN), respectively of OECD 487 recommended maximum concentration (10 mM), we observed significant induction of micronucleus without much cytotoxicity. Our results indicated that

DMN, DEN and therefore related chemicals with low molecular weight will be missed during hazard assessment when tested in HPBL test system according to OECD 487 recommended concentration.

2706 DNA Damages Induced by *Ortho-*, *Para-*, and *Meta*-Chloroaniline Related to the Occurrence of Occupational Bladder Cancer

R. Wang[1], Y. Qi[2,1], H. Horiguchi[2], and T. Toyooka[1]. [1]*Japan National Institute of Occupational Safety and Health, Kawasaki, Japan; and* [2]*Kitasato University Graduate School of Medical Sciences, Sagamihara, Japan.*

More than ten cases of occupational bladder cancer were identified in a chemical factory in Japan, and *ortho*-toluidine, a group I carcinogen as classified by the International Agency for Research on Cancer (IARC), was thought to be the main agent for the disease. However, some other aromatic amines including *ortho*-chloroaniline (OCA) were also used there. OCA has not been assessed for its carcinogenesis by IARC, and its possible role in the occurrence of the occupational bladder cancer is not clear. In this study, we investigated the genotoxic effect of OCA and compared this with its structural isomers, *para*- and *meta*-chloroaniline (PCA and MCA, respectively) as well as aniline, the simplest aromatic amine and group III carcinogen in IARC classification. Human urothelial (1T1) and hepatocyte (WRL-68 or HepG2) cells were treated with OCA, PCA, MCA or aniline at different concentrations for 2-24 hr, and phosphorylated histone H2AX (γ-H2AX), a marker of DNA double strand breaks, and damaged DNA were detected by western blot and pulse field gel electrophoresis, respectively. Results: OCA showed significant γ-H2AX induction both in urothelial and hepatocyte cell lines, and this effect was even stronger than *ortho*-toluidine. PCA and MCA also showed γ-H2AX induction effect. The patterns of induction were different among the three chloroaniline isomers: the induction of γ-H2AX by OCA reached peak at 4 hr and almost disappeared at 24 hr after addition, while the induction by PCA and MCA was becoming strong up to 16-24 hr. The DNA double strand breaks induced by the three isomers of chloroaniline was confirmed on gel electrophoresis. It is speculated that the chloro group position may affect the DNA damaging and/or repairing ability through the metabolic activation. Our results suggested that chloroaniline is a strong DNA damaging agent, and it could play a critical role in the occurrence of occupational bladder cancer if the workers are exposed to the chemical. Further assessment on the carcinogenesis of chloroaniline is necessary for the protection of workers' health.

2707 High-Throughput *In Vitro* Micronucleus Assay in Human Lymphoblastoid Cells

H. Xie, R. Kulkarni, Y. Xu, D. Albert, and S. Roy. *MilliporeSigma, Rockville, MD.*

Micronuclei are chromosome fragments or whole chromosomes that are not incorporated into one of the daughter nuclei during cell division. The *in vitro* micronucleus assay evaluates genotoxic damage by detecting the formation of micronuclei in the cytoplasm of interphase cells. It is a well-established and widely accepted genotoxicity test in preclinical safety assessments to analyze the potential risk for genetic damage in cultured cell lines and primary cells. Traditionally, the *in vitro* micronucleus assay requires a labor-intensive and time-consuming microscopy-based analysis of the treated samples which is low throughput. Here we report a 96-well plate version of the *in vitro* micronucleus assay in which automated scoring of micronuclei and cytotoxicity is achieved by cell-staining approaches with flow cytometer analysis. The p53 proficient and karyotypically stable human B lymphoblastoid cell line, TK6, was used in the assay to reduce the high rate of false positive results that is seen in p53-mutated cell lines and to avoid the donor variability that is seen with human peripheral blood lymphocytes. Seven reference compounds, with positive and negative genotoxic effects, each were tested at 16 dose levels to evaluate the potential to induce micronuclei in TK6 cells in both the absence and presence of an exogenous metabolic activation system. Cytotoxicity and fold-increase in apoptosis/necrosis relative to the vehicle control were also measured. The assay demonstrated a good correlation between the MNT results obtained by the high-throughput assay and the genotoxicity profile of these compounds. The results confirmed that the method may be applied for genotoxicity screening in the pharmaceutical and chemical industry.

2708 Humidity Influence on Slide Preparation in Chromosomal Aberration Assay

L. Gao, L. Wang, D. Chen, X. Shan, M. Tian, W. Lv, and M. Chen. *WuXi AppTec, Suzhou, China.*

The *in vitro* mammalian cell chromosomal aberration assay is used to assess potential genotoxic hazard of test articles and has been used quite extensively in the pharmaceutical industry. In this assay, establishing a method for slide preparation and ensuing quality is particularly important and worth spending on extra effort because it will improve the reliability of results and greatly reduce slide scoring time and technician fatigue in subsequent routine experiments. It is well known that there are differences in chromosome spreading with humidity, however, there is very limited article to elucidate the humidity influence and the optimized humidity for slide preparation. In the past two years, we've been monitoring the humidity in the slide-making area. In this abstract, the seasonal variations are evaluated and an optimized humidity range is proposed. The objective of successful slide preparation is to ensure that the metaphase spreads are kept intact, but the chromosomes are separate and there is as little cytoplasm as possible. In our laboratory, we achieve this by a number of cunning ruses, such as using wet slides, using humidifiers and dehumidifiers to adjust the humidity, by dropping cells from a height to improve spreading or by warming the slides on slide warmer. Before slide preparation, we record the humidity first and then make the slides to check whether the quality meet our criteria, if not, the humidity will be adjusted until the slide can be made successfully. With the air-conditioning, the temperature is stable and around 25°C, but seasonal humidity varies obviously from 19% to 82%. From Oct. to Mar., the humidity are generally below 60% and excellent preparations can be made without adjusting humidity, occasionally the humidifiers will be used to increase the humidity when it is below 30%. From Apr. to Sep., the humidity are generally above 60% and the slides can't be made perfectly without adjusting the humidity, the dehumidifiers will be used to decrease the humidity, sometimes slides will be placed on the vent of dehumidifiers to improve the spreading. Based on about 80 times of slide preparation, the humidity range of 40% to 50% was proposed as the optimized range for slide-making in our laboratory. Our data showed high seasonal humidity variations impacted slide-making and excellent preparations can be made with humidity adjusting. We therefore suggest to monitor and record the humidity in the slide-making area for reference purposes.

2709 Determining Genotoxic Potential and Mode-of-Action in a Single Mammalian Cell Assay

O. Odia, M. Moy, S. Hurtado, M. Wells, L. F. Stankowski Jr., and D. J. Roberts. *Charles River, Skokie, IL.* Sponsor: D. Roberts, Environmental Mutagenesis and Genomics Society

Numerous efforts within the genetic toxicology field aim to move beyond measuring only apical endpoints to assess genotoxic potential. More emphasis is being placed on understanding key molecular events (KEs) in adverse outcome pathways (AOPs) that elicit genotoxicity. Presently, there are assemblies of AOPs (some draft) for DNA reactive and non-reactive modes of action. These biological networks can be used to focus testing strategies on identifying upstream KEs responsible for an observed apical endpoint. Thus, a comprehensive all-in-one mammalian cell assay that can screen for genotoxic potential and assist in identifying relevant AOPs would be of value. Therefore, we implemented flow cytometric analysis of micronuclei (MN) in CHO cells since such scoring facilitates rapid acquisition of induced MN and, uniquely, the CHO test system can discriminate aneuploid daughter cell nuclei that survived non-disjunction (a KE in aneugenic AOPs). Several clastogens (benzo[a]pyrene, cyclophosphamide, etoposide, methyl methanesulfonate, mitomycin C, and quinoline) were tested in a 24-well format with and without metabolic activation (S9) to establish laboratory proficiency prior to challenging the assay with three reference aneugens (carbendazim, colchicine, and vinblastine) and amsacrine (AMSA), a DNA intercalating agent that inhibits topoisomerase II (topo-II). Cells were processed as per the appropriate MicroFlow® kit (Litron Laboratories; Rochester, NY), and up to 10,000 nuclei were analyzed on a BD FACSCanto II. All chemicals evaluated were genotoxic, with significant increases in %MN observed (as compared to the vehicle control; $z' > 0.6$). However, only the three aneugens and AMSA induced significant (>10%) hypodiploidy, a measurement of non-disjunction which is a KE in aneugenic AOPs. Except for AMSA, our results confirm published findings in mammalian cell systems. AMSA and other topo-II inhibitors have shown aneugenic activity *in vivo*, including in germ cells, which is something that was not observed for etoposide during assay proficiency testing. Hence, follow up work will include closer examination of etoposide's dose-response relationship (*e.g.*, testing up to suitable cytotoxicity limits, modifying concentration spacing, etc.) and evaluation of other Topo-II poisons in this assay.

2710 Development of TK6-Derived Cells Expressing Human Cytochrome P450s for Genotoxicity Testing

X. Li, S. Chen, X. Guo, Q. Wu, J. Seo, L. Guo, and N. Mei. *US FDA/NCTR, Jefferson, AR.*

Metabolism plays a key role in chemical genotoxicity; however, most of mammalian cells used for *in vitro* genotoxicity testing are devoid of metabolizing enzymes. We recently developed a battery of TK6-derived cell lines that individually overexpressed one of eight cytochrome P450s (CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C9, 2C19, and 3A4) using a lentiviral expression system. The increased expression and metabolic function of the individual CYP in each established cell line were confirmed using real-time PCR, Western blotting, and mass spectrometry analysis, while their parental TK6 cells and empty vector (EV) transduced cells had negligible CYP levels. Subsequently, we validated these cell lines using two prototypical polyaromatic hydrocarbon mutagens, 7,12-dimethylbenz[a]anthracene (DMBA) and benzo[a]pyrene (B[a]P), that require metabolic activation to exert their genotoxicity. DMBA induced-cytotoxicity, phosphorylation of histone H2A.X, and micronucleus formation were significantly increased in TK6 cells with CYP1A1, 1B1, 2B6, and 2C19 overexpression as compared to EV controls. B[a]P significantly increased cytotoxicity, DNA damage, and chromosomal damage in TK6 cells overexpressing CYP1A1 and 1B1 when compared to EV controls. B[a]P induced-micronucleus formation was also found in TK6 cells overexpressing CYP1A2. These results suggest that our CYP-expressing TK6 cell system is capable of detecting the genotoxicity for compounds that require metabolic activation.

2711 Quantitative Analysis of Aristolochic Acid-Induced Genotoxicity in Rats

N. Mei, X. Li, X. Guo, and T. Chen. *US FDA/NCTR, Jefferson, AR.*

Aristolochic acid (AA) is a group of structurally-related nitrophenanthrene carboxylic acids found in many plants that are widely used by many cultures as traditional herbal medicines. AA is the causative agent for Chinese herbs nephropathy, a term replaced later by aristolochic acid nephropathy (AAN). Evidence indicates that AA is nephrotoxic, genotoxic, and carcinogenic in humans; it induces tumors in forestomach, kidney, renal pelvis, urinary bladder, and lung of rats and mice. Therefore, plants containing AA have been classified as carcinogenic to humans (Group 1) by the International Agency for Research on Cancer. We have conducted a series of genotoxicity and toxicogenomic studies in the rats exposed to AA of 0.1-10 mg/kg for 12 weeks, and the results demonstrated that AA treatments induced DNA adducts and *mutations* in the kidney, liver, and spleen of rats, as well as significant alteration of gene expression in both its target and non-target tissues. We also applied benchmark dose (BMD) modeling to the 3-month AA-induced genotoxicity data. The $BMDL_{10}$s (the lower 95% confidence interval of the BMD_{10} that is a 10% increase over the background level) for inducing *cII* mutations in the kidney, liver, and spleen were 8, 41, and 286 µg/kg/day, respectively. For the H-*Ras* mutations, the $BMDL_{10}$ for kidney (7 µg/kg/day) was about 4-fold lower than that of liver (28 µg/kg/day). The two $BMDL_{10}$ calculated from the dose-response curves of *cII* mutant frequency and H-*Ras* mutation in the kidney were very close, and the obtained $BMDL_{10}$ for AA-induced *mutations* in the kidney of rats was about 7-8 µg/kg body weight per day. With modifying factors (uncertainty or safety factors), the permitted daily exposure (PDE) defined as a pharmaceutically acceptable intake can also be calculated. The more ingestion or inadvertent exposure to AA-containing herbal products, the higher the risk of human diseases, including cancer.

2712 Quantitative Measurement of DNA Adducts in Human Saliva by Nano-Liquid Chromatography-Tandem Mass Spectrometry

C. Liu, Y. Hsiao, L. Chi, and K. Lu. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

There is a critical need to develop a robust method to accurately quantify DNA adducts in the easily accessible specimen which reflects the exposures and responses induced by endogenous exposome and exogenous stimuli. To this end, we developed a high sensitive platform to simultaneously quantify seven kinds of DNA adducts including N_6-Me-dA, N_6-Et-dA, O_6-Me-dG, N_2-Me-dG, N_2-Et-dG, 1,N_2-Etheno-dG, and 1,N_2-Propano-dG using synthetic stable isotope labeled internal standards. This targeted LC-PRM (parallel reaction monitoring) assay analysis was conducted using an UltiMate 3000 RSLCnano system coupled to a Q Exactive HF mass spectrometry. Those seven DNA adducts of targets can be well-separated based on their retention time and accurate mass (<5 ppm mass accuracy) of monitoring product ions in one single run. The detection sensitivity of our optimized assay is able to reach attomole (3.9 attomole for 1,N2-Etheno-dG and 1,N2-Propano-dG; and 1.95 attomole for N2-Me-dG and O6-Me-dG) and sub-attomole levels (0.97 attomole for N2-Et-dG and 0.488 attomole for N6-Me-dA and N6-Et-dA). The calibration curve for each DNA adduct is individually established by plotting the peak area ratios of solutions containing a fixed concentration of isotope labeled internal standard and increasing concentrations of analytical standard without labeling. Moreover, the LC-PRM assay is thoroughly validated by examining the intra- and inter-day accuracy and precision, resulting both less than 15% relative standard deviation (RSD) indicating the robustness of our quantification platform. Next, we applied our assay to detect and quantify of those DNA adduct targets from human saliva samples. In brief, the saliva DNA was extracted and spiked with isotope labeled internal standards prior to digestion to release the nucleosides. The target DNA adducts were purified by off-line reversed-phase fractionation, and thereafter LC-PRM assay analysis. Using our optimized sample preparation and platform, target DNA adducts in human saliva can be successfully quantified. Overall, our study provides a significant improvement and facilitates further applications for quantification of DNA adducts in the easily collected saliva, providing a comprehensive evaluation of human exposome and serving a useful tool to quantify DNA adduct biomarkers for risk assessment of chemicals.

2713 Validation of Duplex Sequencing for *In Vivo* Mutation Detection: Interspecies Comparison

R. Young[1], F. Lo[2], L. Williams[2], C. Valentine[2], S. Minocherhomji[3], M. Fielden[4], and J. Salk[2]. *[1]MilliporeSigma, Rockville, MD; [2]TwinStrand Biosciences Inc., Seattle, WA; [3]Amgen Inc., Thousand Oaks, CA; and [4]Expansion Therapeutics, San Diego, CA.*

Transgenic rodent mutation assays are the gold-standard for measuring *in vivo* mutagenicity. The Big Blue® assays (OECD Test Guideline 488) use transgenic rodents to measure mutations by recovering an integrated shuttle vector through a labor-intensive plaque-based method but provide no genomic information. Duplex Sequencing™ (DS) is a Next Generation Sequencing error correction method that reduces the sequencing error rate by 100,000-fold. This permits measurement of mutant spectra. and for the first time, of mutant frequencies less than 1×10^{-7} for any species, tissue, sex, or DNA segment. Here, we compared DS to the plaque-based assay in BB mice and then extend our analysis into endogenous genes in BB mice and then BB rats. A 15 KB probe set was used in mice focusing on introns and exons of 5 genes. In rats a probe set of 50 KB was selected independent of biological function from approximately equal sized segments from all autosomal chromosomes. Similar low background mutant frequencies and mutant spectra were observed in control mice and rats. Both ethyl nitrosourea (ENU) and benzo(a)pyrene significantly elevated mutant frequency in liver in both species. In mice, the *cII* transgene was included in the DS probe set. In this bridging study the *cII* plaque and DS methods yielded similar fold increases in mutant frequency and shifts in mutant spectra showing equivalence of the two analytical methods to detect mutagenesis. In rats, without *cII* included in the DS probe set, similar patterns of response were seen in the mutant frequency in *cII* plaque and DS in endogenous loci. In both species, unsupervised cluster analysis of simple mutant spectra and trinucleotide spectra showed that each treatment condition produced similar patterns in mice and rats but that there were unique signatures associated with each treatment condition. The data show that DS is equivalent, and in many ways better, at detecting mutations in the *cII* gene. DS is robust in detecting changes in mutant frequency and mutant spectra in endogenous DNA in two rodent species. In summary, our results show that DS is an acceptable method for measurement of *in vivo* mutagenesis and is promising as a new nonclinical biomarker of human cancer risk. DS mutation analysis could be added into any repeat dose study using any wild-type species.

2714 Evaluation of Micronucleus Induction in Erythrocytes of Chicken Embryo-Fetuses Using Flow Cytometry and Laser Scanning Cytometry Approach

Y. Thakkar[1,2]. *[1]Research Institute for Fragrance Materials Inc., Woodcliff Lake, NJ; and [2]New York Medical College, Valhalla, NY.*

The micronucleus assay is a widely used test for detection of mutagenic potential of xenobiotics. The use of techniques such as flow cytometry for detection of micronuclei formation significantly enhances the assay, allowing for high throughput analysis and elimination of several shortcomings of conventional microscopy. Thus, in the current study, flow cytometry and laser scanning cytometry (LSC) were used to evaluate micronuclei formation in erythrocytes of chicken embryo-fetuses in the novel animal-alternative model, Chicken Egg Model (CEM), after exposure to an establish mutagen methyl

methanesulfonate (MMS). For this purpose, white leghorn chicken eggs of undetermined sex were injected with either 20% aqueous solution of Kolliphor® HS15 oil (20% HS-15), which served as a vehicle, or 0.83 mg/egg of MMS on day 9 of incubation followed by collection of blood samples for micronuclei evaluation 24 hours after the injection time on day 10. For flow cytometry detection we utilized the *in vitro* MicroFlow Kit (Litron Laboratories) protocol with few variations, including use of DAPI stain to visualize erythrocyte nuclear DNA. We observed significant increases in the micronuclei formation using blood collected from MMS treated eggs (1.74%) when compared to blood collected from control group (0.70%). In order to establish an optimal detection method, we conducted laser scanning cytometry (LSC) as well as microscopy and both the techniques confirmed the results observed in flow cytometry. Micronuclei formation using LSC in MMS dosed eggs (8.57%) was significantly increased when compared to the control group (3.8%). In addition to blood, livers were also collected for comet assay. MMS produced an increase in DNA strand breaks in the liver (17.4% of DNA in the tail compared to 4.56% in control group). Thus, the results of this study confirms that high throughput techniques, such as flow cytometry and LSC are reliable methods for the detection of micronuclei induction in CEM.

2715 Evaluation of Crop Protection Products for Genotoxicity Potential

R. S. Settivari[1], Z. Yan[2], K. Mikles[1], R. Acosta Amado[2], and C. Terry[2].
[1]Corteva Agriscience, Newark, DE; and [2]Corteva Agriscience, Indianapolis, IN.

Assessment of genotoxic potential is an important component of the safety evaluation process of crop protection (CP) active ingredients (a.i.) and their formulated products (FP). Each a.i. is thoroughly tested for genotoxic potential using bacterial and mammalian tests, *in vitro* and *in vivo*. Upon any positive or equivocal results, a.i.'s is further evaluated in higher-tier genotoxicity tests. Active ingredients are formulated either singly or in mixtures with other a.i's in diverse formulation types. In addition to a.i.(s), CP formulations contain multiple co-formulants, including solvents, surfactants, etc. There is increasing interest to investigate the effect of co-formulants on the genotoxic potential of the final FP. The purpose of this retrospective evaluation was to examine whether genotoxicity results of FPs are consistent with corresponding a.i.(s) and further to evaluate whether co-formulants enhanced the genotoxic hazard of the final FP. In this study, genotoxicity (Ames and *in vivo* micronucleus tests) data for 156 commercial CP formulations and their corresponding a.i.(s) (n=86) and co-formulants were compiled and assessed. The genotoxicity data for a.i.'s was obtained from GLP studies (followed OECD TG) and the data for co-formulants was compiled from ECHA dossiers and safety data sheets. The FPs consisted of 1-3 a.i's and up to 13 co-formulants and comprised of both solids and liquids representing a total of 16- formulation types. The a.i. concentrations in FP ranged from 2 to 75% and co-formulant concentrations up to 85%. In many cases, each a.i was formulated in various forms (salts, acid, amine etc) and in multiple FP (up to 19). Evaluation of the data for a.i.'s and co-formulants suggested lack of genotoxic potential at tested concentrations. The CP formulations data indicated that genotoxicity potential did not change compared to corresponding a.i.'s irrespective of concentrations and number of a.i.'s or co-formulants in each formulation and formulation type. Furthermore, all evaluated FPs were negative for genotoxicity. In conclusion, these results suggested that the combination of a.i's and co-formulants did not increase genotoxicity in a representative group of diverse type of formulations. These data support that additional tests for formulations are not warranted to confirm genotoxicity potential when a.i's are extensively evaluated and all selected co-formulants are non-genotoxic.

2716 Impact of Glutathione (GSH) on the Mutagenicity and Cytotoxicity of Methyl- and Ethyl Acrylate in the Mouse Lymphoma Assay

N. Honarvar[1], E. Fabian[1], R. Landsiedel[1], R. Ellis-Hutchings[2], L. Finch[3], and W. Karin[1]. *[1]BASF SE, Ludwigshafen am Rhein, Germany; [2]Dow, Midland, MI; and [3]Arkema Inc., King of Prussia, PA.*

Ethyl Acrylate (EA) and Methyl Acrylate (MA) are monomer building blocks in the production of polymers and copolymers. The genotoxicity and mutagenicity data sets support a cytotoxic, non-genotoxic mechanisms for these acrylates. EA did not induce mutations in a Transgenic mouse assay *in vivo* (Ellis-Hutchings et al, 2018), whereas treatment of LY5178 mouse lymphoma cells *in vitro* with MA or EA in the thymidine kinase gene mutation assay led to a significant increase in the mutation frequency of the treated cells (Moore et al, 1988). An increased mutation frequency was only observed at cytotoxic concentrations. Considering the high binding affinity of the compounds to the intracellular antioxidant Glutathione (GSH), and known propensity of EA and MA to acutely deplete GSH *in vivo*, we postulated that the observed effects *in vitro* might derive from a depletion of the GSH. In the present study the impact of exogenously supplemented GSH on the mutagenicity and cytotoxicity of MA and EA was analyzed. Pulse treatment of LY5178 mouse lymphoma cells with either MA or EA (10-35 µg/mL) induced concentration dependent cytotoxic effects (relative total growth of 14.1 and 10.2% after treatment with 30 and 35 µg/mL of MA and EA, respectively). Supplementation of the treated cultures with 100 µM GSH abrogated both the observed cytotoxicity as well as the mutagenicity. The quantification of the GSH levels in the cell lysates after the treatment period showed a concentration related decrease in the intracellular GSH levels (down to 18.2 and 13.4% of the corresponding controls for MA and EA, respectively). The present data demonstrate that MA or EA decreases intracellular GSH levels in LY5178 mouse lymphoma cells *in vitro*. The cytotoxic and mutagenic effect was attenuated in a concentration-dependent manner by GSH supplementation. These observations suggest that the previously observed mouse lymphoma mutagenicity of MA and EA was likely due to a depletion of GSH *in vitro* and may explain the differences in the outcome of *in vitro* versus *in vivo* tests.

2717 Effects of Amlexanox and Other Compounds on DNA Repair in Xeroderma Pigmentosum Group C Cells

L. Al-Eryani, S. G. Khan, D. E. Tamura, J. J. DiGiovanna, and K. H. Kraemer.
National Cancer Institute, Bethesda, MD.

Xeroderma pigmentosum (XP) is a rare autosomal recessive DNA repair disorder caused by mutations in 8 genes, XP-A to -G, and Variant with severe sun sensitivity and10,000-fold increased risk of skin cancer. XP-C is the most common type in the US About 12% of XP-C patients have premature termination codon (PTC) mutations that can lead to XPC protein elongation arrest and *XPC* mRNA template degradation by nonsense mediated decay. Previous studies in our laboratory have shown that levels of expression of *XPC* mRNA and XPC protein in fibroblasts derived from XP-C patients with PTC mutations were enhanced by aminoglycosides. Amlexanox, which is an anti-inflammatory, antiallergic and immunomodulator, was reported to increase readthrough in human cells with PTC associated diseases. Amlexanox is a topical paste indicated to treat several inflammatory conditions. Exposure to amlexanox will enhance the expression of *XPC* mRNA in fibroblasts and lymphoblasts derived from XP-C patients with different PTC mutations and different baseline levels of XPC mRNA. Methods: Parallel pairs of fibroblasts and lymphoblasts derived from two unrelated patients along with 2 normal control cells were exposed to amlexanox and/or our previously tested aminoglycosides. *XPC* mRNA levels were measured using standardized qRT-PCR and the results were compared to normal unexposed cells of each type. Levels of *XPC* mRNA increased in XPC fibroblasts exposed to both G418 and amlexanox to a different extent in different cells. Levels of *XPC* mRNA expression changed with amlexanox in parallel pairs of fibroblasts and lymphoblasts in a similar fashion in both patients. Due to the availability of amlexanox and the other tested drugs in our study commercially as topical dosage forms, they could be used as potential therapeutic agents for increasing functional *XPC* protein with less associated systemic toxicity and thereby decrease XP-C associated skin cancer risk. This preclinical test is a step forward towards precision medicine in which it would help with patients selection and determining which drug combination would be optimal to increase XPC function for each patient.

2717a Acetaldehyde-Induced DNA-Protein Crosslinking in Human Bronchial Epithelial BEAS-2B Cells and Hepatic Stellate Cells

J. Zhang[1], H. Chen[1], A. Wang[2], Y. Liu[2], H. Hou[1], Q. Hu[1], and H. Wang[3].
[1]China National Tobacco Quality Supervision and Test Center, Zhengzhou, China; [2]Chinese Academy of Sciences, Hefei, China; and [3]China National Tobacco Quality Supervision & Test Center, Zhengzhou, China.

Acetaldehyde is a common pollutant in air, and also produced by human alcohol metabolism. Acetaldehyde not only causes decreased cell activity, but also induces DNA damage such as DNA-protein crosslinking (DPC) in human cells. DPC blocks the normal transcription and replication of DNA, therefore it can be used as a molecular marker for potential mutations in the body. In the current study, we investigated DNA-protein crosslinking rate both in BEAS-2B cells and hepatic stellate cells (HHSteCs). BEAS-2B cells and HHSteCs were exposed to 4, 8, 10, 12 and 16 mM acetaldehyde for 24h after normally cultured for 24h. DNA-protein crosslinking was estimated by KCl-SDS assay. And DNA was detected by dyed with SYBR Gold nucleic acid stain. The results showed that DPC ratios were significant increased both in BEAS-2B cells and HHSteCs when treated with acetaldehyde. The experiment also indicated a dose-dependent effect. In addition, DPC ratio in HHSteCs was slightly higher than in

BEAS-2B cells, which means HHSteCs might more sensitive than BEAS-2B cells while exposed to acetaldehyde. As an environmental chemical, acetaldehyde induced DNA breakage both in lung cells and liver cells.

2718 Glyoxal-Derived Advanced Glycation End Products Induce Apoptosis in Hepatocytes

J. Kang, Y. Jeong, and K. Lee. *Korea University, Seoul, Korea, Republic of.*

Final products of the non-enzymatic reaction between amino groups of protein, lipids, nucleic acids and reducing sugars are called advanced glycation end-products (AGEs). It has been known that AGEs interact with RAGE, the receptor for AGEs located on the plasma membrane and induce inflammation, and the generation of reactive oxygen species (ROS), triggering oxidative stress. This disrupts the intracellular signaling and gene expression, leading to apoptosis. Apoptosis is highly programmed cell death that is vital for the maintenance of homeostasis in multicellular organisms. Excessive apoptosis on the other hand, leads to acute injuries including fulminant hepatitis and chronic diseases such as viral hepatitis and alcoholic liver disease. According to several studies, AGEs may contribute to hepatic fibrosis and chronic liver disease. Still, the relationship between exposure to AGEs and hepatic apoptosis remains unclear. In this research, HepG2 cells were used to investigate hepatic apoptosis by glyoxal-derived AGEs (glyoxal-AGEs) MTT assay was carried out to assess the cytotoxicity of glyoxal-AGEs. To detect the oxidative stress induced by glyoxal-AGEs, ROS production was measured. Expression level of apoptotic factors such as Bax, Bcl-2, caspase 3, caspase 9 and p53 at mRNA level and protein level were measured using RT-qPCR and Western blot analysis. As HepG2 cells were exposed to glyoxal-AGEs, the production of ROS increased. Additionally, the mRNA level of pro-apoptotic markers such as Bax, p53, caspase 3, and caspase 9 increased while the level of anti-apoptotic maker, Bcl-2 decreased, reducing the Bcl-2/Bax ratio. Western blot analysis also showed that the protein level of same pro-apoptotic markers increased as anti-apoptotic marker Bcl-2 decreased. These results suggest that glyoxal-AGEs may induce ROS-dependent apoptosis in hepatocytes.

2719 Methyl Glyoxal-Derived Advanced Glycation End Products Induced Kidney Cell Apoptosis, Leading to the Endoplasmic Reticulum Stress and Mitochondria Dysfunction through MAPK/JNK Pathway

S. Jeong, and K. Lee. *Korea University, Seoul, Korea, Republic of.*

Diabetic nephrosis, which occurs in proximal renal epithelial cells, is one of the main complications of diabetic patients around the world. If diabetic necrosis occurs, the function of the endoplasmic reticulum (ER) and mitochondria in the kidney cell will deteriorate, interrupting protein synthesis and reducing ATP synthesis, causing inflammation, fibrosis, and cell death. Recent studies have shown that advanced glycation end products (AGEs) are substances that play an important role in inducing diabetes, Among the AGEs from various sugars, especially, those derived from methylglyoxal have recently been found to be a major cause of diabetes. and interact with AGE for receptors (RAGE) located on the cell surface to control multiple signaling systems with mitochondrial dysfunction. When ER stress signal occurs, ER stress leads to activation of c-Jun N-terminal kinase (JNK) and induction of C/EBP homogenous protein (CHOP). Both JNK and CHOP increase the apoptotic effect of Bax and remove the anti-apoptotic effect of Bcl-2 to express in kidney cells. In this study, methyl glyoxal-derived AGE (200 μg/mL) was treated to human proximal epithelial kidney cells (HK-2), and cell viability was measured. We confirmed that methyl glyoxal-derived AGE combined with RAGE, caused ER stress and affected the membrane potential of the mitochondria as the CHOP is controlled through the phosphorylation of JNK. This confirmed that the renal cell function was impaired by an imbalance in the mitochondrial membrane and interaction with Bax/Bcl-2 that affected cell apoptosis due to inhibiting ATP synthesis. This tendency was demonstrated in animal experiments by oral administration of 800 mg AGEs /kg.bw to C57/BL6 mouse for 21 d to demonstrate the expression of ER stress and cell apoptosis biomarkers Bax/Bcl-2 by methyl glyoxal-derived AGEs. Through *in vitro* and *in vivo* test, we are going to provide a new perspective on the diabetic kidney disease mechanism induced by methyl glyoxal-derived AGE and identify the signal pathway system leading to kidney cell dysfunction through the mitochondria membrane imbalance and ER stress.

2721 Moxidectin, a Novel Therapeutic Option for Pediatric Medulloblastoma

K. Kaushik, and S. Srivastava. *Texas Tech University Health Sciences Center, Abilene, TX.*

Pediatric brain tumor is one of the most malignant solid tumors in children and have profound impact on the morbidity and mortality in these patients. Statistically, brain tumors are one of the leading cause of cancer-related deaths in patients from 0-19 years of age. Medulloblastoma (MB) is one of the most common pediatric brain tumors occurring in children. Sonic hedgehog (Shh) activated subgroup of MB is considered to be highly aggressive and metastatic in nature. Shh-MB is characterized by mutations in PTCH1, SMO and SuFu along with amplified activation of Gli1, a major transcription factor of this signaling pathway. In the current study, we have evaluated the anti-cancer effects of an anthelminthic drug 'moxidectin'. Several MB cell lines such as Daoy, UW426, UW228, ONS76, and PFSK1 were treated with moxidectin in a concentration and time dependent manner. Our results demonstrated that moxidectin treatment resulted in significantly reduced proliferation of MB cells. The IC_{50} of moxidectin in all the MB cell lines ranged 10-17μM after 24, 48 and 72 hours of treatment. Moreover, moxidectin was able to induce 3-4 fold increase of apoptosis in all the MB cell lines as evaluated by AnnexinV-FITC/PI assay, and increased cleavage of caspase 3 and PARP. Western blotting analysis demonstrated that moxidectin treatment significantly reduced the expression of Shh and Gli1 and their downstream effector molecules such as Pax-6, Oct-4, Sox-2 and Nanog. Efficacy of moxidectin was evaluated in an *in vivo* tumor model by subcutaneously injecting human Daoy MB cells in the right and left flank of the mice. Our results demonstrated that 5mg/kg and 10 mg/kg moxidectin by oral administration everyday suppressed the growth of Daoy tumors by 70% and 90% respectively. Conclusively, our results indicate that moxidectin effectively reduces the growth of MB tumors by inhibiting Shh signaling. Most importantly, moxidectin is FDA approved drug and is already in clinical use for the treatment of river blindness in humans with an established safety record, therefore any positive findings from our studies will prompt further clinical investigation into repositioning moxidectin for the treatment of MB patients.

2722 Pancreatic Tumor Growth Suppression through Induction of Autophagy by a Novel Anti-Parkinson's Drug, Pimavanserin

S. Ramachandran, and S. K. Srivastava. *Texas Tech University Health Sciences Center, Abilene, TX.*

Pancreatic cancer patients have limited treatment options in spite of several advanced treatment strategies. Pancreatic tumors exhibit high basal autophagy compared to other cancers. Several studies including from our lab reported that enhanced autophagy can lead to apoptosis in cancer cells. In this study, we have demonstrated that pimavanserin (PVT) suppresses pancreatic tumor growth by inducing autophagy-mediated apoptosis. Our results indicated that PVT induced apoptosis and reduced the proliferation of pancreatic cancer cells with IC_{50} ranging between 3-9μM after 24, 48 and 72 hours of treatment. In addition, PVT inhibited the colony formation of pancreatic cancer cells. Treatment of pancreatic cancer cells with increasing concentrations of PVT resulted in a concentration-dependent increase in autophagy as evaluated by acridine orange assay by flow-cytometry. PVT induced the expression of autophagy markers ULK1, FIP200, Atg101, Beclin-1, LC3B and p62 in a concentration-dependent manner in several pancreatic cancer cells. Apoptotic effects of PVT in pancreatic cancer cells was validated by increase in cleavage of caspase3 and PARP. Oral administration of PVT suppressed BxPC3 tumor xenografts by 50% in athymic nude mice. In another *in vivo* experiment, PVT treatment inhibited the growth of orthotopically implanted PANC1 tumors by 75%. Autophagy was confirmed in the tumors of PVT treated mice by western blotting. Apoptosis was confirmed in the tumors of PVT treated mice by immunohistochemistry and western blotting. Chronic administration of PVT did not exhibit any general signs of toxicity or behavioral side effects in mice. Moreover, long-term administration of PVT did not alter the clinical chemistry parameters like ALT, AST, total serum protein, calcium and albumin. Collectively, our results indicate that PVT mediated pancreatic tumor growth suppression was associated with the induction of autophagy and apoptosis. Since PVT is already available in the clinic with an established safety profile, our results will accelerate its clinical development for pancreatic cancer therapy.

2723 Cytotoxicity of Peracetic Acid Vapor Exposures on Human Bronchial Epithelial Cells

N. S. Olgun, J. P. Coyle, B. H. Blackley, A. M. Morris, M. S. Orandle, W. McKinney, and S. S. Leonard. *NIOSH, Morgantown, WV.*

Peracetic acid (PAA) is a highly reactive peroxygen compound that is widely used as a disinfectant in healthcare settings and poultry processing plants. PAA is irritating and corrosive to the eyes, skin, and mucous membranes of the respiratory tract. Workers exposed to PAA vapors from the spraying and fogging of disinfectant solutions have reported symptoms such as headaches, lacrimation, coughing, wheezing, and blurred vision. Using a commercially available solution of PAA (32 weight % in dilute acetic acid), we aimed to identify the possible cytotoxicity associated with vapor exposures on normal human bronchial epithelial cells (NHBEs) *in vitro*, differentiated on porous, transwell membranes at the air-liquid interface. Using an in-house exposure chamber, NHBEs were exposed to filtered air (FA) for 1 hour (h), 2 h, and 4 h. This was to account for differences in temperature, relative humidity (RH) and carbon dioxide (CO_2) as compared to the cell culture incubator. Temperature in the chamber was 74.4 °F, RH was 90.4%, and CO_2 in ambient air was 0.04%. Using the water soluble tetrazolium assay, no significant differences in viability were detected between FA-exposed cells and incubator controls. Next, NHBEs were exposed to either FA (controls), 12 or 22 ppm of PAA for 4 h and then returned to incubators for an additional 4 or 24 h recovery period. Cellular viability, lactate dehydrogenase (LDH) production, cytokine production (IL-1β, IL-6, IL-8, and TNFα) and microscopic changes in cells were assessed at 4 and 24 h post exposures. Compared to FA controls, PAA (22 ppm) reduced cellular viability and increased LDH release, denoting acute cytotoxicity upon exposure at both time points. Cytokine production in FA-treated cells was not significantly different than PAA-treated cells, except for IL-6 at both time points. Microscopic changes were assessed using H&E staining of cells. Compared to controls at 24 h, PAA caused cell necrosis and loss of cilia. Our studies show that exposure of NHBE cells to PAA causes significant changes in viability, LDH production, IL-6 production and microscopic abnormalities when compared to FA. Further studies are needed to delineate the exact mechanism(s) by which this occurs.

2724 Development of a Highly Accurate Genome Sequencing Method and Its Application in the Genome-Wide Analysis of Chemical Mutation Signatures

S. Matsumura, H. Sato, Y. Otsubo, J. Tasaki, N. Ikeda, and O. Morita. *Kao Corporation, Tochigi, Japan.* Sponsor: J. Coleman

Direct detection of rare and mutagen-induce*d mutations* using a genome sequencer will facilitate a more accurate understanding of the mutational profile of mutagens and their relationships with cancer. However, this is difficult due to a higher frequency of errors associated with the existing genome sequencers. Thus, we developed a highly accurate genome-sequencing method utilizing double-strand DNA sequence and analyzed genome-wide mutations caused by exposure to chemicals. We optimized our sequencing method and achieved high accuracy with an error frequency of less than one per 10^7 -10^8 bp. We analyzed DNA samples of mutagen (i.e., *N*-methyl-*N*-nitrosourea (MNU), *N*-ethyl-*N*-nitrosourea (ENU), diethylnitrosamine (DEN), benzo[a] pyrene (B[a]P), and aristolochic acid (AA))-exposed *Salmonella* typhimurium TA100 cells and *gpt* delta mice, and obtained large-scale genome-wide somatic mutation data. In *gpt* delta mice, approximately 2500-63000 mutations per material were detected depending on the materials. Meanwhile, in *S. typhimurium*, approximately 1300-95000 mutations per material were detected. The six-type mutational spectra showed clear mutation patterns that represented the action mechanisms of each mutagen (e.g., G:C > A:T for MNU). In ENU or AA-exposed samples, significantly different mutational patterns were obtained from *S. typhimurium* and *gpt* delta mice, which suggested the differences in mutagenesis between these species. In MNU-exposed, but not ENU- or DEN-exposed *gpt* delta mice, the 96-trinucleotide mutation signature analysis revealed patterns similar to a known signature of an alkylating agent in human cancer (i.e. signature 11 in the COSMIC database). Furthermore, the signatures for ENU and DEN exhibited a high similarity with each other, suggesting that these mutagens have a common mutagenic mechanism. These results indicated that our sequencing method is useful for precisely characterizing chemical mutagenicity and establishing the link between mutagens and cancer.

2725 Development of a Novel Genome-Wide Mutagenicity Assay Based on Highly Accurate Genome Sequencing: A Case Study Using *Salmonella typhimurium* TA100

Y. Otsubo, S. Matsumura, N. Ikeda, and O. Morita. *Kao Corporation, Tochigi, Japan.* Sponsor: J. Coleman

We developed a highly accurate genome sequencing method that comprehensively detects rare mutagen-induce*d* mutations. To evaluate its applicability and utility, we analyzed DNA samples of *Salmonella* typhimurium TA100 exposed to mutagens. We evaluated 12 mutagens of various structural groups, including those requiring metabolic activation (*i.e.* alkylating agents, aldehydes, aromatic amines, and polycyclic aromatic hydrocarbons (PAHs)), and assessed the detection limit of mutation frequency and the ability to analyze various mutation patterns. Our method detecte*d* mutations caused by all 12 mutagens, including those with low mutation frequency such as aldehydes (c.a. 7-fold increase compared to the control), which induced nearly 2-fold increase in the number of His^+ revertants compared to control in Ames test. Although PAH-induce*d* mutations were detected, the sensitivity was not sufficient to assess mutagenic mechanisms. TA100 may not have been sufficiently exposed to these mutagens in the liquid culture due to their extremely low water solubility. Therefore, we modified the exposure conditions for these chemicals. For this, TA100 was allowed to form His^+ revertants on agar plates post mutagenic exposure. Then, genomic DNA was extracted from these cells for mutational analyses. Thereby, 7,12- dimethylbenz[a]anthracene- and 3-methylcholanthrene-induce*d* mutations on the major spectrum (G:C > T:A) increased by ~5.4 and 4.1 times relative to liquid culture samples. Therefore, our method can sensitively detect most TA100-positive mutagens. Furthermore, mutagens from the same structural group exhibited similar mutation spectra (*e.g.* G:C > A:T for alkylating agents), which reflected the mutagenic mechanism of each group. Next, we evaluated the 96-trinucleotide mutational signatures using the obtained mutational data. Signatures of the alkylating agents (*e.g. N*-methyl-*N*-nitrosourea) were similar. Similarly, those of aldehydes, aromatic amines, and PAHs were similar to each other (broad spectra of G:C > T:A). These signatures were also similar to known mutational signatures of alkylating agents and tobacco in human cancer, respectively (*i.e.*, signature 11 and 4 in COSMIC database). Our method provides detailed data on mutagen-induce*d* mutations and promotes understanding of their mechanism of action and relationship with human cancer.

2726 Development of an Intracellular Microtubule Stability Assay Using GFP-α-Tubulin

I. Brandsma, R. Derr, P. van Rossum, N. Moelijker, and G. Hendriks. *Toxys B.V., Leiden, Netherlands.*

Aneuploidy, the presence of an abnormal number of chromosomes, is often observed in cancer and several classes of chemicals are known to cause aneuploidy. To detect aneugenicity as result of chemical exposure, typically the micronucleus assay is used. However, both broken DNA fragments caused by clastogenic agents and mis-segregated chromosomes caused by aneugenic agents can lead to the formation of micronuclei. To confirm an aneugenic mode of action, a laborious centromere or FISH staining is needed to assess whether broken chromosomes or complete chromosomes are present in the micronucleus. Aneugenicity can be caused by any process that interferes with chromosome segregation during mitosis, including microtubule disruption or inhibition of cell cycle kinases like Aurora A/B. Here we established an assay to study the effect of substances on tubulin stability, to provide more insight into the cause of aneuploidy upon substance exposure. Several *in vitro* and cellular assays are available to measure tubulin stability. However, most of these assays are dependent on a tubulin labelling step on fixed cells. Here we developed an assay using GFP-tubulin, allowing the direct visualisation of microtubuli, using either live cell microscopy to follow the dynamics during the cell cycle or flow cytometry. First a GFP-Tubulin reporter was stably integrated into mouse embryonic stem cells. We confirmed that the GFP-tubulin was properly integrated in microtubuli. To measure the effect of microtubule disrupting substances, cells were treated with various tubulin poisons and the amount of GFP-tubulin signal in microtubules was quantified using flow cytometry. A DNA staining was included to assess the effect of the agent on the cell cycle distribution. In the assay, both tubulin stabilising and tubulin destabilising substances could be detected. Treatment with both types of substances resulted in an accumulation of cells in G2/M phase. Treatment with agents that affect cell cycle progression but not microtubule stability, such as DNA damaging agents or Aurora kinase inhibitors, did not affect tubulin stability. In conclusion, we developed a microtubule stability assay in mouse embryonic stem cells that can efficiently detect both stabilising and destabilising microtubule disruptors and can be used to detect an aneugenic mode-of-action of genotoxic compounds.

2727 The Impact of Structural Modification of Oxaliplatin on Cell Survival

J. R. Schlabach, J. S. McManus, L. Freeman, and B. B. Williams. *Western Kentucky University, Bowling Green, KY.*

The platinum compounds cisplatin, carboplatin, and oxaliplatin are FDA approved cancer treatments in the US These platinum compounds are cell-damaging agents with comparable structures that are used for the treatment of different cancer types. They each have two ligands attached to the platinum atom: a leaving and a non-leaving ligand, both of which vary across compounds. Despite the diversity of platinum-based compounds, the mechanism of cytotoxicity is similar, triggering apoptosis by interrupting replication, the specific compound to be used in treatment is determined by the tissue of origin. We hypothesize that the structural differences in these novel compounds will alter cell-specific cytotoxicity and intracellular accumulation, as compared to oxaliplatin. In this study, two novel compounds, derivatives of oxaliplatin were tested for toxicity in several cell lines. Oxalato((1R,2R)-N,N-dimethyl-1,2-diaminocyclohexane)platinum(II) (Pt(me2dach)(ox)), differs from oxaliplatin as in that a hydrogen on each nitrogen of the non-leaving ligand has been replaced with a methyl group. Oxalato(S,S)-1,2-diaminocyclohexane (Pt(S,S-dach)(ox)), differs from oxaliplatin only in the stereochemistry of the leaving ligand. Both novel compounds have an oxalate leaving group identical to oxaliplatin. The toxicological profile of our novel compounds was determined in cell lines derived from embryonic kidney cells (HEK 293), melanoma cells (SK-Mel-5), and colon cancer cells (HT-29). The cell lines are individually plated at equal concentrations at time 0, then at 24 hours exposed to increasing concentrations of the platinum compound. After a total of 48 hours, an MTT assay is performed to determine cell survival. From the survival concentration-response curve, the IC50 value is determined. The difference in the cell survival between the cell types is established by comparison of the IC50. Pt(me2dach)(ox) has lower cell death than oxaliplatin in melanoma (SK-Mel-5) and preliminary data suggests the same trend in embryonic kidney cells (HEK293). Pt(me2dach)(ox) causes higher cell death in HEK 293 cells than in SK-Mel-5. Concerning the novel platinum Pt(S,S-dach)(ox), the comparison of the IC50 values between HEK293 and HT-29 show an increased cell survival at higher concentrations in the HT-29 cells. This compound also showed a lower IC50 than oxaliplatin in HEK293.

2728 Induction of Aromatase Expression in Breast Cancer Cells through a Non-Genomic Signaling of Estrogen Receptor Alpha 36

G. Lee, J. Park, J. Kim, and H. Jeong. *Chungnam National University, Daejeon, Korea, Republic of.*

Estrogens play an important role in the development and progression of breast cancer. In addition, estradiol has been show to modulate aromatase expression in breast cancer cells. The enzyme responsible for the production of estradiol is aromatase, a member of the cytochrome P450 family. The effects of estrogen are mainly mediated by their interaction with the estrogen receptor (ER). 17β-Estradiol (E2) has reported to induce the development and growth of various ER-negative breast cancers. The effects are rapid and non-genomic, suggesting that a membrane-associated ER (mER) is involved. ERα36 has been shown to mediate rapid, non-genomic, membrane-associated effects of E2 in several cancer cell lines, including triple negative MDA-MB-231 breast cancer cells. The aim of this study was to determine if ERα36 mediates aromatase expression, and to elucidate the mechanism involved. Treatment with BSA conjugated E2 (BSA-E2)-induced aromatase protein expression in human breast cancer cells; enhancing aromatase gene expression, and promoter activity. Treatment with G15, an estrogen receptor antagonist, did not affect the inductive effects of BSA-E2 on aromatase expression. In addition, BSA-E2 increased the phosphorylation of Akt, ERK and CREB in their signaling pathways in human breast cancer cells. ERα36-silencing was used prior to these treatments to determine the role of ERα36 in these effects and to determine which signaling molecules were involved. We found that ERα36 in fact mediates the increased aromatase expression by BSA-E2 in breast cancer cells. Therefore, these results suggest that estradiol promote to aromatase expression through ERα36-mediated phosphorylation of Akt, ERK and CREB. In addition, it is provide that ERα36 may be a potential target for drug design against breast cancer, particularly triple negative breast cancer.

2729 *In Vitro* Assessment of the Transactivation of Chicken Estrogen Receptor by Bisphenol Analogs

M. Sakata[1], Y. Yoshinouchi[1], H. Nakata[1], E. Kim[2], and H. Iwata[1]. *[1]Ehime University, Matsuyama, Japan; and [2]Kyung Hee University, Seoul, Korea, Republic of.*

Bisphenol A (BPA) has been used for the manufacture of polycarbonate plastics and epoxy resins. BPA and its analogs (bisphenols; BPs) are widely detected in the environment, and their potential estrogenic effects on wild animals are of great concern. It is known that some of BPs elicit estrogen-like responses. However, little information is available for the effect of BPs on the estrogen receptor (ER) signaling pathway in birds. There are also still unanswered questions about the structural preference of BPs by ER and the molecular mechanism of ER activation. To assess the transactivation potency of BPs *via* chicken ERα (ckERα), we measured the potencies of 26 bisphenol analogs (BPs) by using the *in vitro* reporter gene assay system that ckERα was transiently expressed in COS-1 cells. Results showed that 4,4′-methylenebisphenol (4,4′-BPF), 2-[(4-hydroxyphenyl)methyl]phenol (2,4′-BPF), bis(4-hydroxyphenyl)methanone (HBP), and 4,4′-thiobisphenol (TBP) had dose-dependent responses, whereas 4,4′-(1-methylethylidene)bisphenol (BPA), 4,4′-[2,2,2-trifluoro-1-(trifluoromethyl)ethylidene]bisphenol (BPAF), 4,4′-ethylidenebisphenol (BPE), 2,2′-methylenebisphenol (2,2′-BPF), 4,4′-sulfonylbisphenol (BPS), 4,4′-(2,2-dichloroethenylidene)bisphenol (BPC2), 4,4′-(1-phenylethylidene) bisphenol (BPAP), and 1,1′-(1-methylethylidene)bisbenzene (DPP) had no transactivation potency. Relative potencies (E_2-REP_{20}) estimated from relative effective concentrations (REC_{20}) of tested BPs that induce the response corresponding to 20% of the maximum 17β-estradiol (E_2) response indicated that HBP had the highest E_2-REP_{20} (5.0×10^{-4}), followed by 2,4′-BPF (1.0×10^{-4}), 4,4′-BPF (7.3×10^{-5}), and TBP (6.1×10^{-5}).

2730 Regulation of ARNT Alternative Splicing upon T Cell Activation

A. Cooper, I. Muro, M. Kuyumcu-Martinez, and C. Wright. *University of Texas Medical Branch at Galveston, Galveston, TX.*

The aryl hydrocarbon receptor (AHR) is a cytosolic receptor that mediates the effects of environmental contaminants on the body. When activated, AHR translocates to the nucleus and dimerizes with the aryl hydrocarbon receptor nuclear translocator (ARNT) and together they bind to xenobiotic response elements of AHR-ARNT related genes. Early studies have shown that AhR-deficient mice have altered lymphocyte numbers in the spleen, thus showing the importance of AHR for homeostasis of the immune system. In fact, AHR has been found to be functionally up-regulated during naïve T cell activation and promotes the expression of the pro-inflammatory cytokine IL-22. This up-regulation of AHR and IL-22 is essential to allow T cells to respond and promote an inflammatory response when exposed to environmental contaminants like tobacco smoke. The immune system requires a high degree of diversity to adapt and respond to these changes in the environment. Upon T cell activation, about 10-15% of alternative exons undergo a >10% change in inclusion which is critical for eliciting an immune response. The main binding partner of AHR, ARNT is alternatively spliced to produce two main isoforms, ARNT isoform 1 and 3, which differ in the inclusion of exon 5 found in ARNT isoform 1. Interestingly, naïve lymphocytes have equal amounts of ARNT isoform 1 and 3, whereas during T cell activation there is an increase in the amount of ARNT isoform 1. We have identified that RBFOX2, an RNA binding protein up-regulated during T cell activation, as a key regulator of ARNT alternative splicing. Targeted suppression of RBFOX2 in a T cell cancer line showed a decrease in the amount of ARNT isoform 1 with an increase in isoform 3. Site-directed mutagenesis was used to map RBFOX2 binding to specific sequences in the downstream intron which promotes the inclusion of ARNT exon 5 into the final mRNA transcript. Through targeted suppression of either ARNT isoforms it was found that the loss of ARNT isoform 3 promoted an increase in expression of the crucial T cell activation cytokine IL-2. This study has identified a novel role of how ARNT is alternatively spliced to produce an isoform that is up-regulated after naïve T cell activation and is critical in promoting a proper T cell response to adapt to environmental changes.

2731 Regulation of Co-regulator Recruitment by an AhR-Activation-Directed, CK2-Mediated Phosphorylation of ARNT Isoform 1

L. Bourner, I. Muro, and C. Wright. *University of Texas Medical Branch at Galveston, Galveston, TX.*

The aryl hydrocarbon receptor (AhR) is a cytoplasmic bound receptor that is activated by interaction with various endogenous or exogenous ligands. Once activated, AhR translocates to the nucleus where it associates with the aryl hydrocarbon receptor nuclear translocator (ARNT) to form a functional DNA binding heterodimeric transcription factor, which is involved in numerous physiological processes including toxicant responses, immunological function, and development. Interestingly, ARNT is alternatively spliced into two distinct isoforms, ARNT isoform 1 and ARNT isoform 3. These two ARNT isoforms differ by 15 amino acids that make up exon 5 of ARNT isoform 1. This exon encodes a unique phosphorylation site at serine 77 (S77), which can be robustly induced upon exposure to both exogenous and endogenous AhR ligands. Recently, we have determined that ARNT rapidly undergoes phosphorylation in human T cell lines following AhR activation, however the function of this phosphorylation event remains unclear. We hypothesized that upon AhR ligand exposure, ARNT undergoes phosphorylation that is mediated by casein kinase 2 (CK2) to perform a crucial role in AhR target gene transcription and co-regulator recruitment, thus allowing for a specific toxicant response. We have determined that ARNT isoform 1 phosphorylation is dependent on AhR activation as the inhibition or knockdown of AhR results in a significant reduction in phosphorylation compared to samples with intact AhR function. We have also found that upon inhibition and knockdown of CK2, the phosphorylation event of ARNT isoform 1 is abolished and correlates with a significant decrease of AhR target gene transcription and a decrease in recruitment of the well-documented co-regulator, CREB binding protein (CBP), while not effecting the interaction of ARNT with AhR. These data suggest that ARNT isoform 1 phosphorylation serves to promote a more robust and, possibly, a specific AhR signaling response.

2732 Evaluating the Effects of PCB 126 on Hepatic Energy Metabolism in AhR Knockout Mice

J. Jin, B. Wahlang, K. Z. Head, K. C. Falkner, R. A. Prough, and M. C. Cave. *University of Louisville, Louisville, KY.*

Epidemiologic studies have shown that exposures to polychlorinated biphenyls (PCBs) are associated with liver toxicity including nonalcoholic fatty liver disease (NAFLD). Based on their structure and ability to activate the aryl hydrocarbon receptor (AhR), PCBs are classified as dioxin-like (PCB126) or non-dioxin-like. Previously, our group demonstrated that acute exposures to low doses of PCB126 caused hepatic and pancreatic toxicity in male mice and upregulated AhR target genes. Because the AhR regulates a numerous physiological and pathological processes, the current study aims to examine if the observed PCB 126 hepatic/pancreatic effects are mediated primarily through AhR activation. Male C57BL/6J and $AhR^{-/-}$ mice were obtained from Taconic Biosciences and exposed to low-dose PCB 126 (20 µg/kg) by gavage. After 2 weeks, mice were euthanized, and blood and tissue samples were collected for histology and other downstream analyses. Compared to wildtype C57BL/6J mice, $AhR^{-/-}$ mice had lower liver weight/body weight ratio, higher white adipose tissue/body weight ratio and higher body fat composition. Importantly, $AhR^{-/-}$ mice demonstrated hepatic lipid accumulation (steatosis) as demonstrated by histological analysis (H&E, Oil Red O staining). $AhR^{-/-}$ mice also showed higher levels of hepatic free fatty acids and triglycerides, and PCB 126 exposure exacerbated this effect. In contrast, $AhR^{-/-}$ mice had lower plasma triglyceride and cholesterol levels, implicating systemic dyslipidemia. Additionally, AhR ablation altered hepatic gene expression resulting in upregulation of lipogenic genes (CD36, FASN) and downregulation of fatty acid oxidative genes including PPARα. Glucose tolerance test demonstrated that $AhR^{-/-}$ mice had lower fasting blood glucose and insulin levels, while PCB 126 exposure decreased area under the curve, irrespective of genotype. $AhR^{-/-}$ mice also exhibited increased pancreatic weight relative to body weight. Finally, AhR deficiency altered hepatic expression of other PCB receptors, including upregulating pregnane-xenobiotic receptor and downregulating constitutive androstane receptor, suggesting xenobiotic receptor cross talk. Taken together, the results implicated that AhR plays a pivotal role in maintenance of lipid metabolism and energy homeostasis, and suggest that PCB126 may act through non-AhR pathways to trigger hepatic toxicity.

2733 Isoflavones as Ah Receptor Agonists in Colon-Derived Cell Lines: Structure-Activity Relationships

H. Park[1], U. Jin[1], S. Safe[1], A. Orr[1], L. Davidson[1], C. Allred[1], R. Chapkin[1], A. Jayaraman[1], K. Lee[2], and P. Tamamis[1]. *[1]Texas A&M University, College Station, TX; and [2]Tufts University, Medford, MA.*

Many of the protective responses observed for flavonoids in the gastrointestinal track resemble aryl hydrocarbon receptor (AhR)-mediated effects. Therefore, we examined the structure-activity relationships of isoflavones and isomeric flavone and flavanones as AhR ligands based on their induction of CYP1A1, CYP1B1 and UGT1A1 gene expression in colon cancer Caco2 cells and young adult mouse colonocyte (YAMC) cells. Caco2 cells were significantly more Ah-responsive than YAMC cells and this was due, in part to flavonoid-induced cytotoxicity in the latter cell lines. The structure-activity relationships for the flavonoids were complex and both response and cell context-specific, however, there was significant variability in the AhR activities of the isomeric substituted isoflavones and flavones. For example, 4′,5,7-trihydroxy isoflavone (genistein) was AhR-inactive whereas 4′,5,7-trihydroxyflavone (apigenin) induced CYP1A1, CYP1B1 and UGT1A1 in Caco2 cells. In contrast, both 5,7-dihydroxy-4-methoxy substituted isoflavone (biochanin A) and flavone (acacetin) induced all three AhR-responsive genes; 4′,5,7-trimethoxyisoflavone was a potent AhR agonist and the isomeric flavone was AhR-inactive. These results coupled with simulation studies modeling flavonoid interaction within the AhR binding pocket demonstrate that the orientation of the substituted phenyl ring at C-2 (flavones) or C-3 (isoflavones) on the common 4-H-chromene-4-one ring strongly influences the activities of isoflavones and flavones as AhR agonists.

2734 Effects of *In Utero* and Lactational Exposure of Mice to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin

J. Bhuju, K. M. Olesen, R. W. Read, C. H. Sutter, and T. R. Sutter. *University of Memphis, Memphis, TN.*

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) is the prototypical environmental contaminant in the class of dioxin-like chemicals. Studies by others have reported that mice with keratinocyte-specific constitutively active aryl hydrocarbon receptor (AHR) develop atopic dermatitis (AD)-like symptoms during their lifetime. In this study, we investigated the effects of perinatal exposure to TCDD, a potent AHR ligand, on the development of epidermal barrier and susceptibility to AD-like skin condition in C57BL/6J mice. Mice were exposed *in utero* to TCDD at a dose of 5 µg/ kg bw on embryonic day 12 and the effects on barrier formation and function were studied from postnatal day (PND) 1 through adult life stages. Pups exposed to TCDD were born with diffuse epidermal hyperplasia; however, this effect did not persist in adult life stages. The animals grew with no visible signs of eczema and had normal levels of IgE between PND 35-135. Because TCDD is immunosuppressive, we used a vitamin D analogue (MC903) to induce AD-like inflammation in skin. No significant differences in response to MC903 were observed between TCDD-exposed and the control animals. Animals in both groups exhibited visible skin inflammation with epidermal hyperplasia and high levels of serum IgE, indicating a normal Th2 response. Compared to control animals, levels of CYP1A1 RNA and protein were increased in TCDD-exposed mice. Levels of CYP1A1, CYP1A2, and CYP1B1 were highest at PND 13-21, then decreased to control levels by PND 70. While CYP1A2 and CYP1B1 were expressed throughout the epidermis, CYP1A1 was localized at the infundibulum of hair follicles, junctional zone and sebaceous glands. Histological analysis (H&E and Oil Red O staining) showed signs of sebaceous hypoplasia. Overall, perinatal exposure of mice to TCDD results in a chloracne-like pathology of the epidermis, without evidence of atopy.

2735 AH Receptor Ligand-Specific Modulation of Prostaglandin D_2 Metabolism in Human Keratinocytes: Evidence for a Critical Involvement of the Epidermal Growth Factor Receptor

C. Vogeley[1], M. Nakamura[2], S. Maass[1], M. Pollet[1], C. F. Vogel[3], J. Krutmann[1], C. Esser[1], D. Lang[4], and T. Haarmann-Stemmann[1]. *[1]IUF—Leibniz-Research Institute for Environmental Medicine, Duesseldorf, Germany; [2]Nagoya City University, Nagoya, Japan; [3]University of California Davis, Davis, CA; and [4]Bayer AG, Wuppertal, Germany.*

Prostaglandin (PG) D_2 is released by mast cells and plays an important role in the development of cutaneous allergic reactions and atopic dermatitis (AD) by activating CRTH2 (chemoattractant receptor-homologous molecule expressed on Th2 cells) and stimulating Th2 cell-driven immune responses. PGD_2 either spontaneously hydrolyzes to the anti-inflammatory PPARγ agonist 15Δ-PGJ_2 or is reduced by aldo-keto reductase (AKR) 1C3 to 9α,11β-PGF_2. The latter metabolite is less potent in activating CRTH2 than PGD_2 but metabolically stable, thus prolonging cutaneous allergic inflammation. By using LC-MS analysis, we here provide evidence that exposure of human HaCaT keratinocytes to the polycyclic aromatic hydrocarbon (PAH) benzo(a)pyrene (BaP), but not to the dioxin-like polychlorinated biphenyl (PCB) 126, fosters the 11-ketoreduction of exogenous PGD_2 to 9α,11β-PGF_2 in an aryl hydrocarbon receptor (AhR)- and AKR1C3-dependent manner. Further studies revealed that, in contrast to PCB126, BaP treatment induced AKR1C3 expression through an epidermal growth factor receptor (EGFR)-dependent non-canonical AhR signaling pathway. Both AhR agonists, however, activated the soluble tyrosine kinase c-Src, stimulated phosphorylation of the metalloproteinase ADAM17 and the associated ectodomain shedding of cell surface-bound EGFR ligands. Surprisingly, this release of EGFR ligands stimulated EGFR activity only in BaP- but not in PCB126-treated cells. By means of EGFR internalization assays using Alexa Fluor™ 555-conjugated EGF, we provide evidence that PCB126, but not BaP, is capable of displacing EGF from the extracellular domain of EGFR, thus acting as a potent inhibitor of EGFR activity. Taken together, this study identifies (1) an inhibition of EGFR by PCB126 as being causative for the observed AhR ligand-specific effects on AKR1C3 expression and 9α,11β-PGF_2 formation, and (2) a potentially clinically relevant mechanism by which PAHs, but probably not dioxin-like PCBs, may exacerbate the course of cutaneous allergic eruptions and chronic inflammatory skin diseases, such as AD.

2736 Understanding the Relationship between the Aryl Hydrocarbon Receptor (AhR) and the Translocator Protein (TSPO) in Regulating Mitochondrial Function in Mouse Lung Epithelial Cells

A. D. Rivera-Ruiz[1], A. M. Jurgelewicz[2], M. Steidemann[2], and J. J. LaPres[2]. *[1]Universidad Ana G. Méndez Gurabo, Gurabo, PR; and [2]Michigan State University, East Lansing, MI.*

The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor and part of the Per-Arnt-Sim (PAS) superfamily of environmental sensors. The AhR mediates most, if not all, of the toxicity induced by certain environmental pollutants, such as 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). In contrast to TCDD-induced toxicity, the AhR also plays a role in normal developmental and homeostatic processes, presumably upon binding to putative endogenous ligands, such as cholesterol, heme, and tryptophan derivatives. Interestingly, studies suggest that a portion of the cellular pool of AhR resides within the mitochondria, though its function in this organelle is not defined. Another important mitochondrial protein is the translocator protein (TSPO). TSPO was identified several decades ago, however, its cellular function is not understood. TSPO is also known to interact with cholesterol and heme derivatives, similar to the AhR. Given their shared location (i.e. in the mitochondria) and ability to bind similar metabolites, we hypothesized that crosstalk between the AhR and TSPO regulates mitochondrial metabolism and the efficiency of the electron transport chain (ETC). To test this hypothesis, we measured the oxygen consumption rate (OCR) and mRNA expression of critical genes via quantitative real time polymerase chain reaction in wild type mouse lung epithelial cells (i.e. MLE12s) and MLE12s that are null for the AhR and TSPO. Our mitochondrial stress test results suggest that crosstalk between AhR and TSPO modulates ETC efficiency as we observed changes in our WT cells we did not see in the $AhR^{-/-}$ and $TSPO^{-/-}$ cells. Also, upregulation of IDO1 and IDO2 in WT cells treated with AhR and TSPO ligands further supports our hypothesis.

2737 Free Fatty Acids Receptor 1/4 (FFAR1/4) Agonists, GW9508, and TAK875 Attenuate Agonist-Induced Shortening in Human Airway Smooth Muscle (HASM) Cells

S. Xu, A. Schwab, N. Karmacharya, G. Cao, R. Panettieri, and J. Jude. *Rutgers Institute for Translational Medicine and Science, New Brunswick, NJ.*

Asthma is an airway disease characterized by airway hyper-responsiveness, inflammation and remodeling. Enhanced contractile phenotype of airway smooth muscle (ASM) cells mediates bronchoconstriction in asthma. Obesity is associated with asthma development, severity and response to treatments. The mechanisms linking obesity and asthma are yet to be determined. Free fatty acids receptors (FFARs) are G-Protein Coupled Receptors (GPCRs) and are emerging as crucial signaling molecules with importance in metabolic and inflammatory diseases like asthma. Therefore, we hypothesized that the free fatty acid receptors FFAR1 and FFAR4 modulate cell shortening in HASM cells. In our experiments, HASM cells were treated with vehicle (DMSO) or synthetic FFAR1/4 agonists, GW9508 or TAK875 (0.1 - 10 μM), for a short duration (5, 10, 20, or 30 min), followed by stimulation with contractile agonists carbachol (CCh, 10 μM) or histamine (2.5 μM). Myosin light Chain (MLC) phosphorylation and agonist-induced cytosolic Ca^{2+} ($[Ca^{2+}]_i$) were determined as a surrogate measure of ASM cell shortening. In parallel experiments, histamine-induced cellular stiffness was measured in HASM cells by magnetic twisting cytometry (MTC). To determine whether ASM relaxation signaling is altered by FFAR1/4 agonists, isoprenaline-induced cyclic AMP (cAMP) levels were measured in HASM cells in the presence of vehicle, GW9508 or TAK875. Both GW9508 and TAK875 significantly attenuated agonist-induced MLC phosphorylation in HASM cells in a concentration and time-dependent manner. Histamine-induced HASM cell stiffening was similarly reduced by GW9508 and TAK875, although the decrease was not statistically significant. FFAR1/4 agonists had little effect on agonist-induced $[Ca^{2+}]_i$ or isoprenaline-induced cAMP levels in HASM cells. Our findings show that FFAR1/4 agonists, GW9508 and TAK875, attenuate agonist-induced HASM cell shortening by inhibiting MLC phosphorylation. FFAR1/4 may be novel therapeutic targets to broncho-protect human airways in airway diseases such as asthma and COPD.

2738 Ligand Activation of Peroxisome Proliferator-Activated Receptor-β/δ (PPARβ/δ) Inhibits Growth of Human Prostate Cancer Cell Lines

S. Su[1], X. Zhu[1], X. Wang[1], F. J. Gonzalez[2], and J. M. Peters[1]. *[1]Pennsylvania State University, University Park, PA; and [2]National Cancer Institute, Bethesda, MD.*

Peroxisome proliferator-activated receptor-β/δ (PPARβ/δ) mediates complex roles in many cellular processes, including lipid and glucose homeostasis, cell proliferation, differentiation, and inflammation. However, the role of PPARβ/δ in carcinogenesis remains controversial due to inconsistent results in the literature. To critically examine the role of PPARβ/δ in human prostate cancer tumorigenicity, two stable cell lines overexpressing PPARβ/δ were generated with a MigR1 retroviral vector system. Both an androgen receptor (AR) positive and AR-negative cell lines were created using LNCaP and PC3 cells, respectively because previous evidence by others suggested that AR-positive prostate cells increased proliferation following ligand activation of PPARβ/δ whereas this effect was not observed in AR-negative prostate cancer cells. Expression of PPARβ/δ was markedly higher in MigR1-hPPARβ/δ LNCaP and PC3 cells as compared to parent and vector controls. The expression of the PPARβ/δ target gene angiopoieten-like protein 4 (*ANGPTL4*) in MigR1-hPPARβ/δ LNCaP and PC3 cells was significantly higher in response to a specific PPARβ/δ ligand as compared to controls. Ongoing efforts are assessing the effects of ligand activation of PPARβ/δ in these cell lines on anchorage-dependent and anchorage-independent clonogenicity and tumorigenicity using both *in vitro* and *in vivo* approaches. Preliminary results from these studies indicate that ligand activation of PPARβ/δ inhibits growth and potentially tumorigenicity and that higher expression of PPARβ/δ is associated with inhibitory effects in a prostate cancer model, regardless of expression of AR. This result is similar to effects observed in estrogen receptor (ER)-positive and ER-negative breast cancer cell lines.

2739 The Effect of Selenium Isosteric Replacement on the Efficacy of a PPARβ/δ Ligand in a Human Melanoma Cell Line

T. R. Runkle[1], E. M. Kehres[1], K. M. Lewis[1], A. K. Sharma[2], S. Amin[2], J. M. Peters[3], and M. G. Borland[1]. *[1]Bloomsburg University of Pennsylvania, Bloomsburg, PA; [2]Pennsylvania State University, Hershey, PA; and [3]Pennsylvania State University, University Park, PA.*

The persistent low survival rate of melanoma patients requires the search for new therapeutic approaches for this disease. Peroxisome proliferator-activated receptor-β/δ (PPARβ/δ) may be a suitable molecular target for this purpose due to its reported ability to inhibit melanoma carcinogenicity. Interestingly, selenium (Se) can inhibit tumorigenesis and its isosteric substitution for sulfur (S) in compounds can increase the potency/efficacy of cancer therapeutics. The present study examined the efficacy of the PPARβ/δ ligand GW501516 and its selenium analog Se-GW501516 in a human melanoma cell line (UACC903). Both PPARβ/δ ligands similarly inhibited proliferation of UACC903 cells. Over-expression of PPARβ/δ caused greater sensitivity to this effect, as Se-GW510516 led to reduced cell proliferation sooner than GW501516. Whereas neither ligand modulated clonogenicity in control cells, both ligands inhibited clonogenicity in UACC903 cells over-expressing PPARβ/δ. Both ligands activated PPARβ/δ as shown by an increase in the PPARβ/δ target gene angiopoietin-like 4 (*ANGPTL4*) in UACC903 control cells. These effects were greatly enhanced in UACC903 cells over-expressing PPARβ/δ. There was no change in the mRNA expression of the putative PPARβ/δ target gene 3-phosphoinositide-dependent protein kinase 1 (*PDPK1*), a known modulator of the protein kinase B (AKT) pathway. Finally, the ability of ligand activation of PPARβ/δ to modulate ultraviolet (UV) radiation-induced cysteine-aspartic proteases-3/7 (CASPASE-3/7) activity was examined. All cell lines increased CASPASE-3/7 activity in response to UV irradiation; UACC903 cells over-expressing PPARβ/δ exhibited a heightened response. Whereas neither PPARβ/δ ligand modulated protease activity after 4h administration, a 24h pre-treatment with either ligand increased CASPASE-3/7 activity compared to controls in UACC903 cells over-expressing PPARβ/δ. Collectively, these studies provide further evidence that PPARβ/δ expression and/or ligand activation inhibited proliferation and clonogenicity, and enhanced apoptosis in UACC903 melanoma cells. Isosteric substitution of S for Se only modestly influenced these endpoints, but further studies are needed to assess novel approaches to targeting PPARβ/δ as a cancer therapeutic.

2740 Effect of Activating Retinoic Acid Receptor (RAR) and Peroxisome Proliferator-Activated Receptor-β/δ (PPARβ/δ) in a Human Melanoma Cell Line

M. G. Borland[1], D. P. Callen[1], T. R. Runkle[1], J. M. Peters[2], and E. M. Kehres[1]. *[1]Bloomsburg University of Pennsylvania, Bloomsburg, PA; and [2]Pennsylvania State University, University Park, PA.*

New targets for melanoma are needed due to low survival of patients with this disease. High expression and/or ligand activation of peroxisome proliferator-activated receptor-β/δ (PPARβ/δ) can inhibit carcinogenicity of a human melanoma cell line (UACC903). All-trans retinoic acid (atRA), which activates retinoic acid receptors (RARs), is postulated to activate PPARβ/δ and increase expression of 3-phosphoinositide-dependent protein kinase 1 (PDPK1) and protein kinase B (AKT). This study examined whether atRA and a PPARβ/δ ligand (GW0742) could influence PPARβ/δ activity in UACC903 cells. UACC903 cells cultured with atRA exhibited reduced proliferation and over-expression of PPARβ/δ conferred greater sensitivity to this effect. Expression of the RAR target gene cytochrome P450 26A1 (*CYP26A1*) was increased by atRA in UACC903 cells but over-expression of PPARβ/δ did not influence this effect. By contrast, the mRNA expression of the PPARβ/δ target gene, angiopoietin-like 4 (*ANGPTL4*), or *PDPK1* were unchanged in response to atRA in both UACC903 control and PPARβ/δ over-expressing cells. Co-treatment of UACC903 cells with atRA or GW0742 inhibited proliferation as compared to controls, but no synergy or additivity in this effect was observed. Whereas ligand activation of PPARβ/δ inhibited anchorage-dependent clonogenicity in cells over-expressing PPARβ/δ, co-treatment with atRA did not impact this effect. Expression of *CYP26A1* mRNA was elevated in response to atRA in UACC903 control cells and those over-expressing PPARβ/δ compared to controls. Expression of *ANGPTL4* mRNA was increased by ligand activation of PPARβ/δ in control UACC903 cells and this effect was enhanced in UACC903 cells over-expressing PPARβ/δ; no synergy or additivity were observed. In contrast, the mRNA expression of *PDPK1* was unchanged by either ligand activation of RAR or PPARβ/δ, or both. Collectively, these studies show that UACC903 cells over-expressing PPARβ/δ are sensitive to the anti-proliferative effects of either an RAR or PPARβ/δ ligand. The latter could be due in part to enhanced activity of the PPARβ/δ heterodimerization partner RXR. Co-treatment with an RAR or PPARβ/δ ligand did not cause any additional PPARβ/δ activities. These studies provide further evidence that atRA does not activate PPARβ/δ or the PDPK1/AKT pathway in a human melanoma cell line.

2741 Ciglitazone, a Human PPARγ Agonist, Disrupts Dorsoventral Patterning in Zebrafish

V. Cheng, S. Dasgupta, A. Reddam, and D. C. Volz. *University of California Riverside, Riverside, CA.*

Peroxisome proliferator-activated receptor γ (PPARγ) is a ligand-activated transcription factor that regulates lipid/glucose homeostasis and adipocyte differentiation. While the role of PPARγ in adipogenesis and diabetes has been extensively studied, little is known about PPARγ function during early embryonic development. Within zebrafish, maternally-loaded ppaγ transcripts are present within the first 6 h post-fertilization (hpf), and *de novo* transcription of zygotic ppaγ commences at ~48 hpf. Since maternal ppaγ transcripts are elevated during a critical window of cell fate specification, the objective of this study was to test the hypothesis that PPARγ regulates gastrulation and dorsoventral patterning during zebrafish embryogenesis. To accomplish this objective, we relied on 1) ciglitazone as a potent PPARγ agonist and 2) a splice-blocking, ppary-specific morpholino to knockdown ppaγ. We found that initiation of ciglitazone - a potent human PPARγ agonist - exposure by 4 hpf resulted in concentration-dependent effects on dorsoventral patterning in the absence of epiboly defects during gastrulation, leading to ventralized embryos by 24 hpf. Interestingly, ciglitazone-induced ventralization was reversed by co-exposure with dorsomorphin (DMP), a bone morphogenetic protein (BMP) signaling inhibitor that induces strong dorsalization within zebrafish embryos. Moreover, mRNA-sequencing revealed that lipid- and cholesterol-related processes were affected by exposure to ciglitazone. However, ppaγ knockdown did not block ciglitazone-induced ventralization, suggesting that PPARγ is not required for dorsoventral patterning nor involved in ciglitazone-induced toxicity within zebrafish embryos. Our findings point to a novel, PPARγ-independent mechanism of action and phenotype following ciglitazone exposure during early embryonic development.

2742 Unexpected Induction of *cyp3a65* mRNA in Zebrafish Harboring a CRISPR-Mutated Pregnane x Receptor

M. C. Salanga[1,2], N. R. Brun[2], R. D. Francolini[2], J. D. Guimond[1], J. J. Stegeman[2], and J. V. Goldstone[2]. *[1]Northern Arizona University, Flagstaff, AZ; and [2]Woods Hole Oceanographic Institution, Woods Hole, MA.*

More than half of all pharmaceuticals used by humans are metabolized by the CYP3A4 enzyme and most vertebrates express a CYP3A ortholog. Pregnane x receptor (PXR; NR1I2) is a nuclear receptor that regulates transcriptional responses to drug or xenobiotic exposure, including activation of *CYP3A* transcription. PXR is a promiscuous receptor, responding to a wide range of ligands that differ across species and make functional studies on its role in the chemical defensome most relevant when approached in a species-specific manner. In zebrafish embryos, the ligand pregnenolone has been shown to activate Pxr leading to induction of *cyp3a65* and *pxr* transcription that can be abrogated through microinjection of translation-blocking morpholinos that inhibit Pxr production. Genetic knockout studies in rodents targeting *Pxr* support a critical role for PXR activation of *CYP3A* expression, however genetic knockouts in zebrafish have not previously been explored. Here, we report on two different zebrafish lines created by CRISPR-mediated gene editing. One line harbors a 107 bp deletion in exon 2 that includes coding sequence for Pxr's DNA binding domain and results in a frameshift and subsequent early termination codon that are detectable in the expressed transcripts. The second line is characterized by a 37 bp deletion in exon 7 and total deletion of intron 7 and exon 8, with the expressed transcript showing a direct splicing of exon 6 to exon 9. Notably, exons 7 and 8 contribute coding sequence for translation of the ligand binding domain. The obvious prediction for these mutations is a loss of functional gene products. To our surprise, larvae homozygous for either of the *pxr* mutant alleles retain their ability to induce *cyp3a65* mRNA expression averaging 1.9-fold enrichment. Additionally, auto-induction of *pxr* expression follows the same pattern observed in wildtype fish, with *pxr* mRNA expression averaging a 2.6-fold enrichment in response to pregnenolone exposure. These data suggest a compensatory mechanism may be responsible for *cyp3a65* and *pxr* induction. Two alternative possibilities are that Pxr is not required for the pregnenolone effect or that the mutated alleles produce truncated yet functional protein. To further investigate the above possibilities, we are currently testing two newly created CRISPR mutants with targeted deletions in exons 3 or 6. It is crucial that we develop a better understanding for the role of Pxr in this important biomedical test species. *Support for these experiments comes from NIH P42 ES007381 and R21HD073805 (JVG), Swiss National Science Foundation P2EZP2_165200 (NRB).*

2743 Assessment of Receptor Occupancy via Flow Cytometry: Benefits and Pitfalls of Two Common Approaches

A. S. Wong, M. Patel, and T. Rogers. *Altasciences, Everett, WA.*

Receptor occupancy assays can be a powerful tool to determine drug dosage. Recently, flow cytometry has been the method of choice to assess receptor occupancy due to its ability to measure drug-target binding interactions on multiple cell populations simultaneously. Receptor occupancy assays using flow cytometry involve measurement of target receptors bound by the drug, number of receptors not bound to the drug, and the total number of receptors present. The methods for measuring these parameters, particularly for antibody-based therapeutics, can be categorized into two approaches based on the detection antibodies used. Here, we discuss the benefits and pitfalls to these methods. In one approach, fluorescently labelled competing and non-competing antibodies to the drug were used to detect free and total receptors respectively. In this approach, the competing antibody is often the labelled drug itself. One of the main obstacles in method development is to identify a non-competing antibody with comparable binding affinity to the target as the drug tested. We observed that when competing and non-competing antibodies display different affinities to the target, the results can be difficult to interpret. In addition, it is imperative that in a multiplex assay, competing and non-competing antibodies do not interfere with each other's binding to the target. The other approach utilized a single, fluorescently labelled secondary antibody to detect both bound and total receptors. Samples from animals treated *in vivo* were first incubated with excess drug *ex vivo* to fully saturate all targets, then stained with secondary antibody to detect total receptor. Staining with a single-detection antibody ensured that a direct comparison could be made between bound and total receptors, and removed challenges related to different binding affinities between reagents. Identifying a suitable secondary antibody was crucial, especially when the targeted populations consist of sticky cells such as granulocytes and monocytes. In addition, we found that incubation of samples *ex vivo* with excess drug can lead to downregulation of the target, leading to underestimation of the total receptors and overestimation of receptor occupancy of the drug. The technical considerations presented will aid to determine the most suitable approach and avoid common pitfalls in assay designs when incorporated early in the RO design phase.

2744 The Aryl Hydrocarbon Receptor Undergoes Chaperone-Mediated Autophagy in Triple Negative Breast Cancer Cells

J. Chen, W. Russu, and W. K. Chan. *University of the Pacific, Stockton, CA.*

The aryl hydrocarbon receptor (AhR) is a well-known transcription factor which regulates many essential biological functions. Human breast cancers express high levels of AhR, suppression of this receptor function alters breast cancer cell growth, suggesting a plausible approach of targeting AhR for treatment of breast cancers. We discovered that a compound called Q18 - (4- (5-ethylpyrimidin-2-yl)piperazin-1-yl)(4-((quinazolin-4-ylamino)methyl)phenyl)methanone - acted as an AhR antagonist and promoted AhR protein degradation via the chaperone mediated autophagy (CMA) pathway in triple-negative, but not in non-triple-negative, breast cancer cells. In triple-negative MDA-MB-468 cells, Q18 induced complete and irreversible lysosomal degradation of AhR in 24 hours. Notably, blockage of CMA by epigenetic silencing of lysosomal-associated membrane protein 2A (LAMP2A), a key CMA effector that translocate cytosolic client proteins across the lysosomal membrane, protected AhR from the Q18-mediated protein degradation. Co-immunoprecipitation and proximity ligation assay demonstrated the physical interaction between AhR and LAMP2A. In addition, activation of the CMA pathway by known methods, such as treatment of 6-amino-nicotinamide and long-term nutritional deprivation, decreased the AhR protein levels in MDA-MB-468 cells. Collectively we have provided evidence supporting that the AhR protein can be degraded via CMA in triple-negative breast cancer cells.

2745 Knockout of the Aryl Hydrocarbon Receptor Increases Pancreas Cancer Lethality

M. Walcheck, C. Bradfield, and S. Ronnekleiv-Kelly. *University of Wisconsin–Madison, Madison, WI.*

Only 10% of those diagnosed with pancreatic ductal adenocarcinoma (PDAC) live beyond 5 years. These dismal outcomes reflect a poor understanding of PDAC pathogenesis hindering efforts to develop more effective PDAC therapies. Recent discoveries suggest the Aryl Hydrocarbon Receptor (AhR) plays a crucial role in the pathogenesis of several cancers through mediation of effector immune cell infiltration. The AhR is a ligand activated transcription factor involved in many cellular processes, including regulation of immune function in the GI tract, liver and skin. Although there is some data suggesting a putative tumor suppressor function in PDAC, the extent AhR suppresses pancreas cancer development has not been well studied. For this reason, we sought to evaluate the effect of AhR loss in the development of PDAC *in vivo* using a novel mouse model. A widely accepted PDAC model, where the primary PDAC *Kras* mutation is present in pancreas lineage cells (KC mice) was crossed with AhR null ($A^{-/-}$) mice to explore the effects of AhR heterozygosity ($A^{+/-}$KC) and loss of AhR ($A^{-/-}$KC) on PDAC formation. At 9 months, rate of survival, grade and incidence of pancreatic intraepithelial neoplasia (PanIN) and PDAC are evaluated in KC, $A^{+/-}$KC, $A^{-/-}$KC and the control groups. To date, 30 KC and 17 $A^{+/-}$KC mice have been evaluated. So far, these mice develop a range of pathology (PanINs and PDAC) at about the same rates. In each group, 100% of mice had chronic pancreatitis and PanIN 1 lesions, the earliest form of neoplasia. Both KC and $A^{+/-}$KC mice have shown a 7% incidence of PanIN 2 lesions, while PanIN 3, the highest grade lesions, have only been seen in KC mice (7%). Additionally, PDAC was seen in 16% and 18% of KC and $A^{+/-}$KC respectively. This data suggests no histopathologic difference exists in pancreas between KC and $A^{+/-}$KC mice. Interestingly, a dramatic decrease in survival of the $A^{-/-}$KC mice compared to the KC and $A^{+/-}$KC groups has been found. The $A^{-/-}$KC mice (N=26) have a 35% survival rate compared to the 70%, and 66% survival rate of KC (N=44) and $A^{+/-}$KC (N=86) respectively. Due to this high mortality of the $A^{-/-}$KC mice, of the 26 that have been produced, only 2 have made it to 9 months for pathologic evaluation. Of these 2 mice, both had chronic pancreatitis and PanIN 1, 1 had PanIN 2 while neither had a PanIN 3 or PDAC. Although early, it appears loss of AhR may exacerbate the progression of PDAC given the higher mortality in the $A^{-/-}$KC. This suggests AhR may play a protective role in PDAC development and warrants further investigation.

2746 Aryl Hydrocarbon Receptor (AhR) Ligands Are Estrogen Receptor Alpha Degraders in Breast Cancer Cells

X. Zhang. *Texas A&M University, College Station, TX.* Sponsor: S. Safe

Estrogen receptor alpha (ERα, ESR1) expressing breast cancers initially respond to endocrine therapy, however later stage ER-positive tumors develop drug resistance and second-line therapies including selective ER degraders (SERDs) are being developed. These drugs directly bind ERα and induce their degradation. It has previously been shown that ligand dependent inhibitory aryl hydrocarbon receptor (AhR)-ER crosstalk is due, in part, to activation of proteasome-dependent degradation of ERα. Initial studies showed that 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) decreased ERα expression in MCF-7 breast cancer cell lines, and we also observed that some AhR ligands including 1,1-bis (3'-indolyl) methane (DIM) and the microbiome metabolite 1,4-dihydroxy-2-napthoic acid (DHNA) also decrease expression of ERα protein in MCF-7 cells. In contrast other microbial-derived AhR ligands including tryptamine, indole, indole-3-acetate and indole-3-pyruvate did not affect ERα expression. Moreover, cotreatment of MCF-7 cells with TCDD, DIM and DHNA with the proteasome inhibitor MG132 resulted in partial inhibition of AhR ligand-dependent ERα degradation demonstrating that ERα degradation by selected AhR ligands was proteasome-dependent. Approximately 40% of late stage metastatic ER-positive breast tumors express ER mutations Y537S or D538G in the ligand binding domain of ERα and MCF-7 cells expressing these mutants have been generated by gene editing technologies. Treatment of mutant MCF-7 (Y537S) or MCF-7 (D538G) cells with AhR ligands showed that both DIM and DHNA also induced proteasome-dependent degradation of ERα in MCF-7 cells expressing the mutant receptor. Thus, selective AhR ligands represent a new class of ERα degraders and current studies on the mechanism of AhR/ligand-mediated ERα degradation are ongoing.

2747 Role of the Aryl Hydrocarbon Receptor (AhR) in Mediatiing the Effects of Coffee in the Colon

U. Jin, H. Park, L. Davidson, Y. Fan, A. Jayaraman, R. Chapkin, and S. S. Safe. *Texas A&M University, College Station, TX.*

Coffee is the most widely consumed beverage worldwide and epidemiology studies show that there is an association between coffee consumption and health benefits including protection from Parkinson's disease, metabolic disease, several cancers and decreased rates of mortality. In addition, coffee drinkers are protected against inflammatory bowel disease and colon cancer and since these responses are similar to effects observed for the aryl hydrocarbon receptor (AhR) and its ligands we hypothesized that coffee extracts are AhR-active. Commercially available ground roasted coffee was extracted with hot water and the water extracts were also extracted with chloroform and both the water and chloroform extracts induced 3 AhR-responsive genes, namely CYP1A1, CYP1B1 and glucuronosyltransferase 1A1 (UGT1A1) in Caco2

cells. In contrast coffee extracts did not induce gene expression in Caco2 AhR knockout cells (Caco2-AhRKO) and extracts of ground unroasted coffee beans were AhR-inactive. Subsequent fractionation studies showed that caffeine was AhR-inactive and norharman and related β-carboline were identified as one of the AhR-active components in the coffee extract. Coffee extracts also inhibited growth of intestinal stem cell enriched organoids *in vitro* and this response was not observed in organoids derived from mice in which intestinal AhR is silenced (Villin^{Cre}AhR$^{fl/fl}$). We also observed that coffee extracts inhibited dextran sodium sulfate (DSS) induced barrier function damage *in vivo* in mice and coffee extract also inhibited DSS-induced expression colon mucosal interleukin-6 (IL-6), IL-10, IL-10 receptor1, interferon-γ and transforming growth factor β. Coffee extracts also modified gut microbial metabolites. These data suggest that the health benefits of coffee extracts in the intestine are associated with the AhR activity of the extract.

PS 2748 Modulation of Ligand-Mediated Aryl Hydrocarbon Receptor Activity Influences HNSCC Resistance to Nutritional and Chemotherapeutic Stress

B. A. Yusko, I. A. Murray, and G. H. Perdew. *Pennsylvania State University, University Park, PA.*

Head & Neck Squamous Cell Carcinoma (HNSCC) recurrence following clinical intervention represents a major obstacle to effective treatment and survival rates. A key feature of tumor recurrence is the capacity of tumor cells to adapt to stresses associated with the nutrient-limited tumor microenvironment and toxic chemotherapeutic agents. Aryl Hydrocarbon Receptor (AHR) expression and transcriptional activity has been previously shown to influence cell cycle progression and pro/anti-apoptotic signaling, among other aspects of HNSCC aggressiveness, implicating the AHR in mediation of tumor cell survival. However, the mechanisms by which AHR promotes HNSCC cell resilience or whether AHR antagonism can restrict HNSCC survival have not been fully explored. Both 2D monolayer and 3D spheroid culture approaches were utilized to examine stress responses and survival in HNSCC exposed to AHR agonists and antagonists. Clonogenicity-survival assays and MTT viability assays revealed a significant increase in HNSCC resilience to either nutritional (restricted nutrient) or chemotherapeutic-mediated (5-fluorouracil) stress in a series of HNSCC lines (HN30, HN2095, OSC19) upon exposure to AHR agonists. In contrast, AHR antagonists prompted a significant decrease in cell survival under stress conditions. Additionally, AHR-mediated changes in resilience was observed during clonogenicity-survival and viability assays conducted in 3D HNSCC spheroid cultures, more accurately representing the conditions of the tumor microenvironment. Exposure to AHR agonists prior to experimental stressors preconditioned HNSCC cells with enhanced expression of stress markers of the unfolded stress response (ATF4, XBP1, CHOP), nutrient transporters (SLC7A5/3A2), nutrient sensing (WARS), drug transporters (ABCC5), and modulators of cell cycle progression (CDKN1A), while AHR antagonists reversed such preconditioning. Activation of the AHR contribute to HNSCC adaptation and survival in the context of nutritional or 5-fluorouracil-mediated stress. Conversely, antagonism of AHR activity severely restricts HNSCC resilience *in vitro*. Such data reveal AHR expression and transcriptional activity as an important adaptive component resulting in enhanced HNSCC resilience, thus implicating AHR antagonism as a potential therapeutic approach to limit HNSCC recurrence.

PS 2749 Effects of Monocyte Chemoattractant Protein-1, Macrophage Inflammatory Protein-1α, and Interferon-α2a on P450 Enzymes in Human Hepatocytes *In Vitro*

M. Czerwinski, K. Gilligan, K. Westland, and B. W. Ogilvie. *Sekisui XenoTech LLC, Kansas City, KS.*

Cytokines response to oligonucleotide drug tilsotolimod can reveal the potential for interactions between the immunomodulator and co-administered small molecules. Tilsotolimod, an agonist of Toll-like receptor 9, stimulated the release of macrophage chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1α (MIP-1α) interferon gamma-induced protein 10 (IP-10), tumor necrosis factor alpha (TNF-α) and interferon-α2a (INF-α2a) in blood obtained from healthy donors. Although tilsotolimod did not directly affect CYP1A2, 2B6 or 3A4 m RNA expression or activity, the cytokines stimulated by the drug reduced CYP2B6 and CYP1A2 enzyme activities in cultured human hepatocytes (1). Number of the cytokines stimulated by tilsotolimod remain uncharacterized for their potential to modify expression of drug metabolizing enzymes. This study sought to identify which cytokines were responsible for tilsotolimod effects on P450 enzymes *in vitro*. Primary human hepatocytes from three donors were cultured in sandwich configuration in the modified Chee's medium supplemented with 10% normal human plasma. Cells were treated with MCP-1 (2, 10 or 50 ng/mL), MIP-1α (0.4, 2 or 10 ng/mL) or INF-α2a (0.1, 0.5 or 2.5 ng/mL) with dosing solutions prepared fresh daily for three days of treatments. These concentrations were 0.2-, 1- or 5-fold the concentration found in plasma stimulated with tilsotolimod (1). Measurements of the levels of selected mRNAs and enzyme activities were described elsewhere (2). Recombinant chemokines MCP-1 and MIP-1α did not alter CYP1A2, 2B6, 2C8, 2C9, 3A4 or signal transducer and activator of transcription 1 (STAT1) mRNA or CYP1A2, 2B6 or 3A4/5 enzyme activity in co-cultures of human hepatocytes and Kupffer cells. INF-α2a, at 2.5 ng/mL, reduced CYP2B6 enzyme activity to 46% of control and increased CYP1A2 and STAT1 mRNA by 2.4- and 5.2-fold, respectively. This study established that INF-α2a, but not MCP-1 or MIP-1α, mediated tilsotolimod effects on CYP2B6 expression in human hepatocytes. 1. Tarantino P, et al, (2018) Cytokine-Mediated Suppression of CYP Enzymes By the Toll-like Receptor 9 Agonist, IMO-2125, in Cultured Human Hepatocytes. Hepatology 68:1444A 2. Czerwinski M, et al, (2015) Anti-CD28 monoclonal antibody-stimulated cytokines released from blood suppress CYP1A2, CYP2B6, and CYP3A4 in human hepatocytes *in vitro*. Drug Metab Dispos 43:42-52.

PS 2750 Bempegaldesleukin (NKTR-214), a Novel IL-2 Based Immunotherapy, Demonstrates Superior Nonclinical Safety Compared to That Reported for Recombinant Human IL-2 (rhIL-2)

S. K. Leung, C. Ji, B. R. Vuillemenot, K. Kennard, C. Henschel, U. Hoch, V. Kumar, D. Fry, and T. Sweeney. *Nektar Therapeutics, San Francisco, CA.*

Bempegaldesleukin (BEMPEG), a novel immunotherapeutic prodrug comprising IL-2 conjugated with polyethylene glycol (PEG), is currently in clinical trials with combination with check point inhibitors for the treatment of advanced cancers. Once administered, the prodrug releases active IL-2-PEG-conjugates that preferentially activate CD122 (the IL-2 receptor beta subunit), resulting in preferential expansion of CD8+ T cells over regulatory T cells in the tumor microenvironment. BEMPEG produces superior antitumor activity compared to recombinant human (rh)IL-2 in several mouse syngeneic tumor models when combined with check point inhibitors[1]. Safety of BEMPEG was evaluated in repeat intravenous (IV) dose toxicity studies in rats and cynomolgus monkeys for up to 15 weeks with an 8-week recovery, at doses up to 0.3 mg/kg in rats and 0.1 mg/kg in monkeys based on IL-2 content once every 2 weeks for 8 doses. Elevated white blood cells, predominately absolute lymphocyte counts, observed in both species are consistent with the expected pharmacology of IL-2. Primary toxicities associated with BEMPEG were inflammatory cell infiltrates, related to expected pharmacology, in multiple organs in both species with partial or complete recovery. Compared to the published nonclinical toxicity profile of rhIL-2[2], BEMPEG resulted in no new toxicities and fewer toxicities overall. Significantly, in contrast to previous reports for rhIL-2, there was no indication of vascular leak syndrome after administration of BEMPEG at the highest non-severely toxic dose in the nonclinical studies. Consistent with nonclinical studies, IV administration of BEMPEG in cancer patients, who previously received multiple anti-cancer treatment, was well tolerated and these patients demonstrated significant elevated absolute CD4+ T cell, CD8+ T cell, and NK cell counts[3]. Out of 26 evaluable patients, 9 patients (35%) had tumor shrinkage and 14 patients (54%) had stable disease. Such desirable outcome triggered the combination therapy development of BEMPEG with check point inhibitors in cancer patients and the clinical trials are still ongoing[4]. [1] Charych DH et al. Clin Cancer Res. 2016, 22(3):680-690. [2] Anderson TD et al. Int Rev Exp Pathol. 1993, 34 Pt A: 57-77. [3] Bentebibel SE et al. Cancer Discov. 2019, 9(6): 711-721. [4] Cancer Discov. 2019, 9(6): OF1.

PS 2751 Nonclinical Species Sensitivity to Convulsions: Survey Outcome of an IQ DruSafe Consortium Working Group Initiative

L. Breidenbach[1], J. K. DaSilva[2], T. Deats[3], D. Li[4], K. Treinen[3], T. Dinklo[5], S. Kervyn[6], G. Teuns[7], M. Traebert[8], and K. Hempel[1]. *[1]Abbvie Deutschland GmbH & Co. KG, Ludwigshafen, Germany; [2]Pfizer Inc., Groton, CT; [3]Sunovion Pharmaceuticals Inc., Marlborough, MA; [4]Pfizer Drug Safety R&D, Pfizer, Inc, Groton, CT; [5]F. Hoffmann-La Roche AG, Basel, Switzerland; [6]UCB Biopharma SPRL, Braine-l'Alleud, Belgium; [7]Janssen Research & Development, Beerse, Belgium; and [8]Novartis Institutes for BioMedical Research, Basel, Switzerland.*

Convulsions are considered severe adverse events, and compounds that carry a convulsion liability either require a large safety margin based on the most sensitive nonclinical species to advance to human clinical trials or will be limited by a strict clinical exposure cap. Within the pharmaceutical industry, dogs are perceived to be particularly sensitive to drug-induced convulsions.

To verify this perception, a survey was constructed within the International Consortium for Innovation and Quality in Pharmaceutical Development (IQ, www.iqconsortium.org) and distributed amongst IQ participating pharmaceutical companies to compare nonclinical species for sensitivity to convulsions. The survey response contained blinded data on 80 compounds from 11 companies. Species sensitivity was assessed by comparing the lowest free drug plasma concentration at which convulsions were observed and the no observed effect level for convulsions between species. Data were also collected on other endpoints including use of the electroencephalogram, premonitory signs, convulsion type, the highest development phase reached and the reason why development was stopped. Key findings from the survey are: 1) the dog was most often determined to be the most sensitive species to convulsion, 2) there was no clear sensitivity ranking of other species, 3) no single reliable premonitory indicator of convulsion was identified, and 4) the lack of convulsions in human in this dataset suggests that convulsion liability is well mitigated with current drug development strategies.

PS 2752 Development of an *In Vitro* System Based on PXB-Cells for Evaluation of Mitochondrial Dysfunction-Mediated Hepatotoxicity

M. Inamatsu[1], M. Yamao[1], Y. Ogawa[1], C. Yamasaki[1], M. Shinohara[2], Y. Sakai[2], Y. Ishida[1,3], and C. Tateno[1,3]. *[1]PhoenixBio Co. Ltd., Higashi-Hiroshima, Japan; [2]University of Tokyo, Tokyo, Japan; and [3]Hiroshima University, Hiroshima, Japan.* Sponsor: T. Yokoi

Fresh human (h)-hepatocytes are considered the best *in vitro* model system for studying xenobiotic metabolism and hepatotoxicity. However, hepatocytes grown in two-dimensional cultures cannot be maintained for more than a week. We previously showed that h-hepatocytes (PXB-cells®) freshly isolated from chimeric mice with humanized livers (PXB-mice®) could be maintained as high-density culture (2.1×10^5 cells/cm^2) expressing major hepatic genes up to 3 weeks. In a conventional cell culture setup, hepatocytes are known to generate adenosine triphosphate (ATP), mainly via cytosolic glycolysis. Such anaerobically poised cells that impair mitochondrial functions are resistant to xenobiotics and are not suitable for the evaluation of mitochondrial toxicity. The susceptibility to mitochondrial impairment is increased by culturing hepatocytes in a galactose (Gal)-based medium, instead of a conventional glucose (Glu)-based medium, under hyperoxia conditions. In this study, we evaluated whether these improvements in culture conditions helped in assessing mitochondrial toxicity in PXB-cells. PXB-cells were cultured in the Gal-based medium under hyperoxic conditions in a multi-gas incubator. Results obtained were compared with those from PXB-cells cultured normally. PXB-cells in hyperoxic conditions (40% O_2) showed high sensitivity to rotenone compared to normal condition (20% O_2), as evaluated by LDH and intracellular ATP assays. PXB-cells are usually cultured in a low Glu-based medium, which is not remarkable different from the Gal-based medium. The oxygen consumption of cells, monitored by an oxygen concentration meter, was higher in the low Glu-based medium than in the Gal-based medium. PXB-cells were expected to exhibit high mitochondrial activity in the low Glu-based medium. Since the low Glu-based medium and the hyperoxic condition maintained the expression of several *CYP* mRNAs and CYP3A activity in PXB-cells equivalent to the normal condition, mitochondrial dysfunction induced by metabolites of a compound would also be checked in this condition. In conclusion, we established a mitochondrial hepatotoxicity assay using PXB-cells as an *in vitro* system.

PS 2753 Biocelerate Nonclinical Protocol Harmonization Initiative

M. A. Carfagna[1], P. Brinck[2], T. Fukushima[3], J. Horvath[4], S. H. Lopes[5], G. Schulze[4], N. Vansell[5], and T. Page[1]. *[1]Eli Lilly and Company, Indianapolis, IN; [2]Novo Nordisk A/S, Copenhagen, Denmark; [3]Shionogi & Co. Ltd., Osaka, Japan; [4]Bristol-Myers Squibb Company, New Brunswick, NJ; and [5]Pfizer Inc., Groton, CT.*

BioCelerate, a subsidiary of TransCelerate BioPharma, Inc., is a nonclinical industry consortium driving initiatives to increase efficiency and productivity in early-stage R&D. Our objective in developing common templates for nonclinical studies is to drive efficiencies in toxicology-study management across the spectrum of Biopharma and Contract Research Organizations (CROs). Our initial project resulted in a protocol template for FIH-enabling repeat-dose toxicology studies. The process to develop the initial protocol template utilized the OECD/FDA GLPs as a starting point and excluded process instructions where large variations in preferences existed. Advantages to using a common template include (1) decreasing the time it takes to develop a protocol and thus start a study, (2) improvement of overall study quality by decreasing errors due to unfamiliarity with protocol formatting, (3) optimization of time in managing multiple studies, and (4) optimizing time spent on subsequent report/SEND preparation and review. Two 2019 webinars introduced the initiative and were used to collect stakeholder feedback. Responses to poll questions indicated that a majority of stakeholders used multiple repeat-dose toxicology protocol templates, and experienced problems associated with protocol inconsistency including process/time inefficiencies and reduced quality of study execution. There was a mixed response regarding the inclusion of SEND information in the protocol. Building on these and earlier discussions, BioCelerate collaborated with CROs, health authorities, and BioPharma to develop a common protocol template for FIH-enabling repeat-dose toxicology studies. Version 1.0 of the protocol was released publicly in 4Q19 for voluntary adoption. The template and supporting implementation materials can be downloaded from the BioCelerate website. BioCelerate provides reports on the uptake/use of the common protocol template and shares critical feedback from early adopters on the gaps as well as the usefulness of the template. BioCelerate will continue to work with collaborators and stakeholders in evaluating options and recommendations for content and structural improvements. Input from all stakeholders will help us develop the next-generation protocol template as well as shaping our next-steps for subsequent common templates (e.g. Common Report Template). These activities will further support BioCelerate's goal of improving toxicology study operational efficiency and quality.

PS 2754 Induction of Malignant Lymphoma in Rats Given a Novel EZH2 Inhibitor for up to 13 Weeks

D. A. Dalmas[1], S. Mohanan[1], M. Watkins[1], J. Kumar[2], S. Knight[1], M. McCabe[1], D. Petrucci[1], and T. Hart[1]. *[1]GlaxoSmithKline plc, Collegeville, PA; and [2]GlaxoSmithKline plc, Ware, United Kingdom.*

Novel potent small-molecule epigenetic inhibitors of Enhancer of zeste homolog 2 (EZH2), a histone methyltransferase, are under consideration for development to treat solid tumors and lymphoma. Genetic- and pre-clinical data suggest potential pro-oncogenic effects of EZH2 inhibition based on the presence of EZH2 loss-of-function mutations in mouse models of pre-malignant myeloid conditions and development of hematopoietic malignancies in mice bearing a hematopoietic-specific deletion of EZH2. These findings have raised safety concerns of the carcinogenic potential early in the development of EZH2 inhibitors (EZH2i's). The FDA has recommended conducting a 13-week rodent toxicity study with EZH2i's earlier in development than required in ICH S9. To address this concern, in lieu of a 4-week toxicity study to enable a Phase 1 study in cancer patients, a novel potent orally bioavailable small molecule EZH2i was given once-daily for up to 13 weeks by oral gavage to Wistar Hanover rats (10/sex/group) at doses of 0 (vehicle), 5, 15, 30, and 45 mg/kg/day. At necropsy beginning as early as Day 58, thymic masses were observed along with increased thymus weights, and spleen enlargement at doses ≥15 mg/kg/day. These findings correlated with malignant lymphoma (12% incidence vs. 0.01% historical control rats of similar age) composed of neoplastic cells consistent with lymphocyte morphology, in thymus along with numerous hemolymphoreticular tissues (e.g. spleen, lymph nodes, etc.). Further evaluation of thymus and mesenteric lymph node for CD3 and CD79a expression (T-cell and B-cell markers, respectively) by immunochemistry (IHC), indicated that the lymphoma observed was predominantly composed of neoplastic lymphocytes positive for CD3 staining and negative for CD79a (i.e. T-cells derived). The data suggest that the lymphomas noted in this study are consistent with observations in mice with EZH2 loss-of-function mutations and/or EZH2 hematopoietic-specific knock-out. Overall, although further investigations are needed to confirm the carcinogenic mechanism, the data provide evidence confirming a risk for carcinogenicity following pharmacologic inhibition of EZH2.

PS 2755 Regulatory and Practical Perspectives on the Nonclinical Safety Testing in Support of Pediatric Medicine Development

G. Krishna, P. Karoon, Z. Huang, and P. Roy. *Parexel International Corporation, Bethesda, MD.*

The Best Pharmaceuticals for Children Act became law in 2002 which has led to testing of drugs in pediatric population. In support of this, testing in juvenile animals has become a practice and an expectation. There has been significant discordance on the modalities of expectations of such studies from both regulatory and drug developers' perspectives. This has been captured in the latest 2018 ICH S11 Step 2 draft guidance. The purpose of this presentation is to review the evolution of such research, to share lessons learned (educational) and discuss authors' experience on regulatory interactions. To this end, pertinent literature was reviewed, expert opinions were sought, and authors' personal experiences are discussed considering the principles

of 3Rs (Replacement, Reduction, and Refinement). Results showed: in about 40% of cases, companies felt they had received discordant advice on such studies from the health authorities. Most juvenile toxicity studies have been performed due to lack of scientific knowledge or regulatory experience, or because there was a "perceived" uncertainty or risk, rather than a "truly" identified concern that needed to be addressed. ICH S11 guidance takes a more holistic view of the topic by ensuring that its focus is not limited to toxicological concerns alone, rather address pharmacology considerations, ensure such studies cover the relevant developmental stages of animals in relation to intended pediatrics, offer advice on the selection of appropriate endpoints, and such studies are required if they can add value. While designing such studies considerations on: selection of the best species (80% used rat and the rest used other rodents and nonrodents, based on scientific rationale), sponsors shall make a case for right animal age, dosing regimen and appropriate endpoints with a focus on not to "just add what you can do" rather "to do what you need to do". Authors' up to 10 interactions with regulators concurred this practice. Other considerations include: pediatric-first and pediatric-only indication where 2 species like the adult-setting, but in young animals with additional measures of developmental endpoints. It is concluded that new ICH S11 draft guidance captures the lessons learned, gives the option for sponsors to make a case. Such experiences were shared by the authors' regulatory interactions. These findings are of value to all stakeholders conducting such research to make a difference in those "waiting" pediatric patients.

PS 2756 AAV Vectors on the Move: Safety Studies in Nonhuman Primates for Second-Generation Gene Therapy Products

S. Korte, A. Dütting, B. Pajaziti, F. Ludwig, S. Grote-Wessels, S. Zander, B. Korbmacher, and L. Mecklenburg. *Covance Preclinical Services GmbH, 48165 Muenster, Germany.*

The field of gene therapy has matured in recent years to bring forward potential treatment or cure for life-threatening monogenetic diseases. For *in vivo* gene delivery, a viral vector containing the gene of interest is administered and DNA/RNA is either directly inserted into the host genome (e.g. retroviral vectors) or is delivered via episomes in the nucleus of transduced cells (e.g. adeno-associated virus (AAV) vectors). AAV is by far the most commonly employed technology for gene delivery into cells. The first AAV-based gene therapy (GT) products are already available to patients in various indications and even more are undergoing preclinical and clinical development. The conduct of a clinical trial for an investigational GT product is guided by the Code of Federal Regulations (CFR) Title 21, Part 312 in the USA and by a variety of guidelines published by the European Medicines Agency in Europe. As with other medicinal products, preclinical pharmacology and toxicology studies need to support the decision that a clinical trial in human subjects is reasonably safe and scientifically feasible to conduct. Those studies are typically conducted in nonhuman primates (particularly the cynomolgus monkey), given that it shares > 98% homology to the human genome. This publication summarizes experience with a broad range of GT products that have been investigated in cynomolgus monkeys. It covers in total 125 animals, that were placed on 4 different studies, investigating 4 different GT products. One product was based on AAV5, two were based on AAV8, and one was based on AAV2/AAV8/AAV9. One product was administered into the *striatum* via convection-enhanced delivery, one was injected into the *cisterna cerebromedullaris*, one was administered below the *retina*, and one was injected intravenously. The publication describes selection of animals based on the presence of endogenous antibodies against AAV serotypes, outlines the prototypical design of NHP safety studies for such products, and summarizes the approach to determine distribution and transduction efficiency of these products.

PS 2757 Is Acidification of Urine a Preanalytical Requirement for the Measurement of Urine Calcium, Phosphorus, and Magnesium in Nonclinical Studies?

A. Pinçon, J. McCartney, A. Provencher, A. Varela, and F. Poitout-Belissent. *Charles River, Senneville, QC, Canada.*

Introduction: Measurement of urinary calcium (Ca), inorganic phosphorus (iPHOS) and magnesium (Mg) is often performed in nonclinical studies to monitor renal function and bone turnover in different laboratory species. To limit the potential underestimation of minerals present in urine, acidification is recommended to dissolve complexes formed by Ca and Mg cations with phosphate anions. Calcium oxalate crystals are commonly observed in rat and non-human primate (NHP) urine, and triple phosphate crystals are frequent in dog, hence sequestering a certain quantity of minerals. Although reducing the urinary pH is necessary to limit the formation of these crystals, calcium carbonate crystals may form in acidic urine in these species. We investigated the necessity of pre-analytical acidification in nonclinical urine samples in rats, dogs and NHPs. Methods: Urine samples were obtained from Cynomolgus monkeys, Beagle dogs and Sprague-Dawley rats during an overnight or morning collection. One aliquot of each sample was acidified by addition of HCl (1:10) to reach a pH ≤5.0, incubated for 30 minutes, centrifuged and analyzed. Urine Ca, iPHOS and Mg were measured on a Cobas® 6000 analyzer (Roche) on both, acidified and non-acidified samples. Results: The mean differences in urine concentrations between nonacidified and acidified samples in rats, dogs and NHP were 4.4%, 10%, 25% for Ca, 6.6%, 27%, 24% for Mg, and 3.4%, 11.2% and 58% for iPHOS, respectively. Large percentage differences were due the low mineral concentrations observed in NHP, and absolute concentration ranges remained similar between both methods. Ca and Mg concentrations were higher in acidified samples compared to non-acidified, while iPHOS concentrations were generally lower in monkey acidified samples compared to non-acidified. These differences were not statistically different and were not judged to exceed the biological variability. Conclusion: Acidification of urine did not result in noteworthy differences in the measurement of Ca, iPHOS and Mg, and was considered an unnecessary procedure in the context of nonclinical studies.

PS 2758 Toxicology Species Selection for Preclinical Safety Assessment of TLR7/8 Prodrug Agonist

J. Gunther, S. Kivimae, E. Tonkin, M. Maiti, W. Nieves, Y. Kirksey, C. Fanton, W. Rubas, and T. Sweeney. *Nektar, San Francisco, CA.*

NKTR-262, a prodrug of TLR7/8 agonist (TLRX) conjugated to PEG via a releasable linker designed for slow release of TLRX to reduce toxicity, is in clinical development as an immuno-oncology drug. *In vitro* hepatocyte metabolism, cellular, and molecular studies, and *in vivo* measurements of target engagement demonstrated that rat and dog are relevant toxicology species. In human and dog peripheral blood mononuclear cells (PBMCs), TLRX induced comparable pERK1/2 phosphorylation levels with mean EC50s of 942 and 778 ng/mL, respectively. In contrast NKTR-262 failed to induce pERK1/2 in human cells; in dog cells induction occurred only at very high concentration. After 24 h stimulation of human, rat and dog PBMCs, TLRX induced dose-dependent IL-6 and TNFα secretion with similar potencies of 1.1 - 2.2 μM in dog and human cells and roughly 25-fold higher potency in rat cells at 0.05 μM. NKTR-262 elicited vastly less potent cytokine response in all 3 species consistent with a prodrug design. *In vivo* pharmacological responses to TLRX after single s.c. administration of NKTR-262 to rat (0.3mg/kg) and dog (up to 1 mg/kg) were evaluated by qRT-PCR measurement in blood cells for type I interferon and NFκB related gene expression (*MX1*, *Cxcl10*, and *Tnfa*) and induction of proinflammatory serum cytokines (IL-5, IL-6, IL-10, INFγ, TNFα and CXCL10 (IP-10)). In rat, expression of all 3 target genes was robustly induced. Amplitude of induction varied between 5- to 10-fold for *Tnfa* to ~2000-fold for *Cxcl10*. Expression of all 3 genes returned to near baseline levels by 48 h post dose. Rapid increase in all measured proinflammatory cytokines was observed in rat with serum levels returning to baseline by 48 h post dose. However, IP-10 showed substantially prolonged elevated levels at all dose levels which may be due to the high *Cxcl10* gene expression. In dog, NKTR-262 did not affect levels of IL-5, IL-6, IL-10, INFγ, and TNFα. IP-10 levels increased in most time points compared to baseline, however, due to variability within replicates and fluctuations within time points, no significant correlation could be attributed to NKTR-262 administration. TLR7/8 engagement by NKTR-262, and more potently by TLRX, was confirmed in rat and dog by *in vitro* and *in vivo* assessments. The type and extent of metabolites were consistent across human, rat and dog in *in vitro* hepatocyte assays. These results verify rat and dog as relevant toxicology species for the safety assessment of NKTR-262.

PS 2759 Evaluation of Rat Hepatoxicity of a GalNAc-Conjugated siRNA After Repeated Bolus Administration versus Continuous Infusion

S. Maczko, A. Hayes, W. Davis, P. Gedman, B. Carito, K. Harding, L. Moran, C. Wong, K. D'Angelo, K. Ghimire, Y. Jiang, E. Castellanos-Rizaldos, and J. E. Sutherland. *Alnylam Pharmaceuticals Inc., Cambridge, MA.*

Subcutaneous injection (SC) of small interfering RNAs (siRNAs) conjugated to a trivalent *N*-acetylgalactosamine (GalNAc) ligand are an established tool for targeted hepatic delivery and subsequent degradation of target mRNAs. Screening of GalNAc-siRNA candidates has identified compounds that elicit hepatotoxicity at suprapharmacological doses in rats. Hepatotoxicity in rats has been hypothesized to result from RNAi mediated off-target effects, disruption of endogenous RNAi pathways, and/ or accumulation of siRNA and metabolites in target tissues. In this study, the test article, siRNA1, is a tool-kit siRNA-GalNAc conjugate directed against a rodent-specific liver-expressed mRNA target. siRNA1 was previously shown to produce hepatotoxicity in both the mouse and rat by a mechanism that is not related to pharmacodynamic

reduction of the target mRNA. The objective of this study was to determine if the hepatotoxicity observed with siRNA1 after three once weekly SC bolus doses over a two-week period could be mitigated by instead administering the equivalent cumulative dose via a continuous SC infusion. Male Sprague Dawley rats (n=4/group) were administered vehicle (0.9% NaCl), 40 mg of siRNA1, or 100 mg of siRNA1 via an implanted osmotic pump over a two-week period. The animals were sacrificed on Day 15. The analysis included clinical observations, assessment of body weight, organ weight, histopathology, and clinical pathology. One male at 40 mg siRNA1 and one male at 100 mg siRNA1 were found moribund on Day 14 and exhibited a > 15% loss of body weight compared to previous weekly weigh-in. Animals in the 40 and 100 mg dose groups displayed rough haircoat, thin appearance, hunched posture, or pilo-erection beginning on Day 13 and lasting until Day 15. Animals in the 40 mg and 100 mg siRNA1 dose groups had lower mean body weight gain compared to controls on Day 14. The histopathology and clinical pathology results following SC infusion were similar to those observed following repeated bolus administration of similar cumulative doses of siRNA1 suggesting that there was little to no mitigation of toxicity with continuous infusion.

PS 2760 Evaluation of the Toxicity Study by Using Cynomolgus Monkeys in *PiggyBac* Transposon-Mediated Chimeric Antigen Receptor T Cells

H. Mochizuki[1], H. Morokawa[2,3], M. Tanaka[2,3], S. Saito[2,3], S. Yagyu[2,4], Y. Nakazawa[2,3], and A. Shimoi[1,2]. *[1]Ina Research Inc., Ina-shi, Japan; [2]Shinshu University, Matsumoto-shi, Japan; [3]Shinshu University School of Medicine, Matsumoto-shi, Japan; and [4]Kyoto Prefectural University of Medicine, Kyoto-shi, Japan.* Sponsor: H. Mochizuki, Japanese Society of Toxicology

Recently, the first CAR-T cell medicines were approved, and development of new CAR-T cell medicines targeting other blood and solid tumors is expected. For any new drug, it is necessary to conduct various nonclinical safety studies during development. However, CAR-T cell medicines are quite different from conventional pharmaceuticals. In nonclinical safety evaluation of CAR-T cell medicines, cytokine-release syndromes, on-target/off-tumor reactions, elimination of effects of heterologous GVHD, and dose setting of imported CAR-T cells require consideration. Therefore, it is necessary to establish 1) an autologous model in which donor and recipient are the same species, 2) a primate model of high antigen homology with humans, and 3) a large animal model allowing dose setting for nonclinical safety evaluation. To solve these problems, we engineered several CAR T-cell therapies using a non-viral piggyBac transposon system by electroporation and performed toxicity studies in cynomolgus monkeys with the support of the AMED (Japan Agency for Medical Research and Development) "Basic Technology Development Project for Industrialization of Regenerative Medicine and Gene Therapy". GMR CAR-T cells were produced from peripheral blood of cynomolgus monkeys using a GM-CSF receptor (GMR) CAR transposon vector and administered intravenously to each donor animal. Control animals received non-genetically modified T cells. Parameters included general condition, body weight, food consumption, hematology, blood chemistry, coagulation tests, TK analysis and cytokine profiles. Fourteen days after administration, all monkeys were euthanized for histopathology examinations. The obtained simian GMR CAR-T cells expressed anti-human GMR CAR and almost completely killed a human acute-myeloid leukemic cell line. GMR CAR-T cells were detected in all treated animals, but no abnormalities or postmortem findings were noted. These results show we successfully generated non-virally modified CAR T cells from cynomolgus monkeys, and more long-term studies using these CAR-T cells are planned.

PS 2761 Is It Hypertension or Are You Just Excited to See Me?

K. R. Kearney, M. White, N. Adkins, C. Appleby, C. Jenkins, R. B. Borders, and B. M. Roche. *Charles River, Ashland, OH.*

In alignment with the 3Rs, and in an effort to maximize study endpoints, safety pharmacology (SP) parameters are being collected within the scope of toxicology (Tox) assessments with greater regularity. These additions serve to assess both acute and cumulative pharmacodynamic effects on the vital organ systems (CV, CNS, and respiratory) following administration of an investigational entity. While both disciplines (SP and Tox) share commonality to identify liabilities preceding clinical evaluation, these disciplines differ in the sensitivity with respect to acute changes in evaluated endpoints. As it is regulatory expectation that studies evaluating SP endpoints on Tox must maintain the same rigor to that of a stand-alone SP study, careful consideration should be given to study design and logistics. Considerations range from schedule of the evaluation intervals, to control of the data collection environment. To illustrate the sensitivity of SP endpoints, heart rate and blood pressure were evaluated in male beagle dogs and non-human primates (NHPs) following animal room entry to determine the potential impact on data interpretation. Data were evaluated to assess average impact (increase of SP parameters) following room entry (minute 1 following entry) and animal manipulation (clinical observation and/or blood draw). Control data were evaluated from 27 subjects over 7 studies (3 dog/4 NHP studies) to calculate maximal increases in each parameter and duration for the subjects to return to pre-entry. On average, heart rate (HR)) increased 18% (32 bpm) and 113% (96 BPM), and systolic blood pressure (SBP) increased 17% (21 mmHg) and 23% (39 mmHg), in NHPs and dogs, respectively. Additionally, the data supported these non-manipulative (exclusive of handling or sample collections) interruptions required an average of 30 and 35 min, for animals to return to pre-entry values, for NHPs and dogs, respectively. For procedural events requiring phlebotomy, this duration increased, on average, up to 73% (52 min interruption). The data support careful consideration for control of the collection environment to minimize alterations in cardiovascular responses to external stimuli. Additionally, procedural activities should be limited; specifically surrounding T_{max} in an effort to avoid confounding interpretation.

PS 2762 Evaluation of the Safety and Skin Irritancy of a Novel Anhydrous System: PermE8 Anhydrous Gel, W06 Anhydrous Topical Gel, and VersaBase Anhydrous HRT in Human Epidermis Model

G. Song[1], D. Banov[1], G. S. Bassani[1], and J. Qiao[2]. *[1]Professional Compounding Centers of America, Hosuton, TX; and [2]University of Texas Southwestern Medical Center, Dallas, TX.* Sponsor: J. Qiao, American Association for Cancer Research

A novel anhydrous system that includes three proprietary bases: PermE8 Anhydrous Gel (PermE8), W06 Anhydrous Topical Gel (W06) and VersaBase Anhydrous HRT, has been developed for a broad range of dermatological and cosmetic application. PermE8 and VersaBase Anhydrous HRT are both for transdermal drug delivery, while VersaBase Anhydrous HRT is more specific for female hormone replacement therapy (HRT). Different from the other two bases, W06 is designed to use topically. With water activity below 0.6 (Aw<0.6), the anhydrous bases provide an unfavorable environment for microbial growth, are therefore allowed extended default beyond-use dates (BUDs) without compromising their drug delivery capabilities. The aim of this study was to evaluate the safety and skin irritancy potential of the anhydrous system. An *in vitro* reconstructed human epidermis model (Epiderm) that contains normal human-derived epidermal keratinocytes was used. PermE8, W06, and VersaBase Anhydrous HRT were applied and spread evenly on top of EpiDerm. Cell viability was determined by MTT assay after 1, 4, 17 and 24 hours of application. After 24 hours, viable cells were 94.78±1.28%, 89.34±2.11% and 51.66±2.73% in PermE8, W06 and VersaBase Anhydrous HRT treated Epiderms, respectively. Viabilities were all above the irritation classification threshold of 50%, suggesting these tested bases are non-irritants. The exposure time required to reduce cell viability by 50% (ET-50) was more than 24 hours for PermE8 and W06, 24 hours for VersaBase Anhydrous HRT, and 9 hours for 1% Triton X-100, which was a positive control and moderate-to-mild irritant. Based on the correlation between *in vivo* and *in vitro* irritancy response, the irritancy of a product with ET-50 of 24 hours is as mild as baby shampoo. In conclusion, none of the three bases in this novel anhydrous system showed signs of cell toxicity after 24-hour treatment. All bases are non-irritants, and the irritancy is milder than baby shampoo. This study provides safe options to physicians and compounding pharmacists when choosing bases for topical or transdermal drug delivery.

PS 2763 Neratinib Causes Persistent Damage and Decreases Drug-Metabolizing Enzyme in Gut

G. Tao, L. Wang, and R. Ghose. *University of Houston, Houston, TX.*

Neratinib (NERLYNX®) is a pan-HER tyrosine kinase inhibitor newly approved by FDA in 2017 and its European counterpart in 2018 to treat adult patients with HER2-positive breast cancer, but the approval of neratinib has been controversial. Recent retrospective analysis showed that neratinib did not impact patients' quality of life based on questionnaire, while another cost-benefit analysis indicated that neratinib was not cost-effective, due to severe side effect and high economic cost. ExteNET trial, the phase III trial of neratinib showed that 96% of the patients taking neratinib experienced diarrhea. However, very few mechanism studies have been reported about neratinib-induced gastrointestinal (GI) toxicity. Hereby, we performed toxicity studies in mice to characterize the potential mechanism underlying such adverse effect. C57BL/6 J (female, 5-weeks old) mice were randomly separated into three groups A, B, C. Group A received vehicle while group B was orally dosed with 100mg/kg neratinib once daily for 18 days. Group C was dosed

with 100mg/kg neratinib for 12 days and switched to vehicle afterwards for 6 days. Intestine and liver were collected for further analysis. Our results showed that 12 days treatment of neratinib caused persistent histological damage in mouse GI tract, including intestinal ulcer, blunted villi in jejunum and ileum, and remarkable inflammatory infiltrate in colon. In addition, we found that the gene expression of Cyp3a11 was significantly reduced (over 90% decrease, $p<0.005$) in small intestine but not changed in liver, which is the major enzyme metabolizing neratinib. The gene expression of proinflammatory cytokines, for example TNF-α and IL-6, increased remarkably (over 5 folds, $p<0.05$) throughout the GI tract. Such persistent damages were not recovered even after 6 days without neratinib treatment. In summary, neratinib caused the release of proinflammatory cytokines and downregulated the expression of Cyp3a11. With lower level of Cyp3a11, there is likely neratinib accumulation in gut. It eventually leads to high risk of diarrhea. Our findings give new insight into the mechanism of neratinib-induced GI toxicity. It also questions the current perspective that neratinib does not affect the physical well-being of patients.

2764 Chronic Subcutaneous Administration of 30% (w/v) Aqueous Sulfobutyl Ether 7-β-cyclodextrin (Captisol™) in Wistar Han Rats Causes Malignant Sarcomas at the Injection Site

J. Ciallella[1], R. Bruner[2], H. Thomas[3], and A. Sargeant[1]. *[1]Charles River, Spencerville, OH; [2]Research Pathology Associates LLC, Clemson, SC; and [3]Aclairo Pharmaceutical and Development Group Inc., Collegeville, PA.*

Cyclodextrins solubilize and stabilize drugs and improve drug delivery. A polyanionic variably substituted sulfobutyl ether of β-cyclodextrin [sulfobutyl ether 7-β-cyclodextrin (SBE-β-CD; Captisol™)] interacts well with neutral drugs to facilitate solubility and chemical stability, and is used in products approved by the Food and Drug Administration. Five groups of 60 male and 60 female Wistar Han rats were administered a dose volume of 3 mL/kg saline control (Group 1), 30% (w/v) SBE-β-CD in sterile water for injection, final pH 7.2±0.5 (vehicle control/Group 2), or SBE-β-CD combined with low, mid, and high doses of a test article (Groups 3-5) by once daily subcutaneous administration in a 2-year carcinogenicity study. Due to rapidly expanding subcutaneous tumors in all groups except the saline control, males were terminated early during Week 60 and females were terminated early during Week 83. The subcutaneous tumors were initially observed after approximately 9 months of dosing and required humane euthanasia after approximately 4-6 weeks of growth. The tumors consisted primarily of pleomorphic fibrosarcomas and fibrosarcomas and were attributed to chronic irritation in the subcutaneous tissue related to SBE-β-CD administration. There was no exacerbation of tumor development by the test article. SBE-β-CD-related non-neoplastic findings included cytoplasmic vacuolation of epithelial cells in the kidney and prostate, parathyroid chief cells, and macrophages in the subcutaneous injection site. Chronic subcutaneous administration of 30% (w/v) SBE-β-CD causes malignant sarcomas at the administration site that result in high mortality and preclude its use as a vehicle for subcutaneous administration in 2-year carcinogenicity studies in rats.

2765 The Utility of hERG Inhibition Data in the Derivation of Pharmaceutical Occupational Exposure Limits

S. B. Bandara[1], J. A. Parker[2], L. G. Liang[1], S. Chen[2], A. Maier[3], and E. S. Fung[2]. *[1]Cardno ChemRisk, San Francisco, CA; [2]Cardno ChemRisk, Aliso Viejo, CA; and [3]Cardno ChemRisk, Cincinnati, OH.*

The human ether-a-go-go (hERG) channel is a highly-expressed voltage-gated potassium (K^+) channel in the human heart. Specifically, the hERG channel conducts the delayed rectifier K^+ current (IKR) and reestablishes resting potential, a crucial component of cardiac action potentials. Inhibition of the hERG channel leads to a decrease in the outward flow of K+, delayed repolarization, and consequent QT prolongation. Because QT prolongation may lead to a fatal arrhythmia known as Torsades de pointes (TdP), pharmaceutical drug candidates that exhibit potent hERG channel inhibition often fail early in clinical trials. However, many drugs with both cardiac and non-cardiac indications proceed to market despite having hERG channel inhibitory activity through various mechanisms. We identified classes of drugs with hERG inhibitory activity and evaluated the relationship between their cardiac toxicity and published occupational exposure limit (OEL). A total of 58 cardiac drugs across four classes (class I, class II, class III, and class IV) and 104 drugs with non-cardiac indications (e.g., psychiatrics, antibiotics) with published hERG channel IC_{50} values were identified. Published OELs or ranges were identified for 23 cardiac drugs and 46 non-cardiac drugs. A clear correlation between hERG IC_{50} potency and OEL values was observed in cardiac drugs; specifically, drugs with less potent hERG IC_{50} values had correspondingly higher OEL values. However, there was no apparent relationship between the hERG IC_{50} and OEL for non-cardiac drugs. Interestingly, 19 drugs had both a potent hERG IC_{50} (<25 μM) and a contrastingly large OEL value (>50 μg/m^3). Together, these data indicate that cardiac effects are likely the most sensitive endpoint (i.e., point of departure) driving the OEL value for cardiac drugs. On the other hand, the therapeutic effect used as the most sensitive endpoint driving OEL value for non-cardiac drugs may not have fully considered potential cardiac effects. Thus, we present a framework for consideration of cardiac effects when deriving OEL values.

2766 Survey of Spontaneous Clinical Observations in the Cynomolgus Monkey (*Macaca fascicularis*)

Y. Zhang, S. McPherson, and Z. Chengen. *Wuxi AppTec, Suzhou, China.*

The Cynomolgus Monkey (*Macaca fascicularis*) is routinely used in preclinical toxicity testing and clinical observations are one of the many parameters used to assess the potential toxicity of a xenobiotic during the conduct of *in vivo* toxicology research. During the course of the study the frequency of clinical sign assessment varies depending on the type of study but will usually be conducted at least once daily with control animals being evaluated at the same time. Clinical observations from control animals were compiled and evaluated from 66 studies to assess the occurrence of common observations. The animals were characterized by their source/vendor, study duration, and genders. All the animals were social housed in stainless steel cages equipped with a bar type floor and an automatic watering valve. Typical observations noted included assessments of animal activity, appearance, presence of masses, discharge, normality and consistency of the stool, and any other unusual observations. Data were presented in a concise database allows for easy access to this historical background data. Clinical signs with higher incidences (approximately or higher than 1%) were alopecia, scab, bruise, anogenital regions swelling, vaginal discharge, toenail missing, skin discolored, tail deviation, abrasion, swelling, digit complete/portion missing, tooth missing, and soft stool. Husbandry related clinical signs were considered as alopecia and scab. The comparison duration of dose administration, the incidences of alopecia increased and scab were reduced for both sexes. The incidence of alopecia in females were higher than that in males. Technical related (dosing or blood collection) clinical signs were considered as bruising, vomitus, regurgitation, and toe nail missing. Sporadic and transient abnormalities included tremors, inappetence, slight salivation, distended abdomen, dry skin, skin scaling, erythema (thorax/dorsal), increased respiratory rate, and rash (abdomen) were noted in one or two studies. Access to such data bases will enable and facilitate the toxicologist to put the observed clinical signs in perspective during the course of a toxicological study and will help identify those signs that are truly related to the administration of the test material.

2767 Drug-Induced Seizures: Considerations for the Underlying Molecular Mechanisms

M. Accardi[1], Y. Zhong[1], R. Kubaszky[1], and S. Authier[1,2]. *[1]Charles River, Laval, QC, Canada; and [2]Université de Montréal, St-Hyacinthe, QC, Canada.*

Drug-induced seizure (DIS) liabilities pose a life-threatening risk both in drug development and to the general population, significantly contributing to compound attrition and new-onset non-epileptic seizures in patients, respectively. Broad spectrums of known chemicals have been previously associated with DIS risk, emphasizing the importance of central nervous system drug safety assessments across various drug classes (e.g., antidepressants, antipsychotics, antibiotics, and analgesics amongst others). However, despite its importance within drug safety testing, a full understanding of the molecular mechanisms underpinning DIS is often lacking. The etiology of DIS is understood to be a result of either a deficit in inhibitory (e.g., gamma aminobutyric acid) or elevation in excitatory (e.g. glutamate) signaling, although other neurotransmitter systems are also known to play a role. However, how this altered neuronal signaling occurs and how these changes interact with other non-brain receptor driven DIS-associated changes such as metabolic disturbances, electrolyte imbalances, altered drug metabolism and withdrawal effects are poorly understood. Here, we aim to summarize and discuss important molecular mechanisms which were identified in the initiation of DIS for several known drugs and/or drug classes associated with DIS. With a better understanding of the molecular mechanisms underpinning DIS, mechanism targeted *in vivo* or *in vitro* strategies may be applied both pre- and post-marketing to characterize and mitigate DIS-risk during drug development. Our data shows that susceptibility stratification based on GABA-related drug in-

duced seizure presents species differences in the following order Beagle dogs > Sprague-Dawley rats > Cynomolgus monkeys > Göttingen minipigs with a more than 2-fold difference between canines and minipigs.

2768 Interim Safety of Intrathecal AAV9/GAT1 Gene Therapy

F. Shaffo, S. Gray, X. Chen, and M. Rioux. *University of Texas Southwestern Medical Center, Dallas, TX.*

SLC6A1 gene encodes the highly conserved gamma-aminobutyric acid (GABA) transporter GAT-1, a protein crucial for GABAergic signaling in the central nervous system (CNS). A subset of patients presenting with rare forms of infantile encephalopathy with intellectual disability (ID) have been shown to be heterozygous for loss-of-function mutations in SLC6A1. Broad delivery the SLC6A1 gene across the CNS using adeno-associated virus type 9 (AAV9) to restore normal GABAergic signaling may prove to be an effective strategy to treat patients with SLC6A1 genetic disorder. While the safety profile of AAV9 has been well established in both preclinical and clinical models, potential toxicity of overexpression and/or non-neuronal expression of the GAT-1 transgene is of concern. Two vector designs with different promoters were used; one is a weak universal promoter (P1), while the other is a stronger, neuronal-specific promoter (P2). Postnatal day 28-35 wild type C57BL/6 mice received the maximum feasible dose (7.5 and $7.0x10^{11}$ vector genomes (vg) for P1 and P2 constructs, respectively), four-fold lower dose, or vehicle control (PBS + 5% sorbitol) via a 5 µL intrathecal (IT) lumbar injection. Six males and six females were included in each dose group. Animals were weighed and observed weekly for body condition for four weeks, and monthly thereafter. Submandibular blood draw was taken at three weeks post-injection for serum chemistry analysis. No adverse reactions were observed post-injection in any animals, and all treated animals appear healthy up to 12 weeks post-injection and have normal bodyweight. Serum chemistry results show that aspartate aminotransferase (AST), blood urea nitrogen (BUN), albumin (ALB), and creatine kinase (CK) levels are not statistically different from vehicle control animals. Total bilirubin (TBIL) was significantly lower in both high-dose groups, although there is no known pathology associated low TBIL. These results help support the safety of IT delivery of AAV9/hGAT1opt transgene with either promoter. These animals will be followed to a year post-injection, at which point tissue will be harvested and assessed by a trained pathologist. With additional safety and efficacy testing, these preclinical data could be used to support the application this gene therapy approach to patients suffering from SLC6A1 haploinsufficiency disorder.

2769 Toxicological Safety Assessment of Extractable and Leachable from Printing Inks for Post-marketing Change of Parenteral Drug Products

H. Li, C. Li, B. Quach, and A. Hsueh. *B. Braun Medical Inc., Irvine, CA.*

Regulatory authorities in US and EU have increased scrutiny and focus on extractable and leachable compounds over last several years. The safety assessment should be specifically discussed in Modules for Toxicology Written Summary/Other Toxicity of the ANDA/NDA/PAS/CBE submission. Nonclinical review of extractable/leachable studies is FDA hot topic, but unsure where reviewers will focus. To address these regulatory concerns, companies are spending significant time assessing toxicity of extractable\leachable (E/L) compounds. The Label Materials (such as adhesive, paper, ink, varnish, etc) are defined as "no direct contact" materials Per USP <1661>, which do not come into direct physical contact with drug products. However, depending on the container permeability and the label application process on the containers, the label materials can be considered as "potentially interacting" components. The presentation will discuss E/L studies design for post-marketing change in printing inks, E/L study results by using different analytical techniques (LC/PDA/MS, GC/MS etc.). Several extractables were detected from the ink extractions by High Performance Liquid Chromatography with a Diode Array Detector and Mass Spectrometry Detector (HPLC/PDA/MS) and Gas Chromatography with flame ionization detector and Mass Spectrometry Detector (GC/FID/MS). The presentation will also discuss how to determine the Safety Concern Threshold (SCT), calculate the Analytical Evaluation Threshold (AET) for drug products, and conduct toxicity/safety assessment for extractables and leachables per PQRI, ICH M7 as well as USP <1664> for drug products.

2770 Development of Claudin-5 Modulators and Evaluation of Their *In Vitro* Permeation-Activity of Solutes across the Blood-Brain Barrier in a Mammalian Model

Y. Hashimoto[1], K. Shirakura[1], Y. Okada[1], H. Takeda[2], A. Watari[1], T. Sawasaki[2], K. Tachibna[1], T. Doi[1], K. Yagi[1], and M. Kondoh[1]. *[1]Osaka University, Osaka, Japan; and [2]Ehime University, Ehime, Japan.* Sponsor: M. Kondoh, American Society for Pharmacology and Experimental Therapeutics

Introduction: A current bottleneck in the development of central nervous system (CNS) drugs is the lack of drug delivery systems targeting the CNS. The intercellular space between endothelial cells of the blood-brain barrier (BBB) is sealed by tight junctions (TJs). The TJ seal prevents the paracellular diffusion of drugs into the CNS. Claudins (CLDNs), a 27-member protein family of tetra-transmembrane proteins, are the major structural and functional components of the TJ seal. Although the BBB is more permeable to small molecules in CLDN-5-deficient mice than in wild-type mice, CLDN-5 deficient mice died within 10 h after birth. It is still unclear whether CLDN-5 is a safety and efficient target for drug delivery to the brain. In the present study, we generated anti-CLDN-5 monoclonal antibodies (mAbs) and examined the effects of the mAbs on the BBB. Methods: We generated anti-CLDN-5 mAbs by immunizing mice and rats with a plasmid encoding human CLDN-5. The effects of the mAbs on the integrity of the TJ seal were investigated by using MDCKII transfectants expressing CLDN-5 and a commercially available BBB model composed of cynomolgus monkey brain microvascular endothelial cells. Results: Four mAbs targeting the extracellular loop domains (ECLs) of human CLDN-5 were isolated. All four mAbs specifically bound to CLDN-5 but not to the other CLDNs. All of the anti-CLDN-5 mAbs dose- and time-dependently decreased TEER in an *in vitro* BBB model. The anti-CLDN-5 mAbs dose-dependently increased the permeability of the model BBB to the fluorescein dye and fluorescein-conjugated dextran (Mw 4 kDa) without cytotoxicity. Injection of anti-CLDN-5 mAbs also enhanced the permeability to the fluorescein dye without apparent adverse effects. Conclusion: The anti-CLDN-5 mAbs are the first CLDN-5-specific binders. The present results suggest that CLDN-5 is a potential target for drug delivery to the brain and these binders may be a potential lead for the development of novel drug delivery systems targeting the CNS. *Acknowledgements: This work was supported partly by a grant of Research Support from Astellas (RS2018A000674); Grants-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology of Japan (19H04468, 18K19400, 18H03190, 16K13044, and 24390042); a grant for Research on Development of New Drugs from the Japan Agency for Medical Research and Development (AMED); and grants from the Platform Project for Supporting Drug Discovery and Life Science Research (Basis for Supporting Innovative Drug Discovery and Life Science Research [BINDS]) of AMED (JP19am0101077, JP19am0101084, JP19am0101090).*

2771 A Comparison of Environmental Assessment Requirements of New Human Drugs in the US and the EU

I. Mohar[1], T. Lunsman[1], and T. Verslycke[2]. *[1]Gradient, Seattle, WA; and [2]Gradient, Boston, MA.*

Market authorization of new human drugs in both the US and the EU requires an assessment of potential environmental impacts. In the US, drug approval is overseen by the Food and Drug Administration (FDA), and an environmental assessment (EA) is required pursuant to the National Environmental Policy Act. In the EU, market authorization is overseen by the European Medicines Agency (EMA), and an EA is required under Directive 2001/83/EC. Both agencies have published guidance documents outlining EA requirements with the EMA issuing an updated draft guidance in late 2018. While the EA requirements of veterinary drugs is largely harmonized, the framework for conducting EAs of human drugs is much less harmonized. The objective of our analysis was to compare and contrast the EA framework in the US and EU. We reviewed current guidance and incorporated recent EA experience. We identified some general similarities such as the prioritization of endocrine active drugs, the use of tiered testing frameworks, and the preference for guideline studies conducted in accordance with GLPs. However, we identified many important differences in the FDA and EMA frameworks including the production and use criteria that trigger EAs, the points at which physicochemical properties are considered, and the specific tests needed to satisfy EA requirements. For example, in the US, the predicted annual production volume may qualify a drug for EA exemption; while in the EU, both the indicated dosage and certain physicochemical properties must be considered for potential EA exemption. Our analysis illustrates the need for careful and early planning by pharmaceutical companies to ensure global EA compliance.

2772 Threshold for Anaphylactoid Reaction to Polysorbate-80 in Canines

K. Holbrook[1], D. Andrews[1], W. Sutherland[1], A. Coppi[1], S. Barry[1], M. Escamilla[1], S. Authier[2], L. Miraucourt[2], F. Xie[3], B. Rock[3], and J. Bussiere[1]. *[1]Amgen Inc., Thousand Oaks, CA; [2]Charles River Laboratories Montréal ULC, Laval, QC, Canada; and [3]Amgen Inc., South San Francisco, CA.*

Polysorbate 80 (PS80; Tween 80) functions as a dispersing agent or solubilizer in many pharmaceuticals, and as a stabilizer in biopharmaceuticals. Topical or parenteral administration of the low doses of PS80 in biopharmaceuticals has been associated with mild allergic reactions, including local injection site reactions. High doses of PS80, such as levels found in traditional Chinese medicines, have been linked to systemic effects consistent with anaphylactoid-type reactions, which are characterized by the direct release of histamine from mast cells (degranulation). Nonclinical safety assessments of PS80 *in vivo* have mainly focused on canine model systems, a species well established to be particularly sensitive to PS80. However, there is conflicting data about the dose and route of administration of PS80 required to elicit an anaphylactoid-type reaction in this model system. Therefore, studies in anesthetized and conscious dogs were conducted to better define this threshold dose using multiple dosing regimens (with 0.25% PS80), based on a combination of cardiovascular data, clinical signs, and biomarkers of mast cell degranulation. An IV bolus of 1 mg/kg PS80, a 30-minute IV infusion of 1 mg/kg, or subcutaneous bolus of 20 mg/kg elicited a positive anaphylactoid reaction including increased heart rate, hypotension, and clinical signs associated with anaphylactoid reactions (e.g., reddened muzzle). However, no effects were observed with a subcutaneous injection of PS80 (0.25%) up to 15 mg/kg, IV infusions up to 0.5 mg/kg, or an IV bolus injection up to 0.3 mg/kg. These data show that there is a threshold dose for eliciting an anaphylactoid reaction in the most sensitive species (canine) which varies depending on the route of administration. This will allow for safe dosing of biopharmaceuticals with typically low concentrations of PS80 in patients.

2773 The Process and Challenges of Deriving Exposure-Based Limits for Toxicological Risk Assessment for Components and Impurities Present in Cell Therapy Products with Case Studies

A. Chesney[1], B. Welsh[2], A. Kimzey[3], and J. Lansita[4]. *[1]ToxStrategies Inc., Madison, WI; [2]ToxStrategies Inc., Austin, TX; [3]ToxStrategies Inc., Boston, MA; and [4]ToxStrategies Inc., Philadelphia, PA.*

To ensure the safety of drug products, the components within the formulation must be adequately characterized for potential toxicity. Such components may include product and process-related impurities, degradants, solvents, or excipients. In the case of cellular-based therapies, allogenic materials that are stored and processed may also have increased potential for additional components; such as cytokines, nucleases, growth factors, culture media, buffers, and preservatives. As novel cell-based therapies are developed in the clinic, new formulation components are emerging, the safety of which must be considered. Often, nonclinical and clinical data are included in the evaluation to characterize the safety of a component. However, in the case of cell therapies, nonclinical studies may not have been conducted due to the lack of a relevant animal model for toxicology testing. Therefore, additional data must be identified outside the scope of standard toxicology studies to ensure the level of an excipient or impurity present is acceptable for clinical dosing. A systematic and comprehensive review of primary literature databases, regulatory authority websites, and other industry or government literature sources is necessary to consider critical information such as: 1) physical and chemical properties 2) pharmacokinetic/ADME 3) non-clinical toxicology and immunotoxicology 4) clinical safety data, and 5) relevant regulatory limits and/or guidances. This information is summarized in a risk assessment or toxicology monograph in an attempt to derive a health-based exposure limit, e.g. a Permissible Daily Exposure (PDE), or to ascertain key data gaps that may require additional toxicity testing consistent with regulatory guidance (ICH Q3C). The monograph can then be used to set manufacturing specifications during process development or justify specification limits to a regulatory authority. We present the literature review and risk assessment process, including (when applicable) the derivation of an exposure limit in the context of case studies from cell therapy drug products. Case studies are presented and include cytokines, serum used in media, extraneous cells, and a residual vector. Options for when a PDE cannot be calculated are presented and discussed in terms of the impact on the program.

2774 Gut-Selective Exposure of TD-1473 Limits Systemic Effects of Janus Kinase Inhibition in Nonclinical Species

R. N. Hardwick, P. Brassil, K. Perkins, G. Obedencio, D. Bourdet, and E. B. Harstad. *Theravance Biopharma, South San Francisco, CA.*

TD-1473 is an orally-delivered, gut-selective pan-Janus kinase (JAK) inhibitor under investigation for the treatment of inflammatory bowel disease. Gut selectivity was designed into TD-1473 to maximize exposure in the gastrointestinal tract and limit systemic exposure at therapeutic doses, with the goal of minimizing the known systemic pharmacologic effects of JAK inhibition. This approach was evaluated in repeat-dose general toxicity studies up to 26 and 39 weeks in rats and dogs, respectively, and reproductive toxicity studies in rats and rabbits. In all studies, minimal to no systemic findings were associated with TD-1473 at clinically-relevant plasma exposures. At 1000 mg/kg/day in rats, systemic exposures exceeded the range of cellular JAK IC_{50} values for up to 9 hours and resulted in minimal, non-adverse effects on white and red blood cell parameters and decreased splenic weight and lymphoid cellularity. Similarly in dogs, minimal TD-1473 systemic exposures were achieved at supratherapeutic doses (30 mg/kg/day) and were limited to primary pharmacologic changes in red and white blood cell parameters and decreased hematopoietic and lymphoid cellularity. At higher doses (100 mg/kg/day), chronic administration resulted in systemic exposures exceeding JAK IC_{50} values for up to 24 hours and pharmacologic decreases in immunosurveillance characterized by dermal *Demodex* infections and papillomas secondary to systemic JAK inhibition in dogs. In a rat fertility and early embryonic development toxicity study, there were no changes in mating, fertility, estrous cycling, or early embryonic survival up to the limit dose of 1000 mg/kg/day. In embryo-fetal development toxicity studies, TD-1473 was evaluated up to the limit dose and the maximum maternally tolerated dose (60 mg/kg/day) in pregnant rats and rabbits, respectively. No TD-1473-related changes in fetal evaluations were present in either species, consistent with minimal fetal plasma exposure. When plasma exposures at the no adverse effect level in each study were compared to exposures achieved in a Phase 1 multiple ascending dose study in healthy volunteers, TD-1473 exhibited 9.50- to 41.8-fold ratios at the highest tested clinical dose (300 mg QD). In conclusion, the gut-selective approach exemplified by TD-1473 resulted in minimal to no systemic findings in rats, rabbits, and dogs at therapeutic doses.

2775 Interchangeability of Mainland Southeast Asian Sourced Nonhuman Primates Based on Anatomic and Clinical Pathology Parameters

E. Debien[1], A. Wilcox[2], D. Reim[2], and S. Bulera[2]. *[1]Charles River, Sherbrooke, QC, Canada; and [2]Charles River, Reno, NV.*

As non-human primates (NHP) are frequently used in drug safety assessment, particularly cynomolgus monkeys, the importation of this species represents a constant challenge for the biopharmaceutical industry. The recent increase in demand of cynomolgus monkeys in North America and Europe, combined with the economic downturn of 2009-2011 has led to a significant shortage in NHPs. Recent literature compares the genetic profiles of geographically distinct subpopulations of cynomolgus monkeys and there is a general agreement that the species can be subdivided following ancient differentiation and geographical dispersal in two distinct Asian populations: one continental (Indochina; more specifically Cambodia and Vietnam) and one insular (Philippines, Indonesia and Mauritius). To support the interchangeability between cynomolgus monkeys of Chinese and Indochinese origins, and to improve their availability, the historical control data in anatomic pathology and in-house reference intervals in clinical pathology were compared between cynomolgus monkeys of Cambodian and Chinese origins. Anatomic pathology historical control macroscopic, microscopic and organ weight data were collected from 78 cynomolgus monkeys of each sex of Cambodian and Chinese origin, aged 2.7 to 4.1 yrs, comprising the control groups from 45 toxicity studies evaluated at Charles River Laboratories (CRL), Mattawan, MI, between 2016 and 2019, while clinical pathology data (hematology, serum chemistry, and coagulation) were evaluated from 120 naïve cynomolgus monkeys of each sex of Cambodian and Chinese origin, aged 2.4 to 9.4 yrs, housed at CRL, Reno, NV, in 2013. When available, these control data were also compared to concurrent data reported in recent literature, including control data from Vietnamese cynomolgus monkeys. Based on these comparisons, there were no biologically relevant differences in macroscopic or microscopic changes, organ weight data, or clinical pathology parameters between the subpopulations of cynomolgus macaques from mainland Southeast Asia (China, Cambodia or Vietnam). Furthermore, the anatomic pathology historical control data were all comparable to the common reported incidental findings in cynomolgus monkeys of various origins. These data support the interchangeable use of different subpopulations of cynomolgus monkeys from mainland Southeast Asia in our industry.

2776 A Seahorse HEPATOPAC Model for Integrating Metabolic Activity into Assessments of Mitochondrial Toxicity Potential of Pharmaceuticals

L. Liu[1], W. Kang[1], T. G. Griffiths[1], H. Vu[1], A. F. Loughlin[1], Q. Xu[1], M. C. Kuhls[1], M. Yang[2], K. M. Pearson[1], K. Mitra[1], and J. Lebron[1]. *[1]Merck & Co. Inc., West Point, PA; and [2]BioIVT, Westbury, NY.*

Mitochondrial dysfunction is broadly considered a contributing factor for drug-induced toxicity *in vivo*. To avoid mitochondrial liabilities, some pharmaceutical firms routinely screen drug candidates for mitochondrial toxicity *in vitro*. However, evaluations have largely relied upon use of cells and models (i.e. HepG2 cells and isolated mitochondria) that are deficient in drug metabolic conversion and allow only for short-term treatment. We have developed the Seahorse HEPATOPAC® model to assess mitochondrial toxicity *in vitro* under conditions where *in vivo*-like drug metabolism capability is present and extended exposures of drug is possible. This platform integrates rat HEPATOPAC® with Seahorse technology that examines mitochondrial respiration and function, in conjunction with metabolomics approaches to inform biochemical pathway perturbations. 25+ model mitochondrial toxicants and drug candidates have been evaluated using the model. We will summarize the findings and present case studies to demonstrate unique value of Seahorse HEPATOPAC® that results in detection of activity absent in metabolically-deficient cells and correlation of *in vitro* and *in vivo* toxicity observation. We will also discuss utility of the model to inform on mitochondrial liability of drug candidates and impact of metabolic transformation on risk assessment.

2777 Adverse Neuroelectrophysiology Changes of a Hepatitis B Virus Antiviral in 13-Week Rat and Cynomolgus Monkey Studies

A. D. O'Connell[1], K. M. Holsapple[1], J. C. Arezzo[2], T. McDonnell[3], C. H. Tay[4], D. Kato[1], L. M. Gamelin[1], R. Ramirez[1], A. Chester[1], and L. Burns-Naas[1]. *[1]Gilead Sciences Inc., Foster City, CA; [2]Albert Einstein College of Medicine, Bronx, NY; [3]Covance Inc., Madison, WI; and [4]Vir Biotechnology Inc., San Francisco, CA.*

The neurotoxicity potential of GS-8873, a small molecule intended for Hepatitis B Virus (HBV) transcript inhibition was evaluated in rats and monkeys in 13-week GLP toxicity studies with 8 weeks of recovery. Wistar Han rats and Cynomolgus monkeys were dosed daily by oral gavage at 2, 6, 20 and 60 mg/kg/day and 0.5, 1.5, 3 and 6 mg/kg/day, respectively. Area-under-the-curve (AUC) exposure margins were 3- to 70-fold for the rat or 4- to 40-fold in monkeys compared to the predicted efficacious clinical dose. Neuroelectrophysiology parameters were assessed during Weeks 4 and 13 of the dosing phase and at 4 and 8 weeks after the last dose administered. Adverse electrophysiology effects were observed in both species at all doses in a dose-dependent manner when compared to age-matched vehicle controls. Changes in nerve impulse latency with decreased amplitude and nerve conduction velocity (NCV) were evident in both rats and monkeys as early as Week 4. Week 4 mean nerve impulse latency values were increased in the rat caudal nerve (5 to 8%) and monkey cauda equina (5 to 10%) across dose groups. Week 13 nerve impulse latency in rats worsened across dose groups to significantly increased values for the caudal (15 to 41%), digital (12 to 29%) and tibial nerves (7 to 18%) with concomitant NCV reductions in the caudal (-12 to -28%) and digital nerve (-9 to -20%). In monkeys at Week 13 of dosing, significant increases in nerve impulse latency values in the cauda equina (18 to 31%) and sural nerve (16 to 24%) were noted with reductions in peroneal nerve NCV (-11 to -23%). Electrophysiology parameters did not return to age-matched vehicle control values after 8 weeks of recovery although some reversal was evident. Specialized neurohistopathology examinations in the rat at Week 13 and at the end of the recovery phase revealed a primary axonopathy in sensory nerves and the spinal cord. No neurohistopathology effects were observed in the monkey after 13 weeks of dosing or at the end of the recovery phase. In conclusion, the adverse dose and time-dependent functional nerve changes in two species, coupled with the need for a safe, chronically administered HBV therapeutic, resulted in the decision to terminate development of GS-8873.

2778 Safety Assessment of Rolapitant in Juvenile Rats Identified a Critical Exposure Window of Rolapitant Susceptibility in Female Reproductive Systems

H. Wu, K. Gada, P. Pan, P. Vancutsem, and S. A. Roberts. *TESARO Inc./ GlaxoSmithKline plc, Waltham, MA.*

Rolapitant is a potent and selective NK1 receptor antagonist approved for the prevention of nausea and vomiting in the delayed phase associated with highly and moderate emetogenic cancer chemotherapy. Definitive juvenile rat toxicology studies were conducted to support the development of rolapitant in the pediatric population. Rolapitant was administered orally to 3 dose groups (12.5, 25, and 50 mg/kg/day) of juvenile Sprague Dawley rats during postnatal day (PND) 7 to 70, followed by a 42-day recovery period. Findings in female reproductive structure and function were observed, including a delay in balanopreputial separation and acceleration of vaginal patency, lower mean numbers of corpora lutea, reduced early embryonic survival at 25 and 50 mg/kg/day; microscopically, an irreversible decrease in endometrial glands was observed at 50 mg/kg/day corresponding to 2.0~7.5 fold of recommended human exposure. Provided significant irreversible reproductive findings were not noted in the 3-month and 6-month repeat dose studies, wherein PND 49-63 old rats were dosed at similar exposure, it was hypothesized that significant irreversible reproductive effects would be the result of rolapitant exposure only during restricted periods of juvenile reproductive development in rats. To delineate the relationship between the exposure window and rolapitant-related reproductive effects, a segment juvenile rat study was conducted in which dosing period was divided in segments to cover defined periods of rat development (PND 7 to 21, 21 to 42, and 42 to 70) corresponding to the age of definite pediatric populations (age 6-month to 2-Y, 2-Y to 12-Y, 12-Y to 16-18-year old in humans, respectively). The dose 50 mg/kg/day was used in all segment-groups to maximize the potential for observation of adverse findings. Rolapitant at 50 mg/kg/day in juvenile rats resulted in adverse effects, including partial or irreversible lower uterine weights correlated with decreased endometrial glands, significant decreases in the numbers of corpora lutea, implantation sites and live embryos and increases in the pre-implantation loss, the numbers of early resorptions and the post implantation loss from PND 7 to 70 and 7 to 21 groups, but not in PND 21 to 42, or PND 42 to 70 groups. These findings were indicative of a critical window of rolapitant susceptibility on female reproductive organs between PND 7 and 21.

2779 Defining the Edge: A Case Study in Expert Review of *In Silico* Hazard Predictions to Identify Activity Cliffs and Improve Chemical Risk Assessment

B. Hansen, C. Marsh, and J. Cohen. *Gradient, Boston, MA.*

New approach methods for chemical safety assessments are seeing increased regulatory acceptance and use across multiple contexts including medical device and pharmaceutical safety, chemical registration, and product stewardship initiatives. Expert review of predictive methods is a critical step in making informed hazard and risk conclusions. Often, these methods rely on data for structurally similar chemicals either directly *via* read-across or indirectly through nearest-neighbor *in silico* models. While chemicals may be similar in molecular weight, relevant functional groups, and chemical character, they may not behave similarly *in vivo*. In this case study, we investigated a test set of structurally similar compounds selected from established databases of local lymph node assay (LLNA) results. All compounds in the test set share a carbonyl moiety, and trigger the "Schiff base formation" alert for sensitization in Toxtree (v 3.1.0). Lastly, the test set was filtered through a binning clustering model to ensure a reasonable degree of quantitative structural similarity (ChemMine similarity cutoff = 0.4). The resulting set consisted of 12 substituted benzenes of similar molecular weight (106 – 190 g/mol), and predicted physiochemical properties relevant to skin sensitization (water solubility > 100 mg/L; K_{ow} range 0-3). The test set represented a range of experimental results, from non-sensitizing to moderately sensitizing, and a false positive hazard prediction rate based on the Schiff base formation alert alone of 25%. Further review of chemical structures suggest the distance of the carbonyl moiety from the benzene ring to be a possible contributing factor with respect to sensitization potential. Nine of the compounds from chemical test set with experimental data for mutagenicity were also evaluated *via in silico* methods in accordance with ICH M7 guidelines. The expert-rule program Toxtree falsely predicted 8 out of 9 compounds to be potential mutagens. In contrast, (Q)SAR program VEGA (v 1.1.5), and expert rule program Derek Nexus (v 2.2) accurately predicted all 9 compounds to be non-mutagenic. This case study demonstrates the importance of expert review when applying predictive toxicology methods, and highlights a possible activity cliff with regards to Schiff base formation and skin sensitization potential.

2780 Evaluation of Metastatic Pathway Inhibition by Novel Ruthenium-Based Metallodrugs Using the Zebrafish Model

B. F. Karas[1], J. Hotz[2], L. Côrte-Real[3], L. White[1], A. Valente[3], B. Buckley[1], and K. R. Cooper[1]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; [2]NIH, Bethesda, MD; and [3]Universidade de Lisboa, Lisbon, Portugal.*

Cancer progression into metastasis is an incredibly complex, multistep process that is the major cause of cancer-related deaths. Targeting this cancer phenotype would result in decreased mortality. However, therapeutic efficacy is difficult to evaluate *in vitro* due to the complex nature of metastasis. The widely accepted model of testing metastasis is immunosuppressed nude mice, but the field agrees there are limitations and drawbacks to this model. Additionally, small quantities of new drugs make statistical power in mice difficult. Although new potentially therapeutic metallodrugs are being synthesized at high rates, there is currently no robust method for evaluation of toxicity or efficacy in mice or other model organisms. In fact, New Anti-Tumor Metastasis Inhibitor (NAMI-A), a ruthenium (Ru)-based complex, showed antimetastatic properties *in vitro* and in the nude mouse model, but failed clinical trials. As such, there is a need for an alternative method of evaluating therapeutic efficacy, to prioritize the most promising of candidate compounds**.** We investigated two novel Ru-based compounds, LCR134 and PMC79, for metallodrug evaluation in zebrafish. A structure-activity relationship between these compounds and NAMI-A, made antimetastatic activity promising. To evaluate antimetastatic potential, we conducted morphometric anti-angiogenic assays, gene expression analysis and wound repair. LCR134 showed no significant fold changes of six genes involved in metastatic progression. However, the majority of these genes were down-regulated after treatment of with PMC79. In addition, angiogenesis is a critical component of anticancer research. New blood vessels formed at tumor sites are required for tumor survival and growth. Blood vessel growth inhibition was measured after treatment with compounds using live-animal imaging. PMC79 exposure demonstrated larger blood vessel lengths at lower doses and significantly less branching at higher doses. Additionally, preliminary data for wound repair indicated that cisplatin and PMC79 exposure resulted in significantly less tissue regeneration and cisplatin caused significant upregulation of proliferating cellular nuclear assay. Together, these zebrafish-based assays could offer an alternative model for assessing anti-metastatic pathways. *Supported by: NJAES-Rutgers NJ01201, NIH-MIEHS P30 ES005022, and Training Grant T32-ES 007148, FCT (project UID/QUI/00100/2013), FCT2013 Initiative project IF/01302/2013 FCT, POPH and FSE - European Social Fund. Ph.D. Grant (SFRH/BD/100515/2014).*

2781 Preclinical Toxicity Evaluation of LUM-001 (Cyclocreatine) in Sprague Dawley Rats

V. P. Kale[1], J. J. Wallery[1], K. Patton[1], A. Zmarowski[1], B. Sparrow[1], J. Gorospe[1], M. T. Do[2], J. C. McKew[2], and P. S. Terse[3]. *[1]Battelle Memorial Institute, West Jefferson, OH; [2]Lumos Pharma, Austin, TX; and [3]NIH/NCATS, Bethesda, MD.*

LUM-001 (cyclocreatine) is being evaluated for its preclinical toxicity in Sprague Dawley rats. Deionized water as a vehicle control article or LUM-001 was administered by oral gavage twice daily (approximately 12 ± 1 hours apart) in rats up to 26 weeks (60 and 200 mg/kg/day group males and females, and 600 mg/kg/day females) followed by a 28-day recovery period. Due to increased incidences of seizures, the 600 mg/kg/day dose group males were dosed for 16-weeks followed by a 14-week recovery period. Seizure incidences were greater at 600 mg/kg, while occasional incidences were also observed at lower doses. In males, there were no test article-related changes in the food consumption or body weights. In females, increased body weight in the 600 mg/kg/day dose group was consistent from Day 22 through Day 162 (5.8-14.3%). During FOB examination, convulsions in open field, a general attenuation of activity levels in the home cage, and lower rectal temperature were observed in males and females at 600 mg/kg/day, males at 200 mg/kg/day, and females at 60 mg/kg/day at Week 13. The changes in clinical pathology that were considered potentially related to the test article administration included decreased serum and urine creatinine, increased serum ALT and AST in both the sexes; increased serum ALP in males only; and decreased urine potassium in females only. Upon histopathological evaluation, higher incidence of vacuoles in brain at 600 mg/kg/day in both sexes were observed. After 14 weeks of recovery, vacuoles in 600 mg/kg/day males were completely recovered but only a partial recovery was observed after a 28-day recovery period. Thyroid follicular atrophy and follicular cell hypertrophy was observed at a higher incidence in 200 and 600 mg/kg/day dose group males, and 600 mg/kg/day dose group females. Moreover, increased incidences of minimal colloid mineralization in thyroid glands were observed in ≥60 mg/kg/day dose group males and females, while some incidences were also observed in recovery control animals. The incidences and/or severity of seminiferous tubular degeneration and /or interstitial edema in testes were increased in a dose dependent manner at ≥200 mg/kg/day doses with a single incidence at 60 mg/kg/day dose. Mean half-life of LUM-001 was between 3.5 to 6.5 hours. *Disclosure: The research was funded under NCI Contract No. HHSN261200800001E.*

2782 Preclinical Safety Evaluation of LUM-001 (Cyclocreatine) in Beagle Dogs

J. J. Wallery[1], V. P. Kale[1], J. Novak[1], B. R. Sparrow[1], J. W. Gorospe[1], M. Do[2], J. C. McKew[2], and P. S. Terse[3]. *[1]Battelle Memorial Institute, West Jefferson, OH; [2]Lumos Pharma, Austin, TX; and [3]NIH/NCATS, Bethesda, MD.*

LUM-001 (cyclocreatine) is being evaluated for preclinical toxicity in beagle dogs. Deionized water (control) or LUM-001 was administered by oral gavage twice daily (approximately 12 hours apart) to dogs at 40, 80, and 150 mg/kg/day doses followed by a recovery period. Due to toxicity, different groups were terminated earlier than the originally planned 39 weeks of dosing. Animals in the 40, 80 and 150 mg/kg/day dose groups completed 160, 106, and 55 days of dosing, respectively, followed by a 30, 55 and 106 days of nontreatment recovery period, respectively. Of the 12 animals (6 males and 6 females)/group, 3 (25%), 7 (58%), and 7 (58%) were euthanized and/or found dead in the 40, 80, and 150 mg/kg/day dose groups, respectively. In general, LUM-001 was absorbed rapidly with group mean T_{max} values typically within 1 hour. On Day 1, the terminal half-life ranged between 2.17 to 2.79 hours; however, on the final day of dosing, it ranged between 5.80 to 8.77 hours for males and between 10.3 to 13.1 hours for females. Moribundity began with inappetence, frequent emesis and stool abnormalities including a lack of stool, diarrhea, or soft and mucoid stool followed by weight loss and lethargy. Death in the 40, 80 and 150 mg/kg/day dose groups was often preceded by acute respiratory distress. Changes in hematological parameters that were considered to be potentially related to test article included decreased lymphocytes, increased monocytes and increased neutrophils which were likely associated with pulmonary inflammation at all dose levels. The changes in clinical chemistry that were considered test article-related included increased ALP, ALT, AST and creatine kinase, as well as decreased total protein and creatinine. Histopathological evaluation revealed adverse findings in the lungs in all dose groups, of congestion, edema, cellular infiltration, fibrin, and/or hemorrhage. This was consistent with gross findings in the lungs as well as acute respiratory distress, which was determined to be the cause of the death in the 40 and 80 mg/kg groups. The specific cause of death in the 150 mg/kg/day group was not known; there was a lower incidence of lung lesions in this group that could be due to the shorter dosing duration and/or longer recovery period. Additionally, animals in all test article dose groups were found to have perinuclear, cytoplasmic vacuolization in the heart, kidneys, skeletal muscle of the biceps femoris and/or tongue, as well as the smooth muscle of the gastrointestinal tract, aorta, and/or urinary bladder. Taken together, a no-observed-adverse-effect level (NOAEL) could not be determined. *Disclosure: The research was funded under NCI Contract No. HHSN261200800001E.*

2783 Safety Assessment of Metarrestin in Dogs: A Clinical Candidate Targeting a Subnuclear Structure Unique to Metastatic Cancer Cells

M. Bourdi[1], W. Johnson[2], M. Muzzio[2], U. Rudloff[3], J. Marugan[1], and P. S. Terse[1]. *[1]NIH/NCATS, Rockville, MD; [2]IIT Research Institute, Chicago, IL; and [3]National Cancer Institute, Bethesda, MD.*

Pancreatic cancer is a leading cause of cancer-related deaths. 90% of patients with stage IV disease die within one year of diagnosis due to complications of metastasis. The perinucleolar compartment (PNC) is a subcellular structure whose formation closely associates with metastasis. To support the introduction of Metarrestin, a PNC inhibitor, into clinical trials its toxicity, toxicokinetics and safety pharmacology were evaluated in beagle dogs following every other day oral (capsule) administration for 28 days. Based on the results of an earlier pilot toxicity study, the doses selected were: 0.25, 0.75 and 1.50 mg/kg. The test article dosing formulations were prepared at least once weekly (20 mg/mL) in a vehicle of 80% (v/v) Labrasol® ALF / 20% (v/v) caprylic acid. After oral administration, overall median T_{max} across all doses was 3 hours with no sex differences and no consistent relationship to dose. On Day 27, mean $t_{1/2}$ over 168 hours was estimated to be 55.5 hours. Mean $t_{1/2}$ was similar between females and males and did not vary with doses. There was no sex difference in systemic exposure at any dose level or on days 1 and 27. Metarrestin accumulated from Day 1 to Day 27 at all dose levels and in both sexes by an overall factor of about 2.34. Systemic exposure to metarrestin (as C_{max} and AUC_{last}) increased as dose increased on both Days 1 and 27. No mortality occurred during the dosing period; however, treatment-related clinical signs of toxicity consisting primarily of hypoactivity, shaking/shivering, thinness, irritability, salivation, abnormal gait, tremors, ataxia and intermittent seizures were seen

in both sexes at the 0.75 and 1.50 mg/kg dose levels. Treatment-related effects on body weight and food consumption were seen at the mid and high dose levels. Safety pharmacology study showed no treatment-related effects on blood pressure, heart rate, corrected QT, PR, RR, or QRS intervals, or respiratory function parameters. Based primarily on clinical signs of toxicity, the No Observed Adverse Effect Level (NOAEL) in dogs was considered to be 0.25 mg/kg metarrestin after every other day dosing for 28 days with a mean of male and female C_{max} = 82.5 ng/mL and AUC_{last} = 2521 hr*ng/mL, on Day 27. *Acknowledgments: This work was supported by Leidos Contract No. HHSN261200800001E under BrIDGs/NCATS Program.*

2784 Safety Assessment of Metarrestin in Rats: A Clinical Candidate Targeting a Subnuclear Structure Unique to Metastatic Cancer Cells

M. Bourdi[1], T. L. Horn[2], M. Muzzio[2], U. Rudloff[3], J. Marugan[1], and P. S. Terse[1]. *[1]NIH/NCATS, Rockville, MD; [2]IIT Research Institute, Chicago, IL; and [3]National Cancer Institute, Bethesda, MD.*

Pancreatic cancer is a leading cause of cancer-related deaths. 90% of patients with stage IV disease die within one year of diagnosis due to complications of metastasis. The perinucleolar compartment (PNC) is a subcellular structure whose formation closely associates with metastatic potential of cancer cells. To support the introduction of Metarrestin, a PNC inhibitor, into clinical trials we evaluated its toxicity and toxicokinetics in rats when administered every other day by oral gavage for 27 days followed by a 28-day recovery period. Based on earlier pilot toxicity finding, this study consisted of four dose groups: vehicle; 7; 20 and 40 mg/kg. The test article dosing formulations were prepared once weekly at concentrations of 1.75, 5, or 10 mg/mL in a vehicle of 80% (v/v) Labrasol® ALF and 20% (v/v) caprylic acid. Metarrestin levels were detected in plasma as early as 30 minutes after dosing; however, absorption was slow as T_{max} ranged from 4 to 8 hours regardless of dose and sex. Systemic exposure was higher in females than in males at all doses but the difference was less than two fold. Metarrestin appeared to accumulate moderately from study days 1 to 27 in both sexes at all dose levels, with accumulation in females being slightly greater than males. Over all dose levels, the ratios of C_{max} and $AUC_{0\text{-}48}$ were 1.23 and 1.44, respectively, for an overall ratio of 1.33. No treatment-related deaths were seen. No treatment-related adverse signs were noted during the daily cage-side clinical observations or the weekly detailed physical examinations. No treatment-related or toxicologically significant findings were noted for body weights, body weight gains, food consumption, ophthalmic examinations, functional observational battery (FOB), clinical pathology, organ weights, and gross and microscopic pathology. Thus, due to the lack of treatment related toxicologically significant findings, the No Observed Adverse Effect Level (NOAEL) for this study was 40 mg/kg dose administered every other day for 27 days with a mean of male and female C_{max} = 2,141 ng/ml and AUC_{last} = 78,594 hr*ng/mL, on Day 27. *Acknowledgments: This work was supported by Leidos Contract No. HHSN261200800001E under BrIDGs/NCATS Program.*

2785 Comparison of Historical Control Data in CD-1 Mice When Single- versus Group-Housed and Considerations for Successful Group-Housing of Male Mice

A. Adamou, C. Copeman, and C. Brochu. *Charles River Laboratories, Senneville, QC, Canada.* Sponsor: M. Vezina

Male and female mice on toxicology studies have historically been single-housed in stainless steel wire mesh-bottom cages. Subsequently female mice were group-housed in stainless steel solid bottom cages with bedding or in polycarbonate bins with bedding whilst male mice were single-housed due to behavior challenges. Based on continued efforts, male mice have been successfully group-housed for the duration of studies out to two-years in similar housing environments in recent years. A number of factors led to the successful group-housing of male mice. One key factor was the age of the mice (pre-puberty) at which male mice were placed together, housing up to at most 3 male mice per cage unit. In addition, providing nesting material and subsequent transfer of a portion of the bedding to the new cage during cage-exchanges, the order of manipulation (males before females or changing gloves if handling females before males), and minimizing disruptions during the day have all been aspects contributing to the successful outcome. Comparative data from single-housed *vs* group-housed mice were reviewed to assess the effect housing conditions have on body weight, food consumption, survival or palpable masses. Mean body weight for group housed mice appears higher when compared to single-housed mice whereas the opposite holds true for food consumption where group housed mice appear to consume less than single housed mice. Incidences of survival and palpable masses were comparable between the single- and group-housed mice. In conclusion, although challenging, male mice have been successfully group-housed in studies conducted in our facility. An apparent effect on both body-weight (higher) and food consumption (lower) have been noted and should be considered when doing any comparisons of historical data.

2786 Bioluminescent Assays for Investigating Insulin Action and Steatosis

M. P. Valley, D. Leippe, N. Karassina, and J. Vidugiriene. *Promega Corporation, Madison, WI.* Sponsor: A. Niles

Metabolic syndrome is a cluster of conditions - including high blood pressure, central obesity, elevated blood sugar, and high levels of lipids. Two factors connecting these conditions are the action of insulin and the accumulation of lipids (i.e. steatosis). To study these processes, we have developed a set of bioluminescent detection assays for a variety of metabolites (e.g. glucose, lactose, glutamine, glutamate, glycerol, triglyceride, cholesterol, and cholesterol esters). These assays use the same core technology that couples specific metabolite dehydrogenases to the production of NAD(P)H and the generation of light. We have used these assays to follow the differentiation and functional characterization of 3T3L1-MBX adipocytes. To follow differentiation, we used a triglyceride detection assay that does not require organic extraction yet provides quantitative detection of intracellular triglyceride accumulation, from 10 µM in undifferentiated fibroblasts to 590 µM in mature adipocytes. The mature adipocytes were further characterized by measuring the insulin effect on two major insulin regulated pathways, glucose uptake and lipolysis. Insulin dose response curves showed a 10-fold increase in glucose uptake with an IC50 of 0.1 nM, and this was inhibited 2-fold by 50 µM LY294002, a PI3K inhibitor. These mature adipocytes also show a 4-fold increase in extracellular glycerol release upon stimulation with 25 nM isoproterenol, a lipolysis inducer, and this was suppressed 2-fold by 150 nM insulin. We have also used these metabolite detection assays to study liver models. By measuring extracellular glucose, we measure a 4-fold inhibition of gluconeogenesis in liver microtissues by 10 nM insulin. Moreover, using HepG2 cells as a model for nonalcoholic fatty liver disease (NAFLD), we measure a 5-fold increase in intracellular triglyceride upon overnight incubation with 0.3 mM BSA-bound fatty acids. For measuring insulin and glucagon, we have developed a simple "add-and-read" bioluminescent immunoassay. This technology is a structural complementation system comprised of an 18 kD protein and an 11 amino acid peptide that when combined form an active luciferase. By attaching these subunits to antibodies, we have developed in-solution, no-wash immunoassays for measuring insulin and glucagon. The assays are sensitive, with detection limits of 5 -10 pM antigen. Using the insulin immunoassays, we measured a 3-fold increase in glucose-stimulated insulin secretion from INS-1 beta cells.

2787 Taking Toxicology to the Next Dimension: Evaluating the Toxicological Screening Utility of 3D Spheroid Primary Human Hepatocyte Cultures

K. S. Lavrich, S. C. Ramaiahgari, M. J. DeVito, R. S. Paules, and S. S. Ferguson. *NIEHS/NTP, Research Triangle Park, NC.*

Three-dimensional (3D) cell culture models are transforming *in vitro* toxicology through their enhanced translational relevance in exhibiting tissue functionality. Primary human hepatocytes (PHHs) are considered the gold standard for assessing hepatic responses to xenobiotics *in vitro*. However, their toxicological screening utility in conventional 2D culture models is limited due to their short culture longevity (days), the limited number of cells from individual donor livers, the high degree of variability between donor preparations, and high costs. Our goal was to assess the feasibility and human relevance of PHHs cultured as 3D spheroids in modeling hepatotoxicity and compare to 3D spheroids cultures of HepaRG, a liver progenitor cell line. Single-donor spheroids (2000 cell spheroids, 384-well plates, 1 spheroid/well) from 3 individual donor PHH preparations were generated in ultra-low attachment plates and their liver functionality was assessed over time. Spheroids from all donor preparations were viable through at least 28 days and maintained physiologically-relevant activities of major drug metabolizing liver enzymes, including CYP3A4, that were equal to or higher than 3D HepaRG at 14 days. 3D PHHs were exposed in 10-point dose response to a set of reference chemicals for 96 hours and assessed for cytotoxicity (ATP and LDH leakage). Troglitazone, a drug withdrawn from the market due to liver injury, more potently caused cytotoxicity in 3D PHHs compared to its safer analogue, rosiglitazone. Aflatoxin B1, a known hepatotoxicant attributed to metabolic activation, caused concentration-related cell death in 3D PHHs at significantly lower concentrations than 2D PHHs and 3D HepaRG, consistent with their enhanced degree of metabolic competence. 3D PHHs were more sensitive to cell death by the withdrawn drug cerivastatin than the safer alternative atorvastatin, and overall more sensitive to both compounds than 3D HepaRG.

The increased sensitivity of 3D PHH over 3D HepaRG may indicate increased hepatocyte functionality and translational utility of primary cells. Future work will use high-throughput transcriptomics to mechanistically evaluate the relevance of biological responses to a diverse set of chemicals across donor preparations. This work demonstrates the ability of 3D PHHs to predict liver injury potential and sets the stage for modeling genetic diversity *in vitro* for toxicological screening.

2788 A New Medium-Throughput Screening Assay for Identifying Chemical-Dependent Changes in ABC Efflux Transporter Activity at the Blood-Brain Barrier

C. T. Juberg, A. W. Trexler, V. R. O'Quinn, G. A. Knudsen, L. S. Birnbaum, and R. E. Cannon. *NIEHS/NTP, Research Triangle Park, NC.*

The blood-brain barrier (BBB) regulates the entry of blood-borne substances to the central nervous system (CNS). ATP-Binding Cassette (ABC) efflux transporters localized to the luminal membrane of capillary endothelial cells are the primary chemical mediators of the BBB and limit transcellular movement of endobiotics and xenobiotics into the brain. Present methods for analyzing transporter activity are hindered by resource and time requirements, limiting their utility for medium- to high-throughput screening. Given the BBB's role in CNS protection and its role as an obstacle to the delivery of CNS-acting drugs, a new method for screening BBB transporter activity is needed. Herein, we describe the development and feasibility of using the ImageXpress® Micro Confocal System (IXM) from Molecular Devices to screen environmental contaminants for their ability to modulate transporter activity in rat brain capillaries. This method uses confocal microscopy to quantify capillary luminal fluorescence of transporter-specific fluorescent substrates at steady state, measuring transporter activity. Freshly isolated capillaries were loaded in a 96-well plate and pre-treated with a series of compounds followed by the application of transporter-specific fluorescent substrates. Capillaries were scanned on the IXM to capture dozens of capillaries per treatment group. Next, capillaries were analyzed using MetaXpress, an adaptable computer program. The analysis program was written to identify capillaries, quantify luminal fluorescence, and exclude non-capillary fluorescence. Presently, we have demonstrated the ability to distinguish controlled and inhibited capillaries and are beginning to identify positive control treatment groups. As a proof of concept, we confirmed that 2,4,6-Tribromophenol significantly reduces P-glycoprotein activity after five hours exposure at 100nM. Once established, this automated screening assay will aid in the rapid identification of toxicants, drug candidates, and other xenobiotic compounds that significantly alter transporter activity at the blood-brain barrier with further implications for therapeutic treatments at other barrier tissues. *This research was supported in part by the Intramural Research Program of NIH/NCI [Project ZIA BC 011476].*

2789 A Microfluidic Thyroid-Liver Platform to Investigate Thyroid Toxicity Mechanisms in Humans and Rats

D. Karwelat[1], J. Kühnlenz[2], M. Raschke[1], S. Bauer[2], H. Tinwell[3], R. Bars[3], and T. Steger-Hartmann[1]. *[1]Bayer AG, Berlin, Germany; [2]TissUse GmbH, Berlin, Germany; and [3]Bayer SAS, Sophia Antipolis, France.*

The assessment of the human relevance of toxicities observed in animal assays still represents a major challenge for various areas of toxicology. Determining the species-specificity of thyroid effects is key for the regulatory acceptance of the risk assessment. Rodents, which are widely used for regulatory toxicity testing, are particularly sensitive to perturbations of thyroid homeostasis. A recurring problem is thyroid toxicity and determining whether this toxicity is caused by a direct effect or if it is mediated via liver enzyme induction. Emerging microfluidic microphysiological systems (MPS) present a promising approach to reproduce the physiological and toxicological interactions of target organs which up to now can only be investigated in animal studies or during clinical trials. So far MPS technologies have only rarely been adopted by the pharmaceutical or crop science industries due to lack of qualified assays to predict the safety of novel drug candidates and agrochemicals. Here, we present the interconnection of three-dimensional (3D) organ models representing both target organs liver and thyroid of both human and rat origin in a commercially available multi-organ-chip platform. Their systemic functional 14-day homeostasis could reproducibly be demonstrated applying a common culture medium for the first time. Steady glucose consumption, low LDH release and immunohistology of 3D thyroid follicles as well as liver spheroids revealed viability. The organ-specific functions, albumin secretion and urea synthesis for the liver as well as T4 release for the thyroid follicles, were maintained. Finally, a chemically-induced increase in T4 catabolism, determined by accelerated thyroid hormone glucuronidation, was observed when liver spheroids were incubated with reference inducers like beta-naphthoflavone. Thus, we show for the first time a model of the hepatic-thyroid axis within a single *in vitro* assay for two different species. These two chip-based models represent a major step forward to better assess the potential species similarities/differences of toxicity findings observed in rodents with a significant contribution to the 3R principles.

2790 High-Throughput Co-culture as an Emerging Technology for Increased Predictability in Drug and Chemical Screening

T. Jimenez-Torres. *Onexio Biosystems LLC, Madison, WI.*

We have worked to established a high-throughput screening (HTS) compatible *in vitro* nephrotoxicity assay complete with conferred hepatocyte bioactivation. Our goal was to expand the traditional nephrotoxicity assay by adding metabolic competence to increase the *in vivo* predictability of these assays while at the same time constraining compatibility to existing HTS infrastructure. Renal cell lines (HEK293's and RPTEC's) were co-cultured with human hepatocytes (HepG2, HepaRG and PHH). Co-culture was performed in 96, 384 and 1536-well microDUO plates (48, 192 and 786 co-culture pairs respectively) to demonstrate scalability. In addition, 96-well microDUO was directly compared to Transwell® plate co-culture to demonstrate the competitive advantage of the microDUO co-culture technology. The microDUO plate enables co-culture in technically simple and HTS compatible manner that seamlessly integrates with existing robotic infrastructure. To illustrate HTS compatibility we utilized a range of HTS equipment to complete the assays. The microDUO wells were coated with 15ug/ml fibronectin and 0.5mg/ml Collagen Type 1 (HepaRG and PHH wells only) using a Thermo Multidrop™ Combi dispenser. After coating, the plates were washed using a BlueCatBio plate washer. Cells were seeded at 3,000 and 12,000 cell per well for kidney cells and hepatocytes respectively using the Multidrop™ Combi dispenser. Chemicals were dosed using a Labcyte Echo droplet dispenser and cell viability was quantified using CellTiter-Fluor and CellTiter-Glo on a BMG CLARIOstar and PHERAstar plate reader. Renal and hepatocytes cell lines were exposed to 10 different concentrations ranging from 0.1uM to 100uM (6 different concentration in 96-well microDUO) of known nephrotoxic compounds including Sunitinib Malate, Aflatoxin B1, Cyclophosphamide, Aristolochic Acid I, Arsenic Trioxide, Cadmium chloride, and Potassium Dichromate. We have observed that compounds like Sunitinib Malate, Aristolochic Acid I, Cyclophosphamide and Cadmium Chloride, showed cytotoxicity in monoculture but detoxification in co-culture with hepatocytes. On the other hand, Aflatoxin B1 had little to none cytotoxic effect in monoculture but cytotoxicity was observed in co-culture with hepatocytes. Future directions include generating assays to study pulmonary toxicity, digestive track toxicity, neurotoxicity and cardiotoxicity. A fully metabolically competent and truly HTS compatible toxicity assay would be invaluable in identifying potentially toxic chemicals in preclinical development and toxicity testing.

2791 Worm-on-a-Chip Technology: An Emerging 3R Model in Toxicity Testing

C. Mathis[1], L. Mouchiroud[2], M. Cornaglia[2], D. Smart[1], M. Choukrallah[1], K. Luettich[1], J. Hoeng[1], and M. C. Peitsch[1]. *[1]Philip Morris International, Neuchatel, Switzerland; and [2]Nagi Bioscience, Lausanne, Switzerland.*

The nematode *Caenorhabditis elegans* is an excellent model organism when considering alternative approaches in line with the 3R principles. These tiny worms (1-mm long) have been widely used for studying development, stress, and aging and, more recently, as a new model in environmental toxicology. Genes and signaling pathways are well conserved between *C. elegans* and humans, and the development map of *C. elegans* is well described, with >40 years of genetic studies. In this study, we took advantage of a microfluidic system combining high-resolution imaging and image analysis algorithms developed by Nagi Bioscience to evaluate the suitability of this *in vivo* model for assessing the potential toxicity of a battery of known compounds in a high-throughput manner. Hermaphrodite worms were first confined in dedicated microfluidic chambers (1-3 worms per chamber) at larval stage L1. Ten to twenty worms were exposed continuously per condition and experimental repetition to ten chemicals (such as lithium chloride, bisphenol A, and acrylamide) at a wide range of concentrations. The worms were monitored every hour for a 130-h longitudinal observation at constant temperature. Automated image processing and multi-phenotypic analysis were then performed to determine the specific toxicity profile of each testing chemical. We first observed that inter-individual variability was improved by synchronizing worms at the same developmental stage by starvation prior to exposure to the testing chemicals. The no-observed -adverse -effect -level was determined for each testing chemical. Various phenotypic readouts were extracted during the assay (such as worm size, worm lethality, and worm reproduction), allowing ranking of the compounds on the basis of severity of their adverse

effects relative to the respective control. This study highlights the multiple advantages of this new high-throughput screening approach, including: (i) good reproducibility and accurate results by using standardized protocols, (ii) precise and dynamic dosing of compounds with low liquid consumption, and (iii) phenotypic readouts in real-time and at single-animal resolution. Combining a microfluidic system with a high-content screening method makes *C. elegans* a promising model for next-generation toxicity testing.

2792 Application of Cryopreserved Human Intestinal Mucosa (CHIM) in the Evaluation of Regional Differences in NSAID Enterotoxicity

A. P. Li. *In Vitro ADMET Laboratories, Columbia, MD.*

NSAID-associated enterotoxicity is a well-recognized adverse effect of this class of mediation that are widely used for the alleviation of pain and inflammation. NSAID is known to cause serious mucosal damage, resulting in perforation and bleeding throughout the gastrointestinal tract which may have fatal outcomes. Early identification and elimination of drug candidates with serious enterotoxicity therefore will aid the development of drugs acceptable enteric safety. We report here the development of an *in vitro* assay for the evaluation of NSAID-related human enterotoxicity using a novel *in vitro* experimental model of the human small intestine, namely, the cryopreserved human intestinal mucosa (CHIM). We have recently reported preparation of CHIM from human small intestines from organs procured but not used for transplantation. CHIM were found to retained high viability and drug metabolizing enzyme activities upon recovery from cryopreservation. We report here results of our investigation on the application of CHIM to evaluate potential regional differences in NSAID-induced enterotoxicity. In this study, CHIM were isolated from 10 12-inch segment of the small intestines. Robust drug metabolizing enzyme activities were observed, especially for CYP2C9 (diclofenac 4-hydroxylation), CYP3A4 (midazolam 1-hydroxylation and testosterone 6b-hydroxylation), and UGT (7-OH-coumarin glucuronidation). Using the 10 12-inch regions from the small intestines of three donors, the enterotoxicity of two NSAIDs: acetaminophen and naproxen, were evaluated. Dose-dependent decrease in viability quantified as cellular ATP contents were observed for all regions. Naproxen was found to have a higher *in vitro* enterotoxicity in CHIM for in most CHIM segments from all three donors, a result consistent with reported clinical findings. The resulting EC50 values of acetaminophen and naproxen were within the drug concentrations in the intestinal lumen upon oral ingestion. Our results suggest that CHIM may represent a useful model for the rank ordering of drug candidates for drug development based on *in vitro* enterotoxicity. CHIM can also be applied towards the understanding of the mechanism of enterotoxicity, especially in the correlation between enteric drug metabolism and enterotoxic potential. The individual and regional differences in NSAID enterotoxicity suggest genetic and environmental factors may play a role in the manifestation of enterotoxicity.

2793 *In Vitro* Cell-Based Cytotoxicity and T Cell Activation Assays to Assess Safety and Efficacy of Engineered T Cell Therapies

S. Bulera[1], S. Vermond[2], M. Hazenoot[2], J. Overman[2], J. Aarbiou[2], S. Holt[2], A. Zuurmond[2], and J. DeGroot[2]. *[1]Charles River, Reno, NV; and [2]Charles River, Leiden, Netherlands.*

Chimeric antigen receptor (CAR) and T cell receptor (TCR) engineered T cells are part of a big wave of immunotherapies showing great promise in cancer clinical trials. With the first T cell based therapies targeting hematological malignances now approved, their next challenge is solid tumors. Solid tumors create an additional challenge due to the lack of tumor specific target antigens, posing significant safety risks, i.e. on-target on-tumor, on-target off-tumor and off-target toxicities. Toxic effects previously reported vary from mild-severe cytokine release syndrome (CRS) to neurotoxicity and death. We have developed *in vitro* assays utilizing primary human cells from healthy tissue and/or differentiated iPCS-derived cells to assess on-target off-tumor and/or off-target cytotoxicity for engineered T cell therapies. The presence of CAR-T cell mediated cytotoxicity was measured through co-culture with healthy human primary cells to assess unwanted CAR-T reactivity as well as a high target antigen expressing control cancer cell line to confirm CAR-T functionality. The human primary cell type was selected based on its potential safety risk by establishing low level protein expression of the target antigen. Readouts included IFNγ production determined by MesoScale Discovery platform as a measure of T cell activation and Hoechst/PI staining of target cells by flow cytometry. Our study generated high quality data of the CAR-T cell, confirming functionality by showing consistent T cell activation and killing against a positive control cell line. Moreover, we were able establish a clear absence of activity against the primary human cells thus providing insight into the safety of the CAR-T therapy. The developed safety assays provide a robust and rapid platform to assess on-target off-tumor and off-target effects within immuno-oncology therapies, either TCR or CAR-T cells, in both early stage development or late stage testing of the therapeutic product. Through inclusion of a wide range of human primary cells, both high risk tissues and major organs at risk of off-target toxicity, a clear safety profile can be generate *in vitro* for these novel T cell therapies. Safety risks associated with cell based IO-therapies is the biggest challenge for the success of these therapies, performing a thorough safety screen on healthy primary human tissues is therefore crucial.

2794 Vitrofluid: A Versatile Multi Organs-on-a-Chip Platform

D. Bovard, A. Sandoz, K. Trivedi, A. Iskandar, K. Luettich, S. Frentzel, J. Hoeng, and M. Peitsch. *Philip Morris International, Neuchatel, Switzerland.*

In vitro models have limitations in mimicking the processes occurring in the human body. Their inability to mimic complex physiological processes contributes significantly to failure. A combination of 3D *in vitro* models with an engineered microenvironment has been recently developed. These systems, known as "organ-on-a-chip," have the potential to make drug development processes more effective. Recently, Philip Morris International has created a lung-liver-on-a-chip platform to better assess the toxicity of aerosols. The system is composed of a chip plate with 3 circuits, each composed of 2 connected wells. Each circuit is connected to a pump, ensuring medium circulation. In this study, we tested the performance of air-liquid interface bronchial epithelial cultures and HepaRG liver spheroids that were maintained together in the platform for 28 days. The bronchial cultures showed stable transepithelial electrical resistance (TEER) and cilia beating frequency throughout the study. The liver spheroids secreted albumin and maintained their metabolic capacity over the study period. We further tested the role of the liver spheroids in modulating the toxic effects of a known pulmonary toxicant, aflatoxin B1. The results showed that bronchial cultures exposed to aflatoxin B1 in the absence of the liver spheroids exhibited a severe decrease in TEER and adenosine triphosphate content. Conversely, in the presence of the liver spheroids, bronchial cultures were unaffected by the compound. Furthermore, using this platform, we tested whether air-liquid bronchial cultures could be developed faster and more optimally. For this experiment, bronchial cultures were transferred immediately after air-lift and exposed to continuous medium flow for 4 weeks. The cultures were evaluated every week for morphology and functionality. We found that constant medium recirculation improved the homogeneity, pseudostratification, ciliation, and cell polarization of the cultures relative to the cultures matured in standard plates. Collectively, these results demonstrated the versatility of this chip platform and its potential for toxicological evaluation.

2795 Application of Pathway-Specific Permeabilized Human Hepatocytes (MetMax Human Hepatocytes) in the Identification of Activation and Detoxification Pathways

H. Wei, and A. P. Li. *In Vitro ADMET Laboratories, Columbia, MD.*

We have previously proposed that drugs with idiosyncratic toxicity may be identified as drugs where individuals may be sensitized via genetic and environmental factors. Drugs which are metabolically activated and detoxified are hypothesized to have idiosyncratic drug toxicity, as a patient may be sensitized to these drugs if genetic and environmental factors would enhance activation and compromised detoxification. We have recently developed a novel experimental system, cofactor supplemented permeabilized cryopreserved human hepatocytes (MetMax™ Cryopreserved Human Hepatocytes, MMHH). MMHH as an experimental system has the complete phase I oxidation and phase II conjugation drug metabolizing enzyme pathways as that for intact hepatocytes, and the convenience of liver microsomes including storage at -80 deg. and use directly upon thawing without a need for centrifugation and microscopic examination. Further, MMHH can be used at toxic drug concentrations that would diminish drug metabolizing enzyme activities in intact hepatocytes, and that one can select drug metabolizing enzyme pathways via the specification of cofactors. We report here the use of pathway-specific MMHH via supplementation with individual cofactors to identify key detoxification pathways. In this study, cytotoxicity of two protoxicants that require metabolic activation, acetaminophen and cyclophosphamide in HEK293 cells using pathway-specific MMHH as an exogenous metabolic activating system. The pathway-specific MMHH systems were: 1. Oxidation only (MMHH-OX); 2. Oxidation and glucuronidation (MMHH-UGT); 3. Oxidation and sulfation (MMHH-SULT); 4. Oxidation and acetylation (MMHH-NAT), 5. Oxidation and methylation (MMHH-MT); and 6. Oxidation and glutathione conjugation (MMHH-GST). The results showed that the cytotoxicity of both acetaminophen and cyclophosphamide was enhanced in the presence of MMHH-OX,

confirmation metabolic activation of these two protoxicants to cytotoxic metabolites. Cytotoxicity was diminished for acetaminophen in MMHH-UGT, MMHH-SULT, and MMHH-GST, suggesting that all three pathways were important its detoxification. For cyclophosphamide, diminished cytotoxicity was only observed for MMHH-GST, suggesting that GSH-conjugation is the key detoxifying pathway. Our results suggest that pathway-specific MMHH can be used as a tool to aid the identification of key drug metabolic enzyme pathways for metabolic activation and detoxification, leading to the identification of at risk populations and the identification of drugs with idiosyncratic drug toxicity.

2796 *In Vitro* Skin Sensitization Assays: Practical Experiences Performing the DPRA, KeratinoSens, and h-CLAT

D. Kidd, G. Pastore, E. Montague, C. Rothwell, D. Bramham, D. Dreher, L. Hartmann, and J. Clements. *Covance Laboratories Limited, Harrogate, United Kingdom.* Sponsor: D. Macmillan

Validation of New Alternative Methods (NAMs) is one of the crucial challenges facing the drive towards animal-free testing today. Much time and effort has been put into generating documents to guide and support validation processes by organisations such as the Organisation for Economic Co-operation and Development (OECD), the European Union Reference Laboratory for Alternatives to Animal Testing (EURL-ECVAM), the Environmental Protection Agency (EPA) and the Health and Environmental Sciences Institute (HESI) amongst others. To date, formal validation of new assays has required the developer to assess intra-laboratory variability and subsequently inter-laboratory variability to ensure the Final Protocol / Standard Operating Procedure is transferable and the data generated are reproducible. However, the advent of New Approach Methods (NAMs) has introduced complex and specialist instrumentation into assays in the drive to move away from *in vivo* testing and better predict human responses. The consequence of this has been the need for expert knowledge in those techniques in the naïve laboratory adopting the assay and for a more effective transfer of knowledge from the developers to facilitate successful implementation. As a Contract Research Organisation (CRO), we are alert to the challenges of implementing NAMs and have successfully validated a number of these in recent years. Using our experiences with the three *in vitro* skin sensitisation assays (Direct Peptide Reactivity Assay [DPRA], KeratinoSens™ and human Cell Line Activation Test [h-CLAT]) as a case study, we highlight and discuss issues we overcame, questions that have arisen during routine testing for a global client base covering a broad spectrum of substances, and draw conclusions based on our experience for consideration in future documentation.

2797 The Use of Multi-Species Intestinal Organoids as a Preclinical Screen to Assess Gastrointestinal Toxicity

V. Ubertini, S. Hoyle, A. Bonavita, B. Reed, F. Phillips, A. Murdoch, N. Tonge, and C. Booth. *Epistem Ltd., Manchester, United Kingdom.* Sponsor: B. Reed, American Association for Cancer Research

The mouse small intestinal *in vitro* organoid model (Sato *et al*. in 2009), has been used as a tool assay for several diseases and treatments, including cancer. Gastrointestinal (GI) toxicity is a common and often severe dose limiting side effect of chemotherapy. Symptoms include diarrhoea, dehydration and ulceration which increase susceptibility to infection, partly due to damage of crypt and/or villus structures in the small intestine, impairing the barrier function. As novel targeted therapies are emerging, assessment of their potential GI toxicity remains crucial. We have further developed and validated the organoid model as a screening tool to predict GI toxicity and subsequent mucosal regeneration in four species: mouse, rat, canine and human. The culture conditions have been designed to mimic the stem cell niche and allow cell differentiation and proliferation to occur. All intestinal lineages were present in the organoids derived from each species and the epithelial hierarchy closely resembled that observed *in vivo*. The effect of several chemotherapeutic agents known to induce GI toxicity has been assessed, such as Oxaliplatin, 5-Fluorouracil (5-FU), CPT-11 and its metabolite SN38 and various Tyrosine Kinase inhibitors (TKIs). To assess the effect of the treatment, the number of dead, viable unbranched and branched organoids were counted and IC50 values were calculated and compared between species to inform on species-related sensitivity. MOA data generated by RNA-seq is presented elsewhere in the abstract by Tudor *et al*. The *in vivo* translatability of these models was also assessed. For example, rats have demonstrated that they are more sensitive than mice to 5-FU, experiencing more severe diarrhoea and earlier mortality. The 5-FU IC50 value obtained through the *in vitro* organoid assay supported this observation and was lower for the rat organoids than mouse. Human organoids were more sensitive to CPT-11 than 5-FU which also supports clinical data. Oxaliplatin was the least toxic compound within the human organoid assay, reflecting clinical data that shows the lowest incidence of severe diarrhoea. We conclude that organoids are a predictive preclinical model that can be used to identify potential on-target, off-tissue GI toxicities induced by novel therapeutics. Toxicity and mechanism of action (MOA) can all be addressed *in vitro* to potentially reduce *in vivo* experimentation.

2798 Deciphering Intestinal Toxicity via the Use of Short-Term *In Vivo* Studies and Multispecies Organoid Models Combined with Next Generation Sequencing

G. Tudor, V. Ubertini, S. Hoyle, F. Ponthan, and C. Booth. *Epistem Ltd., Manchester, United Kingdom.* Sponsor: F. Ponthan, American Association for Cancer Research

Intestinal toxicity is often manifest as early diarrhea (hours to days post dosing) with histopathology typically examined after a 14 or 28d toxicity study, i.e. long after the onset of toxicity. The epithelial pathologies are often described as villus blunting, crypt atrophy/erosion and hyper/hypoplasia, along with underlying inflammation, hemorrhaging etc. However, given that the epithelium is replaced weekly, with just Paneth and stem cells persisting, the original target cells may be long gone, with new target populations being generated during drug exposure. Deciphering the cause of the toxicity can therefore be a problem, especially when tissues are only collected at the study end. This is compounded by the ever present question of whether toxicity observed in the animal model is representative of the human response. Multiple drug administrations can extend toxicity to additional cell populations depending on timing, bioavailability and status of the cells following the prior exposure. For example, a drug killing the rapidly proliferating epithelial cell population can trigger a regenerative response in more quiescent progenitor cells, making them sensitive to subsequent doses. We have tracked the first cells responding to a single drug administration and used this to predict long term consequences and benchmark new drugs with similar target profiles. For example, doxorubicin has a different target cell profile to 5-FU (clonogenic cells vs the rapidly proliferating cell population respectively). Various Wnt and tyrosine kinase inhibitors have also been profiled. Characterization of gene expression pathways linked to these differing responses were also defined using Illumina Array and HiSeq Next Generation Sequencing platforms. These responses were also evaluated using intestinal organoids derived from 4 key species (mouse, rat, dog and human - described in the abstract submitted by Ubertini *et al*). Using such models we have shown that the responses elicited *in vitro* correlate with *in vivo* data, and that gene expression data for the epithelial responses were also comparable. The use of organoid models therefore allows a faster, cheaper method of evaluating drug toxicity and MOA, deprioritizing drugs with off target cross-reactivities responsible for toxicity (enabling drugs to 'fail faster'). Organoids can also guide the selection of the *in vivo* animal model most closely aligned to the human response.

2799 Optimization of 3D Liver Spheroid Formation and Functionality

C. Cossis. *Novabiosis, Morrisville, NC.*

Spheroids have proven to be an extremely useful *in vitro* model in ADME/Tox research. There is a need for more realistic hepatic models such as spheroids, due to the large amount of costly drug candidate withdraws. Spheroid culture conditions are tested in spheroids of individual hepatocyte donors and non-parenchymal cells in order to determine optimal conditions for the highest functionality. Spheroid formation of hepatocytes and non-parenchymal cells will be studied in culture medium supplemented with minimal FBS, seeded at 1 - 1,500 cells per well in a 96-well ultra-low attachment plate. In this study, 3D spheroids were created using Novabiosis cryopreserved primary human hepatocytes and hepatic non-parenchymal cells from individual donors. Here, various seeding densities and compositions of culture mediums are tested, with differing proportions of FBS and other common culture medium additives such as dexamethasone, glutamax, pen/strep, and insulin, as well as varying ratios of hepatocytes:NPCs. Functionality of the Kupffer cell lots used in culture was determined prior to their addition to the culture by the treatment of LPS and measurement of IL-6 and TNF-α production. Functionality of the hepatocytes in the spheroids was measured by ATP production, albumin secretion, and CYP1A2 (Omeprazole 50μM; SigmaAldrich O104), 3A4 (Rifampicin 10μM; SigmaAldrich R3501), and 2B6 (Phenobarbital 1mM; SigmaAldrich P1636) expression. The ATP production was determined using the Luminescent ATP Detection Assay Kit (abcam ab113849). Albumin secretion was measured using the Human Albumin ELISA Kit (abcam ab108788). Hepatocyte spheroid cultures were also characterized for their transporter activity for transporters OCT, BSEP, NCTP, and OATP. Spheroids were also fixed and had H&E staining performed to show morphology. All

spheroid formation was achieved utilizing ultra-low attachment plates (Corning™ 3474). An optimized spheroid model that improves predictability for translational responses to prototypical and novel drug compounds will be presented.

2800 Optimization of Non-parenchymal and Hepatocyte Co-culture Model

C. Cossis. *Novabiosis, Morrisville, NC.*

When a drug compound encounters the liver and is metabolized, more than just hepatocytes can play a role. The liver is made up mainly of hepatocytes, but also contain non-parenchymal cells such as Kupffer cells, stellate cells, sinusoidal endothelial cells, cholangiocytes, and a few other cell types. The combination of all the cell types beyond just hepatocytes in culture can provide a very useful *in vitro* research tool in the ADME/Tox field. The co-culture composed of hepatocytes and non-parenchymal hepatic cells create a more realistic liver environment as opposed to a hepatocyte culture alone. Novabiosis explored the co-culture conditions with the goal of optimizing the co-culture to give the longest lasting culture with the highest functionality. Varying ratios of non-parenchymal cells to hepatocytes were investigated. While it is hard to predict the exact cell composition in the liver, it has been estimated that Kupffer cells make up a majority of the non-parenchymal cells, followed in quantity by sinusoidal endothelial cells, immune cells, biliary cells such as cholangiocytes, and finally Stellate cells. It was of interest to explore if these percentages were truly preferred by hepatocytes in cell culture or if the exact composition did not contribute to functionality. The hepatocytes were first plated and cultured for 24 hours before the non-parenchymal cell types were added. Cultures were maintained out to at least 14 days. Functionality of the Kupffer cell lots used in culture was determined prior to their addition to the culture by the treatment of LPS and measurement of IL-6 and TNF-α production. Functionality of the hepatocytes was measured by ATP production, albumin secretion, and CYP1A2 (Omeprazole 50μM; SigmaAldrich O104), 3A4 (Rifampicin 10μM; SigmaAldrich R3501), and 2B6 (Phenobarbital 1mM; SigmaAldrich P1636) expression. The ATP production was determined using the Luminescent ATP Detection Assay Kit (abcam ab113849). Albumin secretion was measured using the Human Albumin ELISA Kit (abcam ab108788). An optimized co-culture model could potentially aid in the prediction of DILI side effects from novel drug compounds.

2802 Processed Clay Can Bind Polychlorinated Biphenyls and Mixtures with High Affinity

M. Wang, S. Hearon, and T. Phillips. *Texas A&M University, College Station, TX.*

Polychlorinated biphenyls (PCBs) have been detected as prevalent environmental contaminants in water, food and biota. Its accumulation in the fatty tissues of fish and other animals can be magnified during events such as hurricanes, floods, heavy rain, and storms, when PCB contaminated sediments are mobilized and redistributed, thus enhancing exposures and adverse health impacts in vulnerable humans and animal populations at the site of disasters. To address this problem, we have developed a broad-acting and highly effective sorbent for PCBs using montmorillonite clays reported to be safe for consumption in animals and humans. In this study, montmorillonite clays were processed with acid (APMs) and the sorption of six PCB congeners (PCB 77, 126, 153, 157, 154 and 155) on the surfaces of APMs were characterized. To confirm the safety and predict the *in vivo* efficacy of APMs, we used a living organism (*Hydra vulgaris*) that is sensitive to toxins. In a novel application of this work, APMs were included in algae-based feed for commercial oysters (*Crassostrea virginica)* as prophylaxis and treatment against PCB contaminants during disasters and high level exposures. APMs significantly protected hydra against the toxicity of PCBs and common mixtures (Aroclors 1254 and 1260), and reduced PCB uptake and accumulation in oysters when included in the diet. This finding was supported by *in vitro* studies showing tight binding; high capacity, affinity, and enthalpy; and a low therapeutic dose. APMs have been shown to bind a wide range of PCBs and other environmental chemicals, and can be delivered in food, drinking water and animal feed to mitigate toxin exposures in vulnerable humans and animals at the site of disasters (P42 ES027704).

2803 Endocrine Disrupting Chemical Exposure during Pregnancy and Metabolic Reprogramming

A. K. Merrill, T. Anderson, E. Marvin, K. Conrad, B. Lawrence, M. Susiarjo, D. Cory-Slechta, and M. Sobolewski. *University of Rochester, Rochester, NY.*

Pregnancy is a critical window of susceptibility to disease, as a woman's body undergoes numerous changes coordinated by hormones. Pregnancy is also characterized by exposures to multiple chemical classes of endocrine disrupting chemicals (EDCs). Recent epidemiological research indicates women exposed to mixtures of EDCs, i.e. phthalates, perfluoronated compounds, bisphenols, etc., during pregnancy have a higher chance of developing Type 2 diabetes in their lifetime. To address the possibility, mouse dams were exposed to relatively low doses of four EDCs that share consequences on metabolic function: Atrazine (ATR - 10mg/kg), Perfluorooctanoic acid (PFOA - 0.1 mg/kg), Bisphenol-A (BPA - 50μg/kg), 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD - 0.036μg/kg) and their mixture (MIX), from gestational day 7 until birth. These dams were weighed weekly, but no significant differences in weight were seen. At five months post-delivery, dams underwent a glucose tolerance test. Only MIX exposed dams showed elevated blood glucose. In accordance cholesterol was altered, with MIX females having elevated total cholesterol, LDL, and free cholesterol. MIX dam's livers showed similar results with elevated total cholesterol and LDL. There was no overall difference in insulin concentration, however, control females trended towards an association such that high serum insulin indicated lower blood glucose. However, MIX females showed the opposite relationship, with elevated serum insulin significantly correlating with elevated blood glucose. These data suggest an inability of insulin, despite its elevation, to lower serum glucose concentrations in MIX dams. Metabolic biomarkers, adiponectin, MCP-1, PAI-1 total, and resistin were assessed with no differences observed in the MIX. These changes do not appear to be the result of acute hormonal changes, as serum steroid hormones (estradiol, corticosterone and testosterone) were not changed. These data provide biological plausibility for the epidemiological associations observed between EDC exposure during pregnancy and increased risk to develop Type 2 diabetes. Yet more data are needed on mechanisms of metabolic reprogramming (elevated blood glucose and cholesterol), nearly six months post MIX exposure. Such data are critical for public health prevention and potential intervention strategies focused on pregnancy as a critical window for woman's health.

2804 Polyphenols of Silverskin Coffee and Spent Coffee Produce Cytoprotection in Undifferentiated Neuroblastoma Cell Line

A. Juan-García[1], M. Ruiz[1], C. Juan[1], G. Caprioli[2], and G. Sagratini[2]. *[1]Universitat de València, Burjassot, Spain; and [2]Università degli Studi di Camerino, Camerino, Italy.*

Polyphenols have strong evidence of their beneficial impact on brain function during aging; in fact, caffeine has protective effects against Alzheimer's disease and Parkinson's disease and potential mechanisms to protect against blood-brain barrier leakage. Coffee is an excellent substrate for the growth of mycotoxins and polyphenols exert protective effect as demonstrated in *in vitro* assays. In this study, determination of polyphenols of coffee samples and effect on a undifferentiated neuroblastoma cell line, SH-SY5Y exposed to two mycotoxins α-zearalenol (α-ZOL) or beauvericin (BEA) were studied and three exposure strategies with two coffee by-product extracts (silverskin coffe and spent coffee) were assayed during 24 and 48h. Direct treatment consisted in exposing cells to pure coffee by-product extract or mycotoxins at 1:2 dilutions. Simultaneous treatment: extract at fixed dilution (1:4) of the coffee by-product extract and α-ZOL (50 μM) or BEA (2.5 μM) at dilutions 1:2. Finally, for pre-treatment procedure, cells were exposed as in direct treatment and after 24h cells were exposed to α-ZOL or BEA at dilutions 1:2. Direct treatment of α-ZOL and BEA increased cytotoxicity in SH-SY5Y cells in a time and dose-dependent manner, but only α-ZOL reached IC_{50} values of 25μM and 21μM at 48h and 72h, respectively. Pre-treatment with boiling water extract revealed an increase of cell viability for α-ZOL at 24 and 48h from 10 to 16% and from 30% to 25%, respectively with spent coffee; while with silverskin coffee a decrease was observed. Opposite to this happened for BEA where increase was observed for silverskin coffee at 24 and 48h, from 14% to 23% and from 25% to 44%, respectively; and decreased bellow 50% was observed for spent coffee. Comparison of different silverskin coffee extracts in pre-treatment and BEA revealed that boiling water cytoprotects SH-SY5Y cells either at 24h and 48h with viabilities ~100%. Considering the high viability of silverskin coffee extracts obtained these extracts can presents benefits as natural and sustainable food ingredient. *Acknowledgments: This work was supported by the Spanish Ministry of Economy and Competitiveness (AGL2016-77610-R) and Fondo di Ateneo per la Ricerca from Italy (FAR2018).*

2805 Mixture Designs to Investigate *In Vivo* Interactive Adverse Effects upon Co-exposure to Environmental Cyanotoxins

R. M. Martin, J. Stallrich, and M. S. Bereman. *North Carolina State University, Raleigh, NC.*

Cyanobacteria are found ubiquitously in environmental water reservoirs and produce numerous toxins. Exposure to cyanotoxins has been linked to various neurodegenerative disorders, including sporadic amyotrophic lateral sclerosis, Alzheimer's and Parkinson's diseases. Despite the known co-occurrence of various cyanotoxins, the majority of studies have focused on the investigation of a single cyanotoxin, a nonconical amino acid called β-methylamino-L-alanine, which poorly recapitulates an actual environmental exposure to cyanobacteria. A mixture design of experiment (DoE) was used to screen for interactive effects of various environmental cyanotoxins. Using a combination of viability and behavior-based toxicity assays (i.e., sensitivity startle assays), we evaluated possible interactions between BMAA and its isomers: 2,4 diaminobutyric acid (2,4DAB), aminoethyl glycine (AEG). In addition, we investigated microcystin LR (MCLR) which is known to co-occur with BMAA and its isomers in the environment. A dose response study for each cyanotoxin reveled that the cytotoxic mild-effect, which is defined as the LOAEL (<25% mortality), was 500 μM for BMAA and AEG, 250 uM for 2,4DAB, and 1uM for MCLR. Our results show the potential for interactions between BMAA and its isomers AEG and 2,4 DAB as well as BMAA and MCLR, which is highly prevalent in the environment. Exposure to cyanotoxic mixtures caused a significant increase in mortality rate in zebrafish larvae. Exposure to cyanotoxic mixtures also interfered with the innate threshold of the zebrafish larvae startle response ($p<0.05$, ANOVA), causing the zebrafish larvae to become more hyposensitive or hypersensitive to acoustic stimuli. Taken together, mixture design is a useful as a toxicology method to screen for interactions amongst cyanotoxins as cyanotoxic mixtures have the potential to interact in an *in vivo* system. We highlight the need to study cyanotoxic mixtures when investigating the link between cyanobacteria and neurodegenerative pathologies.

2806 Modeling Induction of Proximal and Distal Endpoints following PPARγ Activation by Ligand Mixtures

J. Schlezinger, W. Heiger-Bernays, and T. Webster. *Boston University School of Public Health, Boston, MA.*

Binding of chemicals to receptors and subsequent activation of transcription are the molecular initiating events (MIE) for a large number of biological processes. Based on this, we developed Generalized Concentration Addition (GCA), a pharmacologically-based mathematical model, to estimate the biological effect of mixtures. GCA successfully predicts experimental data for mixtures of AhR ligands and of PPARγ ligands. Commonly, dose response data used to test the efficacy of additivity models are generated in reporter assays. Here, we experimentally test the ability of GCA to model and predict endogenous biological events proximal (e.g. endogenous gene expression) and distal (e.g., differentiation) to PPARγ activation and to model the biological event distal from the MIE using the dose response data from the proximal MIE. We generated individual dose-response data for two full (rosiglitazone and S26948) and one partial (nTZDpa) agonists using the OP9 cell line (RRID:CVCL_4398). We assessed *Fabp4* mRNA expression after 24 hrs or lipid accumulation (a surrogate of adipocyte differentiation) after 5 days. The dose response curves for activation of PPARγ by rosiglitazone were largely overlapping, whether generated from reporter data, *Fabp4* expression or lipid accumulation. For all chemicals, proximal and distal endpoint dose responses were similar, with a slightly lower potency for induction of Fabp4 expression than lipid accumulation. We then generated mixture data with combinations of chemicals using a grid design. Combinations of full agonists induced maximal levels of Fabp4 expression and lipid accumulation. The partial agonist nTZDpa had agonistic effects at low effect levels and antagonistic effects to rosiglitazone at high levels, as predicted by pharmacological theory. We are comparing the empirical mixture data to that predicted by GCA from the individual dose response curves. Results from these studies will expand the applicability of generating and applying pharmacodynamics models of more complex biological endpoints in GCA.

2807 Impact of Plasma Protein Binding on the *In Situ* Hepatic Uptake and Clearance of Perampanel and Fluoxetine in Sprague Dawley Rats

M. Bteich[1], P. Poulin[1,2], and S. Haddad[1]. [1]*Université de Montréal School of Public Health, Montreal, QC, Canada; and* [2]*Consultant Patrick Poulin Inc., Quebec, QC, Canada.*

There is about 50% of drugs highly bound in plasma (fu_p <0.1) among new molecular entities approved by the FDA between 2003 and 2019, and it is yet unclear how to predict the hepatic clearance (CLh) of albumin-bound drugs with an affinity to other proteins. The main objective is to investigate the effect of albumin (ALB) and/or alpha-1-acid glycoprotein (AGP) on the hepatic uptake and CLh of the drugs that bind, extensively, to both proteins, and that are exclusively metabolized in the liver. From a drug data collection (n= 1907 drugs), two drug candidates are selected based on their physicochemical, metabolic and binding properties (Binding Ratio $_{AGP:\,ALB}$ close to unity): perampanel (PER) and fluoxetine (FLU). Using male Sprague Dawley rats (n= 3 rats/scenario/drug), isolated perfused rat liver (IPRL) experiments are performed to obtain intrinsic clearance (CL_{int}) and CLh values for the two drugs; at perfusate concentrations of 2.5, 7.5, 15, 20, 25 and 35 μM. There are four IPRL experimental scenarios: 1) physiological solution without plasma proteins (WO), 2) solution with bovine ALB (40 g/L), 3) solution with bovine AGP (1 g/L), and 4) solution with mixture of both proteins (MIX); at concentrations of 40 g/L and 1 g/L for ALB and AGP, respectively. The type of kinetics observed, and the metabolic rates are different for the two drugs. For the PER, four Michaelis-Menten kinetics are observed with Vmax= 225.23, 23.16, 112.13 and 17.32 (nmol/min/g liver) and Km= 24.85, 1.90, 37.0 and 0.90 (μM) for the WO, ALB, AGP and MIX, respectively. As for FLU, substrate inhibition (uncompetitive) kinetics are observed with Vmax= $2.84x10^5$, 67.7, $8.7x10^5$, 22.5 (nmol/min/g liver); Km= 205.6, 0.024, 518.4 and 0.0047 (μM) and Ki= 0.116, 0.424, 0.0004 and 1.4 (μM) in all four scenarios, respectively. The CL_{int} ratios (Vmax/Km) increased for PER but decreased for FLU in the presence of ALB and MIX compared to the WO and AGP scenarios. The presence of AGP decreased the CL_{int} ratios (Vmax/Km) for both PER and FLU compared to WO. Furthermore, in the rat liver, PER is poorly metabolized (hepatic extraction= 0.2-0.7), while FLU is highly metabolized in the different scenarios (hepatic extraction= 0.8-0.99). In conclusion, the ALB-mediated hepatic uptake is observed only for PER that is poorly metabolized, and for which the CLh would mainly depend on the CL_{int} that increased due to the binding to ALB. The FLU is a substrate inhibitor and highly metabolized, which makes it difficult to observe an uptake mediated by ALB for FLU since saturation of metabolic rate is not observable and CLh would mainly depend on the perfusate flow instead of CL_{int}.

2808 Estimating the Sensitivity of GARD™skin and GARD™air Assays for Evaluating Skin and Respiratory Sensitization Potential of Complex Mixtures; An Initial Case Study Using Spiked E-liquids

A. Forreryd[1], M. Stevenson[2], U. Mattson[1], K. Rudd[2], L. Czekala[2], G. Phillips[2], L. Simms[2], and T. Walele[2]. [1]*SenzaGen AB, Lund, Sweden; and* [2]*Imperial Brands PLC, Bristol, United Kingdom.* Sponsor: J. Schmidt

Due to the dynamic nature of innovation with e-cigarettes, new assays are required to quickly determine the potential biological response of these products for stewardship activities. It is important to evaluate e-liquid ingredients and formulations for their potential skin and respiratory sensitising properties. We have previously shown that GARD™skin and GARD™air assays can be used to assess skin and respiratory sensitising potential of complex mixtures of experimental and commercial e-liquids. However, it remains to be explored if these assays can detect low concentrations of sensitisers within such complex mixtures. The objective of this study was to assess an experimental e-liquid spiked with different doses of sensitisers in GARD™skin and GARD™air assays. Both assays measure a genomic biomarker signature of a human myeloid leukemia-derived cell line exposed to test substances, and a prediction model is used to classify each sample according to its sensitising potential. An unflavoured experimental e-liquid (50:50 Propylene Glycol, Vegetable Glycerin, ± 1.6% Nicotine) was spiked with different doses of Eugenol (skin sensitiser) or Reactive Orange (respiratory sensitiser) in concentrations from 0-500μM. The experimental e-liquid by itself was determined to be non-sensitising; but became sensitising in GARD™skin and GARD™air, respectively, in a dose-response dependent manner when Eugenol or Reactive Orange were added to the formulations. Using a 4-parametric log-logistic dose-response curve an estimated threshold range for the induction of skin sensitisation in GARD™skin was estimated to between 1-50 μM (0.15-7.5ppm) for the Eugenol spike. Whereas, for GARD™air this estimated threshold range for the induction of respiratory sensitisation falls between 100-380 μM (88-330ppm) for the Reactive Orange spike. The detection of spiked sensitisers within e-liquids

allows us to estimate the minimal level of sensitiser detectable within a complex mixture and highlights the potential of this assay for future ingredient assessment strategies of e-liquids.

2809 Mutagenic Effects of Reference Cigarette 3R4F and E-cigarette Liquids with Different Nicotine Concentrations on L5178Y/TK$^{+/-}$-3.7.2C Mouse Lymphoma Cell

P. Shang, C. Hua, J. Guo, X. Li, J. Zhao, F. Xie, and H. Liu. *Zhengzhou Tobacco Research Institute of CNTC, Zhengzhou, China.* Sponsor: R. Meng

Electronic cigarettes (e-cigarettes) are the most recently developed tobacco products, which are highly advertised across the media, mainly as healthy substitute to conventional cigarettes, aid in quitting smoking addiction or way of circumventing ban on smoking in public places. E-cigarette liquid (e-liquid) is mainly composed of glycerol, propylene glycol, nicotine and various flavors. It is found that the chemical composition of aerosol produced by e-liquid heating is quite different from that of traditional cigarette smoke, and the type and release amount of harmful components are significantly lower than that of traditional cigarettes. The mouse lymphoma assay (MLA) is used internationally for short-term mutagenicity tests, which has been considered as the most sensitive *in vitro* mammalian cell gene mutation assay and therefore is especially useful in evaluating substances with unknown or multiple genotoxic mechanisms.20 3R4F reference cigarettes were smoked according to the ISO condition (35 ml puff volume, 2 seconds duration, 60-second puff interval, with the ventilation holes unblocked). 3 commercial e-liquids with nicotine concentration respectively for 6, 12 and 18 mg/mL were smoked with the same e-cigarette device for aerosol production, according to the Health Canada Intense (HCI) condition (55 ml puff volume, 2 second duration, 60 seconds puff interval, with 100% blockage of filter ventilation holes). After smoking, the cigarette smoke condensate (CSC) and the e-cigarette aerosol extracts (ECEs) of cambridge filter pads were extracted with DMSO at 10 mg/mL and stored at -80 °C until analysis. All CSC and ECEs were studied in the presence of metabolic activation. The final S9 concentration in the treatment medium was 1.25%. The results showed that both the CSC and ECEs showed cytotoxic to the L5178Y cell. TFT resistance Mutation Frequency (TMF) of CSC was more than 3 times higher than that of the solvent control at higher concentrations (80-150 μg/mL), and induced dose-related mutagenic effects in L5178Y cells. There were no mutagenic effects of TK gene appeared in the ECEs in the dose range. Through derivation, the potency of nicotine in CSC (80 μg/mL) and ECE (320 μg/mL, Maximum exposure dose) are 1.536 and 2.365 mg respectively. There may be indicating that the mutagenic effect of the TK gene is mainly caused by the harmful components in the particle phase.

2810 *In Vitro* Assessment of Potential Chronic Toxicity of Smoke from Combustion of Flame-Retarded and Non-Flame-Retarded Furnishings

T. G. Osimitz[1], W. Droege[1], L. G. Higgins[2], L. Chatham[2], F. Zhang[2], M. Blais[3], and G. Hendriks[4]. *[1]Science Strategies LLC, Charlottesville, VA; [2]Concept Life Sciences, Dundee, United Kingdom; [3]Southwest Research Institute, San Antonio, TX; and [4]Toxys B.V., Leiden, Netherlands.*

To address concerns about potential chronic toxicity of smoke from flame retarded furnishings, smoke from combusted furnishings was examined in controlled room burns. Each room contained a cushion couch, chair and flat panel television of identical models/manufacturers purchased from either France, United Kingdom (UK), or US. The UK furniture met BS5852 fire standard and contained flame retardants. The French and US furniture met smolder only fire standards, e.g., TB117 2013, and were not flame retarded. As expected, vast differences were noted in ignition resistance and progression of fires. Smoke from the fires started as white and ended as dense black smoke. Smoke from both phases was sampled via XAD sorbent resin. Potential chronic toxicity of the smoke was assessed with both the ToxTracker reporter assay and Aryl Hydrocarbon Receptor (AHR) activation assay. ToxTracker consists of a panel of mammalian stem cell lines that contain different fluorescent reporters for induction of DNA damage, oxidative stress and protein damage. The differential induction of the GFP reporters as well as cytotoxicity of the tested substances was determined by flow cytometry. AHR transactivation assessed using a commercial reporter cell line. Two dark smoke and one white smoke sample from the French furnishings and one of the dark smoke samples from the US furnishings showed activation of the Bscl2-GFP genotoxicity reporter in ToxTracker which is associated with DNA replication stress and induction of pro-mutagenic DNA adducts and subsequent inhibition of DNA replication. None of the UK samples activated the Bsc12-GFP reported, however one UK black sample induced genes associated with oxidative stress. No other positive results were observed with ToxTracker. For AHR activation, only the two dark smoke and one white smoke samples from the French furnishings and one of the dark smoke samples from the US furnishings showed induction greater than 25% of the positive control, whereas all of the UK samples showed activation of less than 10%. Overall the data suggest that the combustion products from the more flame retarded furnishings showed a lower potential for chronic toxicity that those furnishings least flame retarded. *Supported by the American Chemistry Council's North American Flame Retardant Alliance.*

2811 Stability of Disinfection By-Products (DBPs) within the Complex Mixture Formed during Chlorination

J. E. Simmons[1], L. L. Aume[2], P. I. Feder[2], G. E. Rice[3], L. K. Teuschler[4], M. G. Narotsky[1], A. McDonald[1], Y. M. Sey[1], J. G. Pressman[5], T. F. Speth[5], E. S. Hunter[6], and S. D. Richardson[7]. *[1]US EPA/CPHEA, Research Triangle Park, NC; [2]Battelle Memorial Institute, Columbus, OH; [3]US EPA/CPHEA, Cincinnati, OH; [4]LK Teuschler and Associates, St. Petersburg, FL; [5]US EPA/CESER, Cincinnati, NC; [6]US EPA/CTTE, Research Triangle Park, NC; and [7]University of South Carolina, Columbia, SC.*

Disinfection of water with chlorine effectively reduces microbial contamination but also results in formation of complex mixtures of hundreds of DBPs. Speciation and concentrations of formed DBPs vary as a function of multiple factors, including: the concentrations of natural organic matter, bromide and iodide; time; temperature; pH; the disinfectant used, and the disinfection scenario. These combined factors create a non-steady state environment for DBPs that, coupled with lack of stability data, has hindered the ability to investigate potential health effects from exposure to environmentally realistic complex mixtures. In the present study, 75 regulated and priority DBPs along with total organic halide (TOX), an integrated measure of the total mass of organic halide formed during chlorine disinfection, were monitored by sampling over the course of a comprehensive rat multigenerational reproductive toxicity study (EPA's Four Lab Study). In an effort to enhance stability, the chlorinated water concentrates were provided to the rats by a watering system that held the concentrates dark, cold, and head-space free. Concentrates were analyzed over time for the 44 individual DBPs plus TOX for which at least two sampling events confirmed detection above their respective analytical minimum reporting limits (MRLs). Stability was evaluated by testing the hypothesis that the slope across time of logarithmically transformed DBP concentrations was zero. The criterion for stability was lack of statistical significance when compared to a Bonferroni adjusted significance level of 0.05. The four trihalomethanes (chloroform, bromodichloromethane, chlorodibromomethane, bromoform) regulated by EPA were stable over 14 days. Of the five haloacetic acids regulated by EPA, three were stable (di- and tri-chloroacetic acid, dibromoacetic acid) while two (chloroacetic and bromoacetic acid) were below their MRLs. Overall 39 of the 44 DBPs analyzed for stability met the criterion for stability, as did TOX. In sum, these results indicate that the majority of the evaluated DBPs were stable over the course of the study.

2812 Identification of Co-occurrence Patterns of Persistent Organic Pollutants with Data Mining Methods

D. N. Williams[1], and J. E. Simmons[2]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [2]US EPA, Research Triangle Park, NC.*

Environmental contaminants occur in mixtures, but traditional toxicology and risk assessment focus on single chemicals. Understanding risk associated with exposure to mixtures requires knowledge of those chemical combinations that occur together most frequently. Our objective was to use Frequent Itemset Mining (FIM), a data mining technique, to find the most commonly occurring combinations of items in a dataset. We identified a dataset where 50 persistent organic pollutants (POPs), including polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and organochlorine pesticides, were measured in fish sampled from 540 sites on US rivers. With the POPs from this study, over one quadrillion possible mixtures exist. The goal was to identify candidate mixtures that appear in fish in 25% or more of the river sites. Chemical occurrence data were filtered using three separate methods into presence/absence matrices. The three separate limits indicate different confidence levels for analyte concentrations being greater than zero. These limits, in order of increasing tightness, are: any amount detected, method detection limit (MDL, 99% confident analyte is present), and quantitation limit (QL, 3 x MDL). Using these thresholds, three sets of frequent combinations were identified: 14,290,875 combinations by any amount detected, 611,876 combinations by MDL, and 745 combinations by QL. For all three limits, the 30 most frequently occurring combinations comprised of either two,

three, or four chemicals and appeared in 46-88% of all river sites, and the most frequently occurring mixture by each method was 4,4'-DDE + PBDE-47 (88% any, 87% MDL, 68% QL). Even though the number of combinations decreased as the threshold became more stringent, 21 of the top 30 most frequently occurring mixtures remained the same. Larger mixtures with at least 8 chemicals present were identified: 12,795,381 by any detection, 401,534 by MDL, and 3 by QL. In summary, while infrequently applied to environmental contaminant studies, FIM has strong potential to identify mixtures of concern based on combination frequency. *(This abstract does not reflect US EPA policy).*

2813 Evaluating Toxicity of a Representative Mixture from a Legacy Creosote Site Affected by Wildfire Smoke

B. N. Rivera, C. C. Ghetu, K. A. Anderson, and S. C. Tilton. *Oregon State University, Corvallis, OR.*

Polycyclic aromatic hydrocarbons (PAHs) are a highly abundant group of organic chemicals with numerous man-made and natural sources. Inhalation of PAHs from various sources can have negative impacts on individuals' lung health due to certain PAHs having toxic, mutagenic, or carcinogenic properties. PAHs are formed from the incomplete combustion of sources such as coal, oil, gas, and wood. Increases in temperature and changes in precipitation, as a result of climate change, are increasing wildfire prevalence and severity. Wildfire smoke contains complex mixtures of pollutants such as particulate matter, PAHs, and volatile organic compounds (VOCs). An estimated 339,000 deaths each year (260,000 - 600,000 deaths annually) are attributed to wildfire smoke, however the overall impact on respiratory and cardiovascular health are largely unknown. PAHs can also be found in the air as a result of chemical movement between environmental compartments at contaminated sites such as legacy creosote sites. Creosote oil is a wood preservative derived from coal tar, which is composed of a complex mixture of hundreds of compounds including VOCs and PAHs. However, the primary components of creosote oil that contribute to adverse health effects have not yet been identified. In the summer of 2017 stationary air passive samplers were deployed at a legacy creosote site during the Eagle Creek Fire in Northern Oregon. Sample extracts were analyzed for 63 PAHs using GC/MS-MS. A representative mixture of the top 6 most abundant PAHs (Mix6) from 5 different stationary air samplers was formed at environmentally relevant ratios. The Mix6 was then evaluated for pulmonary toxicity using primary normal human bronchial epithelium cultured at the air liquid interface. Toxicity of the Mix6 was evaluated by measuring tight-junction integrity, cytotoxicity and induction of xenobiotic metabolizing and oxidative stress enzymes. Exposure to the Mix6 resulted in significant (<0.05) induction of transcriptional biomarkers of oxidative stress and xenobiotic metabolism, NQO1 ($p=0.0353$) and CYP1A1 ($p=0.0051,0.0271$), indicating potential mechanisms of toxicity. The toxicological profile of Mix6 will be further evaluated by comparing it to its individual components. Future studies will include conducting benchmark dose modeling in order to evaluate levels at which the Mix6 elicits pulmonary toxicity. Results from this study will help inform relative health impacts from exposure to mixtures of PAHs from inhalation of wildfire smoke and/or living in proximity to a legacy creosote site, and elucidate mechanisms of toxicity of PAH mixtures.

2814 Application of Retention Index in Analysis of 241 Tobacco Flavor Components by Gas Chromatography-Tandem Mass Spectrometry

Z. Ren, L. Chen, T. Shi, F. Xie, X. wang, and H. Liu. *Zhengzhou Tobacco Research Institute of CNTC, Zhengzhou, China.* Sponsor: R. Meng

Tobacco flavor Components are very important to the aroma and taste of tobacco products and greatly influence the quality, characteristics and acceptability of the finished product. The high selectivity and sensitivity of gas chromatography tandem mass spectrometry (GC-MS/MS) with dynamic multiple reaction monitoring (dMRM) mode can satisfy the qualitative analysis of trace level flavor components in complex tobacco matrices. However, the target retention time may drift out of the acquisition time window after the instrument maintenance and method adjustment, and retention time correction is time consuming, especially in the multi-analyte analytical method. In this study, retention index (RI) was used to quickly obtain the retention times in a GC-MS/MS method for the simultaneous analysis of 241 flavor components. The retention indices of 241 target components were determined by detecting tobacco samples spiked with a mixture of n-alkanes and target standards. The difference values of retention indices between experimental determination and NIST17 database information were less than 10 for 211 components, and the retention indices of 30 components were not reported previously. Then, the retention times of the target compounds under different chromatographic conditions were predicted based on the retention indices of targets and the retention times of n-alkanes mixture, and the results showed that the predicted retention times were very close to the experimental measured ones. The time deviations of 232 components were within 0.05 min, and the time deviations of 9 components were within 0.1 min, which can fully meet the requirements of dMRM acquisition time window. It is proved that the retention index has good stability in the complex tobacco matrix, and can be used in the retention time prediction in multi-analyte GC-MS/MS analytical method, and it's accurate and time saving.

2815 Formulation Development and Analysis Methods for Polycyclic Aromatic Compound Mixtures in Support of Toxicology Studies

E. Mutlu[1], B. Stiffler[2], B. Graber[2], C. Rider[1], B. Burback[2], D. Germolec[1], and S. Waidyanatha[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; and [2]Battelle Memorial Institute, Columbus, OH.*

Polycyclic aromatic compounds (PACs) are ubiquitous environmental contaminants which typically occur in mixtures. PACs are of particular concern due to their long life in the environment and potential routes of exposure, such as ingestion, occupational exposures (eg. tar, asphalt etc), and indoor (cookstove emissions) and outdoor pollution (diesel exhaust). 13 PACs and 3 mixing ratios were selected based on individual toxicity data and predictions about mixture effects; an equimolar combination of the individual PACs, the ratio of each PAC at the dose eliciting 50% effect (ED50), and the ratio of each PAC at the dose eliciting 10% effect (ED10). The PACs included, benzo[a] pyrene, phenanthrene, pyrene, acenaphthenequinone (ANQ), benzo[k]fluoranthene, benzo[c]fluorene, dibenzo[a,l]pyrene (DBP), dibenzothiophene, dibenz[ah]anthracene (DBA), chrysene, benz[j]aceanthrylene (BJA), benzo[b] fluoranthene, and indeno[123-cd]pyrene. The goal of the work reported here was to develop methods to prepare and analyze PACs in corn oil formulations. Due to the complexity of the formulations (number of chemicals with similar properties, and the wide concentration range of the test articles), two stocks, one containing 7 and one containing 6 of the chemicals were prepared in corn oil. Serial dilutions of these stocks were prepared and the actual formulations were prepared by combining the dilutions of the stocks. The same analytical method could not be utilized for all compounds. Therefore, the two separate stocks were analyzed for the individual PACs and the combined mixture (formulation) by High Performance Liquid Chromatography with fluorescence detector (all except ANQ) and Gas Chromatography-Flame Ionization Detector (ANQ) for marker compounds. The formulation analysis methods were validated over the concentration range 8.0-38,400 ng/mL (compound dependent). Standard curves were linear ($r^2 > 0.98$) and the method was accurate (relative error (RE) $\leq \pm 15$ %) and precise (relative standard deviation (RSD) $\leq$ 10%) for all concentrations except at the lowest concentration for DBA (RSD $\leq$ 30%) and BJA (RE $\leq \pm 11$%). The formulations were homogeneous for all PACs (RSD $\leq \pm 5$%, except DBP (RSD $\leq \pm$ 15%)). The formulations stored at 2-8°C were stable up to for 44 days except ANQ. In conclusion, we have successfully developed formulation and analysis methods in support of the toxicity assessment of PAC mixtures.

2816 Simultaneous Determination of 69 Aldehydes and Ketones in Tobacco by Gas Chromatography Tandem Mass Spectrometry

L. Chen, T. Shi, Z. Ren, H. Cui, M. Chen, F. Xie, S. Liu, and H. Liu. *Zhengzhou Tobacco Research Institute of CNTC, Zhengzhou, China.* Sponsor: R. Meng

Aldehydes and ketones are very important tobacco flavor Components, which greatly influence the quality and characteristics of the tobacco product. Sensitive and selective multi-analyte analytical methods are needed to satisfy the demand for analyzing trace level flavor constituents in tobacco. A reliable and rapid gas chromatography tandem mass spectrometry (GC-MS/MS) method for the simultaneous analysis of 69 aldehydes and ketones in tobacco was developed and validated using a modified QuEChERS extraction procedure. The mass spectrometry parameters, including parent ions, product ions and collision energy, were optimized. The impact of extraction solvents, soaking conditions, soaking duration, vortex duration and purification methods on extract efficiency were also investigated. Dynamic multiple reaction monitoring mode (dMRM) was applied for the quantification and confirmation of those compounds. The results showed that the calibration curves of all the targets presented good linearity. Average recoveries of all of the compounds in tobacco ranged from 70.1 to 120.1% with relative standard deviations of 0.3-19.7% at three fortification levels. The limits of quantification (LOQs) and the limits of detection (LODs) for 69 aldehydes and ketones were in the range of 2.9-136.9 µg/kg and 0.9-40.9 µg/kg at the signal-to-noise ratio (S/N) of 10 and 3, respectively. The method greatly improved the detection performance

and the range of target compounds, and can meet the requirements for aldehyde and ketone flavor constituent analysis in tobacco with the advantage of accuracy, sensitivity and convenience. The experimental method was successfully applied to the analysis of 15 cigarette samples with different style characteristics, and 55 aldehydes and ketones were detected. A total of 5 compounds with p-value less than 0.01 were screened out as differential components. It further proves the practicality of the developed analytical method.

2817 Assessing Additivity of Chemical Effects at the Gene Expression Level in Complex Mixtures of Environmentally Relevant Chemical Concentrations

D. E. Hines, E. J. Perkins, N. Garcia-Reyero, M. S. Willbanks, J. E. Mylroie, and L. D. Burgoon. *US Army Engineer Research and Development Center, Vicksburg, MS.*

Exposure to complex mixtures at environmentally relevant concentrations can affect both human health and ecological endpoints. The cumulative effects of these complex mixtures are often estimated by assuming simple additivity; however, the additivity of chemical effects at the gene expression level remains poorly understood. We test for evidence of additivity in environmentally relevant concentrations of complex mixture at the gene expression level by comparing differentially expressed genes from exposures to 7 mixtures of up to 20 chemicals, as well as their single chemical constituents, using zebrafish (*Danio rerio*) embryos as a model system. The gene expression profiles of the individual chemical constituents were summed to create theoretical gene expression profiles for each mixture under the assumptions of additivity. We compared differentially expressed genes in theoretical mixtures to empirical measurements to test the hypothesis that exposure to complex mixtures at environmentally relevant concentrations will cause gene expression to change in an additive manner. A Spearman's rank correlation (rho) test was used to compare differentially expressed gene profiles and revealed very weak correlations between empirical and theoretical mixtures (median rho=0.04, maximum rho=0.15). Further analysis of empirical and theoretical mixture comparisons revealed no tendency towards synergism or antagonism in gene expression, and up to 60% of differentially expressed genes were expressed in opposite directions. Thus, we did not find evidence to support simple additivity of effects from exposure to complex mixtures at the gene expression level in zebrafish embryos. This work highlights that low-dose components of environmentally relevant mixtures may not act additively. *The views and opinions expressed are those of the authors and do not necessarily reflect the official policy or position of the US Army. This work was supported by the US Army's 6.1 Basic Research Program, Environmental Quality and Installations.*

2818 Associations of Endogenous Reproductive Hormones and Phthalate Exposure with Subjective Sleep Quality in Midlife Women

K. M. Hatcher, R. L. Smith, C. Chiang, Z. Li, J. A. Flaws, and M. M. Mahoney. *University of Illinois at Urbana-Champaign, Urbana, IL.*

Impaired sleep quality during the menopausal transition reduces quality of life, increases depression, and increases risk of metabolic diseases. Endogenous hormones in midlife women are known to influence subjective sleep quality. Endocrine disrupting chemicals, such as phthalates, may also contribute to the increased prevalence of sleep disturbances in this population. Phthalates are known to impact endogenous hormones, including reproductive hormones, that are associated with sleep. However, the link between phthalate exposure and sleep quality remains unexplored. Thus, we investigated associations between phthalate exposure, serum reproductive hormones, and subjective sleep in the Midlife Women's Health Study (MWHS), a longitudinal cohort from Baltimore, Maryland and surrounding counties. We hypothesized that increased exposure to environmentally relevant phthalate mixtures is associated with impaired sleep in midlife women. Additionally, we hypothesized that this association is mediated by reproductive hormones. Using ordinal logistic regression, we assessed the associations of both phthalate mixtures, measured from urine, and serum reproductive hormone levels with subjective sleep quality. Sleep was measured using survey questions, where participants indicated frequency of sleep disturbances, insomnia, and restless sleep. Statistical models were adjusted for BMI, hot flashes at night, menopause status, CES-D score, and present quality of life, and were stratified by smoking status. We found that progesterone is negatively associated and estradiol:progesterone (E:P) is positively associated with all measures of sleep quality in nonsmokers. Further, we found that the sum of phthalates associated with personal care products (sumPCP) and sum of all phthalates (sumALL) are negatively associated with all sleep measures in former smokers. There was no significant mediation effect of progesterone or E:P on the association between sumPCP or sumALL and sleep quality. These data indicate that reduced progesterone levels and a larger E:P are associated with impaired sleep, and increased sumPCP is directly associated with reduced frequency of sleep impairments. This is one of the first studies to identify associations between phthalates and sleep and adds insight into the role of endocrine signaling in mediating adverse symptoms accompanying menopause. *Supported by NIH R01ES026956.*

2819 *In Vitro* and PBPK Models for a Mixture of Dioxin Like Compounds

M. Easterling[1], M. Devito[2], and K. Shockley[2]. *[1]Social and Scientific Systems Inc., Durham, NC; and [2]NIEHS, Research Triangle Park, NC.*

Mathematical modeling is an important tool in the development of *in vitro* to *in vivo* extrapolation methods. In support of extrapolation from cells to organisms, we wanted to evaluate a smaller step of extrapolation from cell model to physiologically based pharmacokinetic (PBPK) model. We developed PBPK models and *in vitro* system models that share the same detailed pharmacodynamics. The PBPK models are for TCDD, PeCDF and PCB126 as well as a mixture of all three. The *in vitro* model is for hepatocytes and has the same liver kinetics equations as the PBPK models. While the PBPK models yield accurate predictions of kinetic data from the NTP Dioxin Mixture 2-year studies, the *in vitro* model using PBPK parameters fails to match literature data. We show where there are discrepancies going from the PBPK model to the *in vitro* model.

2820 Joint Toxicity Assessment of Perfluoroalkyl Substances (PFAS) Mixtures

M. M. Mumtaz, and H. R. Pohl. *CDC/ATSDR, Atlanta, GA.*

Humans are exposed to multiple perfluoroalkyl substances (PFAS), through a combination of intake of food, water, dust particles, and hand-to-mouth transfer. Communities across the country are becoming increasingly aware and concerned about the presence of these chemicals in their bodies, but the mechanisms of toxicity of PFAS have not been well understood. The 2018 ATSDR mixtures framework recommends three broad approaches for toxicity assessment that are also now used by other federal and state agencies. Of these, the most often used is the hazard index (HI) approach that is based on potency weighted additively of the toxicity of individual components. Recent experimental toxicity studies of mixtures containing perfluorooctane sulfonic acid (PFOS), perfluorooctanoic acid (PFOA), perfluorohexane sulfonic acid (PFHxS), and perfluorononanoic acid (PFNA) as well as an assessment of 17 PFAS found in the general population revealed no major concern for joint toxicity based on the HI approach. ATSDR conducted risk assessment of binary mixtures of PFAS for multiple toxicity endpoints applying this approach. Using estimated lifetime exposures reported in the literature, we determined that a 2-component hypothetical mixture of PFOS and PFOA will yield hazard indices (HIs) of 30, 2.01, and 0.215 for high-exposure scenarios; 8.4, 0.13, and 0.102 for intermediate-exposure scenarios; and 3.63, 0.034, and 0.047 for low-exposure scenarios for developmental, reproductive, and thyroid toxicity, respectively. In these calculations, we utilized the intermediate duration minimal risk levels and target organ toxicity doses. The HI values are used as a screening and prioritization tool, the concern for exposures increase as the HI values increase. For HI values >1, a follow-up including uncertainty factor analysis is conducted. Until further insights are gained in their mechanistic toxicology, based on our current knowledge, the HI approach appears most suitable to address present day PFAS public health concerns. However, this approach must be used cautiously because of the uncertainties related to the large toxicity data gaps that exist for an overwhelming majority of PFAS. *The findings and conclusions in this presentation have not been formally disseminated by the Centers for Disease Control and Prevention/the Agency for Toxic Substances and Disease Registry and should not be construed to represent any agency determination or policy.*

2821 Thyroid Receptor Antagonism of Mixtures Isolated from Personal Silicone Wristbands

C. D. Kassotis[1], K. Hoffman[1], S. C. Hammell[1], N. J. Herkert[1], S. C. Kullman[2], and H. M. Stapleton[1]. *[1]Duke University, Durham, NC; and [2]North Carolina State University, Raleigh, NC.*

Given the inherent difficulties with collecting and assessing human biospecimens, there is a critical need for external, non-invasive samples that can recapitulate human exposures. Silicone wristbands have been shown to support measurements of personal exposure to complex mixtures of semi-volatile

contaminants in the ambient air, encompassing both the indoor and outdoor environments. We previously demonstrated that extracts of household dust promoted thyroid receptor beta (TRβ) antagonism and differentiation of pre-adipocytes *in vitro* and found that these bioactivities were significantly associated with thyroid hormones and body mass index of adult residents. Herein, we conducted a pilot study to evaluate TRβ antagonism of mixtures isolated from silicone wristbands worn by 36 adults recently diagnosed with thyroid cancer and 36 age and sex-matched controls from central NC. Adults wore wristbands for one week, then they were wrapped in foil and frozen until analysis. One-gram sections of the wristband were solvent extracted and analyzed via mass spectrometry to quantify brominated and organophosphate flame retardants. Separate extracts were reconstituted in tissue culture media for use in bioassays and tested for their ability to antagonize TRβ, using a reporter gene assay in human kidney cells. Approximately 70% of extracts tested at 1% (concentration of extract in contact with the cells) exhibited significant TRβ antagonism, with no activity in wristband blanks. These effects occurred independent of toxicity, as measured via lactate dehydrogenase release and constitutive promoter reporter assays. Higher extract test concentrations (5 and 10%) did exhibit significant toxicity. Extracts exhibited a mean of 30% TRβ antagonism (% suppression of half maximal positive control) and a range of 0-100% antagonism at 1% concentration, and a mean of 10% with a range of 0-63% at 0.1%. Thyroid receptor antagonism was positively correlated with wristband concentrations of 2-ethylhexyl-2,3,4,5 tetrabromobenzoate (TBB) and tris (1-chloro-2-propyl) phosphate (TCPP). These results suggest that these personal passive samplers may be useful in evaluating bioactivities of mixtures that people come into contact with on a daily basis; however, more research is clearly needed to understand the drivers of this activity, and to determine if mixtures agonize or antagonize other nuclear receptors.

2822 E-cigarettes: Partnering with Scientists to Enhance Community Engagement

D. Haine, E. Hickman, N. Graves, M. Hughes, M. Rodgers, V. Triana, K. Gray, and I. Jaspers. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

According to the CDC, an estimated 5 million US middle and high school students reported using e-cigarettes in 2019, an increase of 1.4 million youth over 2018. This trend has raised concern in public health circles about youth addiction to nicotine from e-cigarette use and unknown respiratory effects of e-liquid constituents such as flavorings. It has also highlighted a need for youth and community education about the potential health effects of e-cigarettes. In response, researchers investigating the effects of e-cigarette solvents and flavorings on respiratory host defense at the University of North Carolina (UNC) at Chapel Hill partnered with the UNC Center for Environmental Health and Susceptibility's Community Engagement Core (CEC) to engage public health professionals, K-12 audiences, and families in the toxicology of e-cigarettes. For the CEC, partnering with scientists deepens community engagement by providing educational content that is real, relevant and robust; for scientists, partnering with community engagement experts can enhance research endeavors and science communication skills. In this presentation, we will share strategies for effectively involving scientists in community engagement activities and K-12 education by providing examples from the CEC's work to engage broad audiences in learning about the potential health effects of vaping. We will describe (1) hands-on activities developed for use at public science events and (2) a data interpretation activity developed for high school biology students in which students examine evidence that e-liquids and aerosols impair the respiratory immune system. E-cigarettes provide biology students with a relevant context in which to explore and refine what they know about cell structure and function, the immune system, and cellular respiration. We will highlight the process for developing a lesson that incorporates published scientific data and introduces students to the field of toxicology. Though these projects are specific to e-cigarette research, they serve as examples for how scientists in all areas of toxicology can partner with informal science educators to reach broad audiences by developing standards-aligned K-12 and public science education materials.

2823 Integrating New Technologies into High School Toxicology Education

J. N. D'Errico, A. Murray, M. L. Wilkinson, L. M. Aleksunes, D. L. Laskin, and G. L. Guo. *Rutgers, The State University of New Jersey, New Brunswick, NJ.*

Early introduction to the fields of toxicology and environmental health is critical for the development of the next generation of scientists. Towards this effort, the Rutgers Toxicology, Health and Environmental Disease (THED) summer program was established six years ago to provide high school students an opportunity to explore scientific careers and an introduction to principles and approaches fundamental to toxicology. Recently, we integrated interactive technologies into the program. Students were assessed on how effective the technology was in improving engagement, learning, and the overall educational experience. Poll Everywhere, a classroom response system was incorporated into presentations on forensic toxicology, histology, and pathology. Students anonymously answered multiple choice and open-ended questions, participated in word clouds, and responded to clickable image questions in real time using cell phones or laptops. This provided a way to engage students and assess their understanding of the materials being taught; it also provided feedback to instructors on teaching effectiveness. During the summer, THED students also observed a simulation of a patient undergoing cardiac arrest using a high-fidelity simulation mannequin in the Rutgers School of Pharmacy Acute Care Simulation Suite. They also toured the School's Parenteral Sterile Products and Community Pharmacy Simulation Laboratories where they learned about the preparation of intravenous and solid dosage forms of medications and counseling of pharmacotherapy plans, respectively. Using the Likert scoring system (1 low, 7 high), students rated the EMSOP simulation tour experience a mean of 6.4 (0.8 SD, N=53). The pharmacy simulation in the Acute Care Simulation Suite was the highest rated activity for the program overall. Students also commented that they enjoyed the experience and found it relevant to their future career decisions. Overall, the integration of technology into the THED program aided in student engagement and provided real time feedback assessing achievement of learning outcomes. *Supported by NIEHS T32ES007148, P30ES005022, and U54AR055073.*

2824 Lettuce Not Be Salty*:* An Update of a Common Secondary Education Experiment Measuring Seed Germination under Salt-Stressed Conditions

S. Coleman, and J. Mirowsky. *SUNY College of Environmental Science and Forestry, Syracuse, NY.*

Many high school and college classrooms conduct experiments to assess the environmental implications of using salt as a deicer on roadways. Most commonly, this experiment has been completed with sodium chloride as the salt, and seed germination is measured from buttercrunch lettuce seeds. However, as we are becoming a more environmentally conscious society, the use of salt alternatives is becoming more common. Thus, the aim of our work was to update the traditional lettuce seed toxicity experiment to account for two new sodium chloride alternatives and assess their effect on seed germination. For our alternatives, we choose calcium chloride and sodium chloride enhanced with calcium magnesium acetate and a beet juice additive (i.e. beet salt). Calcium chloride is advertised as being more pet-friendly and can be purchased both online and in local and national pet stores. In addition, beet salt is advertised as being less harmful to the environment because it contains the natural ingredient of beet juice and is enhanced with calcium magnesium acetate, which does not contain harmful chlorides. Syracuse, NY - one of snowiest big cities in the United States - launched a pilot program in 2010 to use beet salt on one of its major highways to supplement rock salt, and in 2018 Syracuse started using beet salt on the city's sidewalks to clear the walkways of ice. This suggests that its use may become more common as cities move towards different, more-environmentally friendly salt alternatives. We did a dose- and time-response experiment, utilizing 5 different concentrations of the salts while growing the lettuce seeds for up to 5 days. We found that the lettuce seeds grew the best in the beet salt solutions and the worst in the sodium chloride solutions, with comparable seed growth between the water control and calcium chloride solutions. With discernible differences in growth between the salt types, our results suggest that this experiment can be successfully updated to examine differences between the effects of different salts on plant life in order to assess and discuss the environmental implications of salts and their derivatives on roadways.

2825 Toxicology for Chemists: A Curriculum Project Connecting Toxicology to Chemistry Education

A. S. Cannon. *Beyond Benign, Wilmington, MA.* Sponsor: P. Spencer

A key sustainability challenge today remains that molecular designers (chemists) are not trained how to address hazards at the very beginning, design stage of a product life-cycle. Chemists lack training in toxicology and the understanding of what makes a molecule hazardous to human health and the environment. This knowledge gap results in chemical products that have unintended consequences. Beyond Benign, a non-profit dedicated to Green Chemistry education, has launched a new curriculum project - Toxicology for Chemists - that is aiming to address this knowledge gap. The project involves the development of curriculum and resources that support current and future scientists (chemists) to better understand molecular hazard how to include the information within their design criteria as molecular designers.

A host of curriculum materials and on-line resources are currently being created that will remain open access for instructors, students and scientists to design chemical products that are safer and healthier for humans and the environment. The Toxicology for Chemists program is guided by a key group of advisors, comprised of professional toxicologists and chemists. Throughout the project, the curriculum will be bridging the two subjects - toxicology and chemistry - and connecting key learning objectives from each discipline. By providing much needed toxicology resources for chemists, this will enable scientists to better design and prepare safer alternatives that have reduced human and environmental hazards.

2826 Expanding the Reach of Undergraduate Education Programs at Regional Meetings: Model Programs at Four Regional SOT Chapters

J. P. Gray[1], L. M. Williams[2], L. M. Aleksunes[3], D. Hardej[4], J. Sacco[5], E. D. Sloter[6], and C. P. Curran[7]. *[1]US Coast Guard Academy, New London, CT; [2]Bates College, Lewiston, ME; [3]Rutgers, The State University of New Jersey, Piscataway, NJ; [4]St. John's University, Jamaica, NY; [5]Drake University, Des Moines, IA; [6]Charles River, Ashland, OH; and [7]Northern Kentucky University, Highland Heights, KY.*

Regional meetings are excellent opportunities for undergraduate students to learn about toxicology and to interact with a variety of professional toxicologists. However, the scientific programs at these meetings are often at depths beyond an undergraduate audience, and absent targeted recruiting, undergraduates typically attend only if recommended by an SOT member adviser. The Faculty United for Toxicology Undergraduate Recruitment and Education (FUTURE) committee supports regional chapters with grants and materials to provide undergraduate programming. Several features of undergraduate-focused programming at the SOT Annual Meeting have been successfully adopted at the regional meetings. "Lunch With an Expert" provides an opportunity for undergraduates to interact with toxicologists from alternative career paths to academia, such as industry or government. Undergraduate poster sessions provide an opportunity to present data that is more preliminary, preparing them to later present at national conferences through practice and critical feedback. An undergraduate breakout session has also proven popular among attendees. An "Introduction to Toxicology" slide set provides an overview of career paths and active learning exercises such as the "Opioids" activity have been used at two regional meetings. Both are available at the SOT website in the Learning Resources area for undergraduate educators. A keynote speaker can provide a career-focused talk that describes a pathway to becoming a professional toxicologist. Participants are subsequently encouraged to apply for the national meeting's Undergraduate Diversity Program, or, if they have an abstract, the Pfizer SOT Undergraduate Travel Award. A new unified online program assessment survey was used to provide undergraduate feedback for different aspects of each program for the four regional chapters awarded grants in 2019-2020. Likert scale and free-form responses indicate high satisfaction with all programs, as do comments such as "enjoying meeting people", "enjoyed keynote speakers discussing toxicology and education presentations", and "enjoyed undergraduate breakout session."

2827 Revision of Introductory Toxicology Course and Applications beyond the Classroom in Sierra Leone

R. Wilson[1], F. Arowolo[1], M. Walcheck[1], C. Bradfield[1], and A. Njai[2]. *[1]University of Wisconsin–Madison, Madison, WI; and [2]University of Sierra Leone, Freetown, Sierra Leone.*

Environmental toxicology is a persistent issue in Sierra Leone in large part due to inadequate waste management, rapid population growth, and the release of high levels of hazardous materials into the environment. As a result, Sierra Leoneans are highly susceptible to environmentally-related deaths. While access to education has steadily improved over the last two decades, many adults in Sierra Leone lack resources and tools to combat persisting environmental challenges. Specifically, many members of the government and industry are in positions of influence yet operate with little to no understanding of the basic toxicological problems that plague their communities. In 2018, our group developed the first ever toxicology course taught in Sierra Leone. This course was designed using evidence-based teaching practices, including the incorporation of active learning activities, minimal lecturing, and group work to promote a growth mindset and learner-centeredness. These concepts were tailored towards college students in Sierra Leone such that we employed case studies and local examples that are relevant to this unique environment. The course was taught in the Spring of 2019 and drew nearly 20 students of both graduate and undergraduate standing. Students successfully completed the course by submitting a research paper detailing the science behind a toxicant of interest. After receiving feedback from the students and using the recent publication of the learning framework for undergraduate toxicology courses as our guide, we modified the curriculum to align with the research-backed learning objectives as published (Gray et. al, 2019). The curriculum was also modified to target a broader audience, specifically members of the community such as government officials and industry workers that would benefit from a toxicology education. While the materials were developed for a semester long course, we modified them to be taught in a weeklong certificate program. We retained many of the core concepts of toxicology while also maintaining the learner-centeredness of this the original course. We believe that both the workshop and course model can be applied in other developing countries allowing for more widespread dissemination of the core toxicology concepts.

2828 Team Science in a Summer Undergraduate Fellowship: Field Sampling for Metal Contamination in the Raritan River

C. Doherty, C. Smith, D. L. Laskin, B. T. Buckley, and L. M. Aleksunes. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Summer internships provide undergraduate students with intensive one-on-one training experiences in the laboratory. At Rutgers University, we sought to extend this training to promote scientific collaboration and networking through team-based field sampling. During the 2019 Summer Undergraduate Research Fellowship (SURF) Program, twelve undergraduate students collected surface water from the Raritan River aboard the R/V Rutgers following completion of interactive classroom sessions on heavy metal contamination. The river has a history of extensive pollution from industrial facilities and includes multiple Superfund sites along its shore. In collaboration with the Marine and Coastal Sciences program, surface water was collected in duplicate at 6 sites between New Brunswick, NJ and the Raritan Bay. Students kept field notes on sample characteristics as well as weather and water conditions. ICP-MS analysis revealed a large range of metals concentrations in the sampled surface water. Lithium (mean: 33.0 ppb), barium (mean: 20.8 ppb), and arsenic (mean: 16.2 ppb) were the most abundant metals analyzed, while lead (mean: 0.06), cadmium (mean: 0.02 ppb), and cobalt (mean: 0.48 ppb) were the least abundant. Notable changes in metal concentrations were observed in relation to whether samples were collected near and away from industrial and landfill sites, and may provide clues on the primary sources of contamination. Concentrations of lithium, vanadium, chromium, cobalt, nickel, copper, arsenic, cadmium, cesium, and uranium increased up to 14-fold in samples collected between the Edison landfill and Sayreville brownfield, with an overall trend of increasing concentrations toward the Raritan Bay. By comparison, barium decreased toward the Raritan Bay, while lead was highest upstream from the major contamination sites, but remained constant throughout the remaining the stretch of river. Participants rated the surface water sampling activity highly (mean rating = 4.6, SD 0.5) on a Likert scale of 1-5. The students' overall impression of fieldwork was that it was fun to perform research outside, and that the experience provided tangible relevance of toxicology to their lives. *Supported by the SOT Intern Program, R25ES020721, P30ES005022, and T32ES007148.*

2829 Digital Storytelling in Biology: Increased Engagement and Inclusiveness through a Novel Assessment Method

A. L. Smith, and W. H. Powell. *Kenyon College, Gambier, OH.*

Effective active learning pedagogies enable students to identify and solve problems that inspire and intrigue them. While life sciences courses offer content featuring exciting challenges and achievements, common assessment mechanisms--exams and quizzes--frequently fail to inspire or to facilitate deep learning. Rather, they discourage many students, leading them to drop the course or even leave the discipline. This phenomenon disproportionately affects students from underrepresented backgrounds. Here, we describe a digital storytelling initiative, used in place of a comprehensive final exam, in an introductory biology course. Student teams generated a short video narrative ("digital story") to propose a gene editing strategy for curing a heritable disease and to evaluate the feasibility of its implementation in patients. In-class workshops and evening help sessions were employed to teach students to use bioinformatics databases relating to the course modules (genetics, molecular cell biology, evolution). Students then exercised their new skills to investigate the genetics and molecular mechanisms of a heritable disease and develop a gene editing strategy. Each digital story integrated multiple course concepts and inspired students of diverse backgrounds and test-taking abilities to view material through the lens of their own interests and motivations. We hypothesized that digital storytelling would increase student investment

and confidence as well as achievement of learning goals and retention. To assess the project's effectiveness, we used student surveys and enrollment data. Survey responses were demonstrably enthusiastic, both for the project content and for the opportunity it provided to demonstrate creativity and deep learning. Remarkably few students left the course or received failing grades. We suggest that digital story projects represent an effective learning strategy that could be readily applied to topic reviews, mock grant proposals, and case studies in introductory toxicology courses, and can increase inclusiveness and retention by promoting student engagement. *Support: Kenyon College Center for Innovative Pedagogy and HHMI Inclusive Excellence Initiative.*

PS 2830 Benefits of Near-Peer Mentoring: The Near-Peer Perspective

H. I. Swanson, and L. Xiang. *University of Kentucky, Lexington, KY.*

Undergraduate research experiences that offer individual participation in scientific research programs can play a key role for preparing our next generation of scientists and health care professionals. A key component of a successful research experience is mentoring which is often facilitated by faculty members, but may also involve near-peer mentors (i.e., graduate students). While mentoring relationships provide substantial benefits to the mentee, benefits that may be obtained by a near-peer mentor are not well-documented. The Summer Undergraduate Research in Environmental Health Sciences (SURES) program at the University of Kentucky is a 10-week program that offers research experiences to rising junior and senior undergraduates. Mentoring is provided by both faculty and near-peer mentors (NPMs). The NPM are recruited and selected by the program director, participate in a mentoring training session and are then matched to their respective mentee following a "speed mentoring" event. The NPMs are asked to meet weekly with their mentees and participate in several weekly SURES events. To evaluate the NPM experience, we conducted pre- and post- program surveys. Our survey results indicate that the top three reasons that NPM participated in the SURES program were overall self-improvement, to improve their teaching and mentoring skills and to develop undergraduate students. In working with their mentees during the 10-week period, they reported focusing their efforts on ensuring that the mentees would feel comfortable contacting them and talking with them as well as feeling emotionally supported. The top benefits of the mentoring experience reported by the NPM were gaining experience and skills in mentoring and coaching, and leadership. NPMs also reported they improved their communication and interpersonal skills, learned about current undergraduate students, and further determined their own career interests. The results from this study provide insights into the benefits provided to NPM who engage in a near-peer mentoring relationship that would contribute to their professional career development.

PS 2831 A Native American Tribe and Its Continuing Toxic Legacy

O. Avenbuan[1], D. DeFreese[2], T. McKeon[3], and J. Zelikoff[1]. *[1]New York University Langone School of Medicine, New York, NY; [2]Ramapough Lunaape Nation, New Jersey, NJ; and [3]niversity of Pennsylvania Perelman School of Medicine, Philadelphia, PA.*

In the early 1960s through the late 1970s, millions of gallons of paint sludge and other toxic materials were dumped by a large car manufacturing plant into abandoned mines, forested areas, and nearby homes in Ringwood, NJ. As a result, sections of Ringwood became riddled with toxic metals in their soil, water and air, placing a large environmental burden on the very people who have lived on this land for generations - the Ramapough Lunaape Turtle Clan Nation. Upon community request, samples of soil, water, plants and fish tissue were collected from community-identified sites by citizen scientists and NYU graduate assistants to evaluate soil metal concentrations from this "remediated" 500 acre Superfund site. Soil samples were collected by digging 3-5 inches deep with a plastic shovel and placed into individual zip lock bags stored at room temperature until analyses. Each dried soil sample was analyzed in duplicate using two independent X-ray florescence (XRF) instruments. Twenty heavy metals, including lead (Pb), arsenic (As) and cadmium (Cd) were analyzed and their levels compared to NJ Direct Contact Soil Standards for dermal, ingestion, and inhalation exposure. Both As and Pb were found in several different soil samples collected around the local Ringwood church at levels exceeding the NJ soil standard of 19 mg/kg and 400mg/kg, respectively. Besides being a carcinogen, ingestion of As has been associated with increased cardiovascular and respiratory diseases. Ingestion of Pb, particularly by children causes decreased neurocognition, hyperactivity, lower IQ scores, and immune suppression. The greatest concern about soil contamination arises primarily from health risks from direct contact with the contaminated soil and secondary contamination of water supplies within and underlying the soil. Given the Native American children who continue to play in this area and the Tribes' tradition of growing their own food, this finding is of serious concern for these already-vulnerable Indigenous people. *Supported by NYU NIEHS P30 Center ES-000260-55.*

PS 2832 Measuring Residential Socioeconomic Factors Associated with Pollutant Releases Using the US EPA Toxic Release Inventory

A. Charette, M. Collins, and J. Mirowsky. *SUNY Environmental Science and Forestry, Syracuse, NY.*

Many environmental justice studies claim that the population groups most exposed to disproportionate levels of pollution from polluting facilities are minorities and low-income individuals. This study sought to test that claim against four counties in upstate New York: Albany, Erie, Monroe, and Onondaga Counties. These counties are located within 300 miles of one another, and all contain major Upstate NY cities, including Albany, Buffalo, Rochester, and Syracuse, respectively. Onondaga County is infamous for its presence of polluting facilities, and their associated chemical releases; this is seen particularly with Onondaga Lake, at one point the most polluted lake in the United States. The four selected counties for this analysis are comparable to one another with respect to size, population, geography, and demographics, allowing a larger geographic area to be examined for pollutant releases, while still looking at similar population information. Nine population identifiers assessing residential socioeconomic status (R-SES) were obtained from the 2000 US Census at the block group level. The demographics were grouped together, based upon their similarities, using a hierarchal clustering method. The method produced seven unique residential clusters that were then mapped across the four counties. The location of each Toxic Release Inventory (TRI) facility within the four counties was then geocoded against the clusters to determine which population characteristics, if any, were more influential in deciding whether a facility was located near a group of individuals. It was seen that minorities and low-income individuals were not disproportionately exposed to these polluting facilities. Instead, we found consistently that the largest predictor of whether a polluting facility was found in a geographic location was for laborers working in non-managerial positions. Our findings could be due to companies considering available and skilled labor when siting their facilities. Moreover, the R-SES cluster with one of the highest percentages of laborers in non-managerial positions,78.59% of residents, released over 10 million pounds of chemicals in 2000 alone. The next highest amount of chemical releases by any R-SES cluster was just under 3 million pounds. This suggests those in non-managerial positions are not only disproportionally located near these facilities, they are also exposed to higher levels of pollutants.

PS 2833 A Pilot Project to Apply a Collaborative Framework to Brownfields Redevelopment in Northern Kentucky

E. Asiedu[1], Y. Sene[1], A. Maier[2], M. Maddaloni[2], J. Patterson[3], and C. P. Curran[1]. *[1]Northern Kentucky University, Highland Heights, KY; [2]Cardno ChemRisk, Cincinnati, OH; and [3]University of Cincinnati, Cincinnati, OH.*

A brownfield is a site formerly used for industrial or commercial purposes where future use could be affected by contamination. The goal of this pilot project was to apply and further develop a collaborative framework to enhance community engagement in chemical risk assessment and decision-making for contaminated site redevelopment. The project began with an intensive search of the scientific literature to identify best practices in community-engaged research and risk communication. We also reviewed publicly available documents on over 300 potential redevelopment sites in Northern Kentucky. Following consultation with environmental experts and government agencies, we narrowed the list of sites to 10 for in-depth consideration. The site furthest along with redevelopment plans was the Marianne Theater, a historic building in Bellevue, KY. We are now working with city leaders and residents to develop messaging regarding the building and its value to the community. We will rely on information gained about three other historic theater projects from other area of Kentucky as well as data gathered on successful and unsuccessful brownfield redevelopment projects. The ultimate goal is to identify critical success factors and obstacles that hinder effective redevelopment. A key lesson learned in the early stage of the project was the importance to communicate more than environmental information to gain wider acceptance of a project within a community and to ensure stronger financial support to complete the remediation and renovations.

2834 Needs and Opportunities to Develop Cost-Effective and Safe Dressings to Treat Chronic Wounds in Lima, Peru

F. L. Casado[1], D. N. Guevara-Mendoza[1,2], Y. G. Hinostroza-García[1], and I. Hernandez-Patino[3]. *[1]Pontificia Universidad Católica del Perú, Lima, Peru; [2]Universidad Peruana Cayetano Heredia, Lima, Peru; and [3]Instituto Peruano de Ingeniería Celular y Manufactura Tisular A.C., Lima, Peru.*

Chronic wounds are a burden for health systems worldwide and deplete health resources despite the existence of evidence indicating that self-care prevention reduces hospitalizations and emergency visits. Healing rates range between 21 and 35% and the recurrence rate is large, leading to high bed occupability, excessive treatment costs and negative effects on quality of life. Therefore, there is a need to innovate in the treatment of wounds of difficult resolution from clinical and health services management perspective. This work analyses interviews with experts in the Metropolitan area of the city of Lima, Peru to identify problems arising when treating chronic wounds. On average, the interviewees stated that they serve ten patients in bed per month and seven patients per outpatient clinic. Thanks to this information, we estimate that in Lima alone there would be at least 16,200 patients with chronic wounds. Likewise, the interviewees stated that they use about ten hydro-colloid or hydro-active dressings per month, which allows estimating that there is an annual demand of 5.8 million dressings. When analyzing the primary interests of stakeholders, it was concluded that their main concerns are the healing time and the bad smell generated by the wounds of the patient. In summary, we conclude that this is a new market in the country, which means that there are no leaders and the market is divided by the different existing commercial products; however, it is the hydrogels that are beginning to position themselves in this market. Thus, a strategic alliance should be made with proactive doctors working in the public sector and private sector revolutionaries to magnify the reception of innovative dressings in the city of Lima, Peru.

2835 Dietary Exposure and Health Risk Estimation of Polycyclic Aromatic Hydrocarbons (PAHs) Levels in Nile Tilapia from a Tropical Creek

A. I. Usese, M. O. Egbuatu, M. P. Kuton, and L. O. Chukwu. *University of Lagos, Lagos, Nigeria.*

Increasing levels of persistent organic pollutants in aquatic ecosystems is a major concern globally due to the potential adverse effects to ecological receptors and humans via the food chain. The study assessed the risk associated with dietary exposure to polycyclic aromatic hydrocarbons (PAHs) in muscle tissues of Nile tilapia, *Oreochromis niloticus* from Agboyi creek in Southwest-Nigeria. PAHs were determined using Gas Chromatography-Mass Spectrometry (GC-MS) following EPA methods. Of the 16 priority PAHs detected, the mean concentration of Acenaphthene (60.51 ± 69.85 µg/kg) accounting for 19 % of total PAHs was the most predominant while Benzo (a) pyrene (0.08 ± 0.17 µg/kg) accounting for 0.03 % of total PAHs was the lowest. Estimated daily intake (EDI) of PAHs through consumption of fish were higher than reference dose (RfD) indicating high risk. The results of Hazard Index (HI) > 1 also emphasized potential negative health effects in consumers. Furthermore, the toxic equivalent concentration (TEC) values for Benzo (b) fluoranthene (35.79 µg/g) and Dibenz (a, h) anthracene (56.25 µg/g) which exceeded USEPA screening value of 0.67 ng/g and the estimated excess cancer risk (ECR) for 7 most toxic PAHs detected in fish tissues suggests that life time exposure in adult consumers would result in cancer risk.

2836 Canaries in the Coal Mine, Canines on the Couch: A Model for Investigating Contaminant Exposures to Support Human Health Research

C. F. Wise[1], S. C. Hammel[2], N. Herkert[2], J. Ma[1], A. Motsinger-Reif[3], H. M. Stapleton[2], and M. Breen[1,4]. *[1]North Carolina State University, Raleigh, NC; [2]Duke University, Durham, NC; [3]NIEHS, Research Triangle Park, NC; and [4]Duke Cancer Institute, Durham, NC.*

Only 5-10% of human cancers can be explained by genetics alone, suggesting the environment plays a strong role in disease etiology. Quantifying the impacts of exposures remains challenging due to latency issues that can take years to manifest after exposure. Dogs may provide valuable insights as a sentinel species for exposure-related human disease because they experience similar environment exposures, have a 6-8 fold shorter lifespan, share many clinical and biological behaviors, and have closely related genomes. We evaluated individual exposures among pet dogs and their paired human companions using silicone dog-tags and wristbands as personal passive samplers (n=30 pairs). Silicone samplers were analyzed for a suite of chemicals across multiple compound classes, including organophosphate esters (OPEs), polybrominated diphenyl ethers, polychlorinated biphenyls, phthalates, and pesticides. As a validation pilot study, we collected urine samples from each study participant and dog, and measured levels of OPE metabolites. 32 of the 41 compounds measured, with a detection frequency >50%, were significantly correlated between dog and human wristbands (r_s = 0.38-0.90; p <0.05), indicating the dog could be a valuable One Health model and potential sentinel species for examining how exposure to consumer product chemicals impact health. The concentrations of several OPEs parent compounds measured on the dog tags were significantly correlated with their respective metabolites in urine (r_s = 0.50-0.71; p <0.01). These data support the value of using the domestic dog as a sentinel species to investigate the potential long-term health impacts on humans from shared exposures.

2837 The Modified Molisch Reaction for Quantitative Determination of Bisphenols

C. J. Deere[1], O. A. Agu[1], S. Babu[2], M. Claville[2], and R. M. Uppu[1]. *[1]Southern University and A&M College, Baton Rouge, LA; and [2]Hampton University, Hampton, VA.*

Bisphenol A [BPA or 2,2-bis(4-hydroxyphenyl)propane] is a high volume chemical mainly used in manufacturing of polycarbonate plastics. Exposure to BPA has been associated with endocrine disruption, birth defects and metabolic syndrome. Among other sources of exposure, contact with thermal paper used at cash registers can be a significant source of BPA exposure and absorption through the skin. We have recently shown that the Molisch test, extensively used for the detection of sugars, with minor modifications can be used to detect BPA in thermal cash receipts. However, since the Molisch test and its modification are just the ring tests with low detection limits, we have examined if the modified Molisch test can be a basis for a quantitative determination BPA and other bisphenols, *viz*., bisphenol-F (BPF), bisphenol-S (BPS), and bisphenol-Z (BPZ). To establish optimal conditions for the quantification, experiments were performed with different sugars (source of furfural derivative) and bisphenols, all being incubated in a strong acid medium at 45±2 ^{0}C. Typically, 0.2 ml of 1% sugar solution (glucose or galactose in water) was mixed with 2 mL of cold 75% H_2SO_4. A 20 µL-aliquot of bisphenol (BPA, BPF, BPS or BPG; ; 0 to 1 mM) in 70% ethanol was added while contents were mixed thoroughly. The final mixtures were heated for periods up to 60 min in a water bath at 45±2 ^{0}C. The samples at various intervals were cooled to the room temperature and read in a Geneses 10S UV-Vis spectrophotometer between 400 and 700 nm. The results were surprising in that, of the various bisphenols studied, only BPA gave the characteristic purple product with a broad absorption maximum centered around 564 nm. In the case of BPA, the product formation reached a maximum by about 35 min and remained constant for periods beyond 60 min. The $\xi_{564\ nm}$ for the BPA reaction product was found to be 35,000 $M^{-1}cm^{-1}$ (detection limit: 0.5 µM). While the exact reasons for bisphenols other than BPA not forming the purple product are not clear, we believe the oxidation of the furfural condensation product with these bisphenols was too slow or negligible. This proposition was confirmed by the apparent lack of purple ring formation in the modified Molisch test performed with other bisphenols used. Apart from providing a sensitive method for determination BPA, the results of BPS not forming a purple product are truly significant given the fact most manufactures of thermal paper are now shifting their attention to BPS or other bisphenols and that BPS, as reported in some recent studies, was present in the samples of human breast milk. Thus, the present study can be of significance to know presence of BPA as an adulterant in other bisphenol formulations.

2838 Suspect Screening for Urinary Metabolites of Imidacloprid after a Single Oral Dose in a Human Volunteer by HR-MS

S. Wrobel[1], D. Bury[1], J. Klenk[2], B. A. Nebel[2], B. Hauer[3], V. N. Belov[4], H. Hayen[5], H. M. Koch[1], T. Brüning[1], and H. U. Käfferlein[1]. *[1]Ruhr-Universität Bochum, Bochum, Germany; [2]Universität Stuttgart, Stuttgart, Germany; [3]University of Stuttgart, Stuttgart, Germany; [4]Max Planck Institute for Biophysical Chemistry, Göttingen, Germany; and [5]Universität Münster, Münster, Germany.*

Imidacloprid (IMI) is one of the world's most widely used insecticides. Despite its global use for more than 20 years, only little is known about its metabolism in humans. However, exposure and risk assessment of IMI using human biomonitoring requires sensitive and specific biomarkers of exposure and knowledge of their respective urinary excretion fractions. Therefore, this study intended to investigate the human metabolism of IMI and to identify urinary

metabolites potentially applicable as biomarkers of exposure. After a single oral dose of 5 mg IMI to a male volunteer, urine samples were collected for 48 h (IRB Reg No. 18-6680-BR). The obtained samples were subjected to enzymatic deglucuronidation and analyzed using LC-Q-Orbitrap-MS with subsequent data mining using a commercial software. In a preliminary analysis, screening hits were identified based on the accurate masses of their (protonated and deprotonated) molecular ions, including ^{13}C and $^{35}Cl/^{37}Cl$ isotopolog signals with corresponding signal intensities. Hits with plausible excretion profiles (peak area vs. time) were included in a confirmatory analysis using data-dependent acquisition of product ion spectra. Screening hits were confirmed as tentative urinary metabolites of IMI if the major mass signals in the product ion spectra could be explained by plausible fragment ions. 6-Chloronicotinic acid, a compound which has been previously suggested to be a metabolite of IMI and other neonicotinoids in humans and, consequently, has been already used for exposure assessment, could not be detected in this first screening. Non-metabolized IMI was found in all urine samples. Moreover, two phase-I metabolites previously described in rats, 5-hydroxy IMI and IMI-olefin, were identified. These metabolites together with their $^{13}C_2$,^{15}N-isotope-labeled analogs have been synthesized for further verification by HPLC-MS/MS. Our results show for the first time specific biomarkers that are actually most suitable for human biomonitoring of IMI.

2839 Aggregated Exposure to Di(2-ethylhexyl) phthalate from Foods and Cosmetics through a Physiologically Based Pharmacokinetic (PBPK) Model and Comparison with Measured Urinary Metabolite Concentrations: Results from the EuroMix Biomonitoring Study

T. Husøy[1], M. A. Martinez Rodriguez[2], V. Kumar[2], R. P. Sharma[2], M. Andreassen[1], F. Sonnet[1], A. K. Sakhi[1], C. Thomsen[1], and H. Dirven[1].
[1]Norwegian Institute of Public Health, Oslo, Norway; and [2]Universitat Rovira i Virgili, Tarragona, Spain.

A human biomonitoring (BM) study was performed to study exposure of chemicals present in foods and personal care products (PCPs). For two 24-hour study periods separated by 2-3 weeks, adult volunteers (44 males and 100 females) in Norway kept detailed diaries on food consumption (type/brand, weight, time and packaging material) and the usage of PCPs (type/brand of product, time and number of applications). In parallel, 24 hours urine samples were collected. Monte-Carlo simulation was carried out by Oracle Crystal Ball ©. This software calculates exposure based on the propagation variable of variability and uncertainty given by each parameter in a probability function, until a certain number of iterations. Individual external aggregated exposure to di(2-ethylhexyl) phthalate (DEHP) aggregating dietary with non-dietary exposure from PCPs was calculated. External exposure estimates were used for internal dosimetry simulation using physiologically based pharmacokinetic (PBK/PBPK) models. Simulated 24 hours urinary concentrations were compared with BM of the urinary metabolites of DEHP, mono-2-ethylhexyl phthalate (MEHP), mono-2-ethyl-5-hydroxyhexyl phthalate (MEHHP), mono-2-ethyl-5-oxohexyl phthalate (MEOHP) and mono-2-ethyl 5-carboxypentyl phthalate (MECCP). The results show that diet is the major contributor to DEHP exposure for both males and females, with an external exposure approximately 10 times higher than for the exposure from personal care products (PCPs). The main contributors to the mean dietary DEHP exposure are milk and dairy products, with a percentage contribution of 69.3 % and 62.8 % of the total exposure for males and females respectively. Additional food groups contributing to DEHP exposure were grains and grain-based products, fruits and vegetables, meat and fish. For both males and females, deodorants contribute most to the exposure of DEHP from PCPs, with a 79 % and a 53 % contribution, respectively. Verification of the exposure data using forward-dosimetry PBK/PBPK model give good convergence with 24 hours urinary concentrations of simulated and measured BM data. The measured concentration of the MECCP metabolite seems to correlate well with the simulated high exposure, while the measured concentrations of MEHP, MEHHP and MEOHP were more dispersed and partly overlapped with both simulated low, medium and high metabolite exposure.

2840 Aggregate and Product-Specific Exposures to Chemicals from the Use of Consumer Products

P. Price, K. Isaacs, K. Dionisio, E. Cohen Hubal, P. Egeghy, and K. Phillips.
US EPA, Research Triangle Park, NC.

Many chemicals are present in more than one consumer product. As a result, an individual will receive multiple doses of a chemical from use of different products and their aggregate (total) dose from all products will exceed the dose received from any single product. The Chemical Human Exposure Model (CHEM) evaluates residential exposures to chemicals having consumer product sources using a population-based, longitudinal model that employs a Monte Carlo simulation method. CHEM simulates the combinations of products used by a household, the composition of the products, and the chemical exposures to an individual that result from the use of the products. We used CHEM to investigate the relationship between product-specific and aggregate doses in the general adult population in the United States. Six compounds known to be used in many types of products were evaluated: propylene glycol; isopropyl alcohol; methyl paraben; linalool; limonene; and di-sodium EDTA. Daily systemic doses were estimated for 1,000 adults for each day of a simulated year. Each adult's dose from their, or another household member's, use of a consumer product was determined and summed to give the aggregate dose for the adult. The model outputs were used to estimate measures of chronic exposures (annual average daily dose) and acute exposures (largest daily dose). The impacts of uncertainty in product composition were also investigated. The number of products used by an individual in a given year that contained a chemical ranged from 0 to 14. The 95% lower confidence limits in the six chemical's doses were less than 10^{-6} mg/kg and the 95% upper confidence limits ranged from to 0.1 to 3 mg/kg. CHEM predicted that chronic average and acute daily doses were similar in size. This occurred because many of the products containing the compounds were used on a daily basis. For insight into the relative importance of chemical exposures from multiple products, the Maximum Aggregate Ratio (MAR), defined as the ratio of an individual's aggregate doses to their largest product-specific doses, was computed. Values of MAR for both chronic and acute exposures of the simulated adults had median values of less than 1.2 for all chemicals and did not exceed 2.7 for any individual and chemical. MAR values declined with increasing aggregate doses for both acute and chronic exposures. These findings suggest that for the six chemicals, adults with the largest exposures had aggregate exposures that were similar in size to their largest product-specific doses. This pattern is consistent with the patterns observed in cumulative exposures to multiple chemicals for humans and environmental receptors.

2841 Characterization of Aerosolized Particles Generated from Machining of Nanoclay-Enabled Composites

E. G. Lee[1], L. Cena[2], J. Kwon[3], H. Park[3], A. Afshari[1], A. Wagner[4], S. Agarwal[4], C. Dinu[4], R. Gupta[4], G. Casuccio[5], K. Bunker[5], T. Lersch[5], S. Friend[1], and T. Stueckle[1]. *[1]NIOSH, Morgantown, WV; [2]West Chester University, West Chester, PA; [3]KOSHA, Ulsan, Korea, Republic of; [4]West Virginia University, Morgantown, WV; and [5]RJ Lee Group, Monroeville, PA.*

Nanoclay-enabled polymer nanocomposites (NPCs) are poised to dramatically impact composite technologies across numerous applications. Release of airborne particulate containing organomodified nanoclays (ONC) at key steps along the NPC life cycle represents an emerging occupational inhalation exposure hazard. This study hypothesized that different types of surface organic coatings, percent ONC loading, and machining process would impact the physicochemical characteristics of generated airborne particulate. Two different ONCs, Cloisite 93A and Cloisite 25A, were embedded in polypropylene (PP) at three different percent loading (0%, 1%, and 4%). Each NPC was characterized for ONC dispersion and strength properties. Next, NPCs were sanded in a controlled exposure chamber with different sanding belt types to generate airborne particulate, which was measured in real-time. Inhalable and respirable fraction samplers were deployed to collect particles for electron microscopy analyses to quantify particle characteristics. ONC type and percent loading influenced NPC strength and toughness, which significantly correlated with particle release. Both 1% ONC and 4% Clois93A NPCs exhibited significantly greater strength, toughness, total particle number, and respirable mass concentration than 4% Clois25A and virgin PP NPCs. A majority of mass from machined NPCs was within the inhalable fraction. A noticeable peak in the respirable fraction (<30 nm) was detected and varied in magnitude, with 1% NPCs producing more ultrafine particulate. ONC type and load influenced the released NPC dust particle size, mass, and elemental composition, which was a complex mixture of NPC and sand particulate. ONC was primarily found protruding from or embedded within NPC composite particles. In summary, abrasion of NPCs produces particulate in the inhalable fraction with 1) protruding ONC platelets and 2) noticeably different concentrations of

sanding particles depending on ONC type, loading, and NPC strength characteristics. These findings implicate the potential for airborne particle exposure during manipulation of NPC materials.

2842 Exposure Assessment of Traffic-Related Air Pollution in El Paso, Texas, Using Personal and Ambient Monitoring

I. Uwak[1], T. Ramani[2], N. Johnson[1], R. Jaikumar[2], J. Aguilera[3], I. Ramirez[3], L. Whigham[3], W. Li[3], and S. Vallamsundar[2]. *[1]Texas A&M University School of Public Health, College Station, TX; [2]Texas A&M Transportation Institute, Bryan, TX; and [3]University of Texas at El Paso, El Paso, TX.*

El Paso is home to one of the largest border crossings in the US and has also been in nonattainment of the National Ambient Air Quality Standards (NAAQS) for particulate matter in the past. Significant sources of emissions have been identified in the US-Mexico border region, where large volumes of cross-border freight and passenger movement occur. These emissions are due to a large number of heavy-duty vehicles/trucks which are often moving slowly or idling while waiting in long lines at the border. The objective of this exploratory study was to characterize human exposure to traffic-related air pollution in El Paso, utilizing both personal and ambient air monitoring. We measured real-time personal exposure to fine particulate matter ($PM_{2.5}$) and black carbon among high school teachers in El Paso using lightweight backpacks containing air monitoring devices over 24 hours. The ambient monitors were placed within the school premises and measured daily $PM_{2.5}$ and black carbon concentrations. Preliminary results from the real-time personal air monitors show the average daily mass concentration of $PM_{2.5}$ was 88.35 μg/m^3, (SD=270.89) and of black carbon was 1.09 μg/m^3, (SD=0.86) but in the absence of one outlier with very high levels of $PM_{2.5}$, the average for $PM_{2.5}$ became 2.68 μg/m^3 (SD=3.34). From the ambient monitors, the average daily mass concentration of $PM_{2.5}$ was 8.98 μg/m^3 (SD=5.45), and for black carbon was 1.12 μg/m^3 (SD=1.67). These low personal exposure levels may be as a result of the teachers spending most of their workday indoors, within the school and infiltration shielding offered by the building. However, further analysis of the filters from the personal air monitors is ongoing to reveal the actual concentrations and the implications for public health.

2843 Longer Commutes Are Associated with Increased Human Exposure to Tris(1,3-Dichloro-2-Propyl) Phosphate

A. Reddam[1], G. Tait[2], N. Herkert[2], S. C. Hammel[2], H. M. Stapleton[2], and D. C. Volz[1]. *[1]University of California Riverside, Riverside, CA; and [2]Duke University, Durham, NC.*

Organophosphate esters (OPEs) are a class of semi-volatile organic compounds (SVOCs) used as flame retardants, plasticizers, and anti-foaming agents. Due to stringent flammability standards in vehicles and the ability of OPEs to migrate out of end-use products, elevated concentrations of OPEs have been found in car dust samples around the world. As many residents of Southern California spend a significant amount of time in their vehicles, there is a potential for increased human exposure associated with longer commute times. With approximately 70% of the University of California, Riverside's undergraduate population commuting, the objective of this study was to use silicone wristbands to monitor personal exposure to OPEs by commute time for a subset of these students. Participants were asked to wear wristbands for five continuous days and complete daily surveys about the amount of time spent in multiple modes of transportation, and these data were then used to calculate a participant-specific total commute score. Phthalates contributed to the vast majority (97%) of total SVOC mass present on the study participant wristbands, followed by OPEs, brominated flame retardants, polychlorinated biphenyls/pesticides, and fluorotelomer alcohols. Components of the commercial flame retardant mixtures Firemaster 550 (triphenyl phosphate, or TPHP, and isopropylated triaryl phosphate isomers) and Firemaster 600 (TPHP and tert-butylated triaryl phosphate isomers) were strongly correlated with other OPEs found within the same mixture. Moreover, tris(1,3-dichloro-2-propyl) phosphate (TDCIPP) was significantly correlated with certain Firemaster 500 components and tris(2-chloroisopropyl) phosphate (TCIPP). Finally, out of all SVOCs measured, TDCIPP was the most strongly and significantly correlated SVOC ($p<0.0001$) with total commute score, indicating that longer commutes are associated with increased human exposure to TDCIPP. Overall, our findings raise concerns about the potential for chronic TDCIPP exposure within vehicles and other forms of transportation, particularly within densely populated and traffic congested areas such as Southern California.

2844 Exposure Assessment and Micronuclei Induction in Populations Occupationally and Environmentally Exposed to Electronic Waste in South-West Nigeria

O. G. Igharo[1], C. F. Harrington[2], E. L. Igharo[1], O. E. Ola-Davies[3], J. I. Anetor[3], and O. O. Osibanjo[3]. *[1]University of Benin, Benin City, Nigeria; [2]Supra-Regional Assay Service (SAS) Trace Element Centre, Guildford, United Kingdom; and [3]University of Ibadan, Ibadan, Nigeria.*

Informal electronic waste (e-waste) reprocessing in Nigeria is reportedly substantial in Africa, putting the growing exposed population at high risk of metal toxicity. The existence and or extent of chromosomal aberration or genotoxicity indicators in the growing e-waste exposed populations in Nigeria have not been documented. In this cross-sectional study, 632 consenting participants were recruited from South-West Nigeria; consisting of 381 e-waste workers (EWW), 120 environmental e-waste exposed participants (EEP) and 131 age-matched unexposed participants (UP), serving as controls. A validated structured questionnaire was used to assess exposure pattern, the Inductively Coupled Plasma-Mass Spectrometry was used to determine toxic metal levels in whole blood while frequency of micronucleated polychromatic erythrocytes (MNPCE)/1000PCE in peripheral blood film was determined by modified Micronucleus Assay. Occupational and environmental exposures were high for EWW; environmental WEEE exposure which was moderate for the EEP, was minimal for UP. A duration of exposure of ≥ 5 years and exposure frequency ≥ 6 hours/day; 6 days/week (9360 hours in any 5 year duration) was observed with both EWW and EEP. Routes of exposure observed in EWW entailed eyes, oral route, nasal cavity, and skin. In addition, the proportion of EWW that used personal protective equipment (PPE) while working was barely 10.24% while non - PPE users constituted the majority (89.76%) of the studied population. Blood levels of the toxic metals (lead, arsenic and cadmium) were significantly raised. The frequency of MnPCE/1000PCE in EWW (22.70 $\pm$ 0.15) was significantly higher than EEP (4.17 $\pm$ 0.28), which in turn was significantly higher than the lowest frequency (0.99 $\pm$ 0.76) observed in UP. The observed exposure pattern and the comparatively higher MN induction in the e-waste populations may suggest risk of significant cytogenetic damage and aberrant chromosomal changes associated with occupational e-waste reprocessing in Nigeria.

2845 Urinary Blood Lead Clearance and Its Relationship to Glomerularfiltration Rate Based on a Large Population Survey

W. C. Thayer[1], G. Diamond[1], J. Brown[2], M. Burgess[3], M. Follansbee[4], L. Gaines[3], and J. Klotzbach[1]. *[1]SRC Inc., East Syracuse, NY; [2]US EPA, Research Triangle Park, NC; [3]US EPA, Washington, DC; and [4]SRC Inc., Portland, ME.*

Decreasing glomerular filtration rate (GFR) in association with increasing blood lead levels (BLL) or bone lead (Pb) concentrations have been reported in epidemiological studies of Pb workers and general populations. A complicating factor in studies that rely on BLL or bone Pb as exposure metrics for studying GFR is that alterations in GFR may directly affect Pb body burden by changing metal clearance. In 2009, the National Health and Nutrition Examination Survey (NHANES) began reporting data which enabled calculation of paired blood Pb clearance (CbPb) and serum creatinine clearance (CsCr), a metric of GFR, for individual subjects. Estimates of CbPb and CsCr were determined for approximately 7,600 subjects with data provided by NHANES for survey years 2009–2016. Eligible subjects included those with Pb concentration in blood and urine, creatinine concentration in serum and urine, urine flow volume(s) and time(s) (to estimate urine flow rate), gender and age. Subjects with GFRs < 10 or >1000 L/day were omitted under the assumption that the GFRs outside of this range indicated disease or potential errors in the data. Median CbPb in adults was 0.04 L/day (5th-95th percentile range: 0.01–0.12). Stepwise linear regression models for CbPb were estimated to identify significant explanatory variables. Variables explored in stepwise regression included BLL, CsCr, and several variables that were significant in linear regression models of CsCr (age, gender, body weight, and height). Regression models explained approximately 68% of variance in CbPb in adults, with >98% of explained variance attributed to CsCr. Significant predictors ($p<0.05$) for adolescents included CsCr, gender, age, and height (R^2 = 0.67), and CsCr accounted for approximately 95% of the explained variance in CbPb. Values for variance inflation factors were <1.6 for all independent variables in all models, indicating multicollinearity was not an issue with the regression models. Our study is apparently the first that quantified individual subject CbPb and GFR in a large sample. The slope for the relationship between CsCr and CbPb predicts a nearly 1:1 relationship between GFR and CbPb where 10% a change in CsCr is associated with a 10% change in CbPb. These results provide an improved understanding of the possible effects of reverse causation in the interpretation of studies of associations between blood Pb and GFR.

2846 The Chemical Landscape of High-Throughput New Approach Methodologies for Exposure

K. K. Isaacs[1], K. Dionisio[1], D. Meyer[2], K. Phillips[1], G. Ruiz-Mercado[2], J. Sobus[1], E. Ulrich[1], B. Wetmore[1], and J. Wambaugh[1]. *[1]US EPA, Research Triangle Park, NC; and [2]US EPA, Cincinnati, OH.*

The rapid characterization of risk to humans and ecosystems from commercial chemicals requires information on both hazard and exposure. The US EPA's ToxCast program and the interagency Tox21 initiative have screened thousands of chemicals in various high-throughput (HT) assay systems for *in vitro* bioactivity. EPA's ExpoCast program is developing complementary HT methods for characterizing the human and ecological exposures necessary to interpret HT hazard data in a real-world risk context. These new approach methodologies (NAMs) for exposure include computational and analytical tools for characterizing multiple components of the complex paths chemicals take from their source to human and ecological receptors. These pathway components include chemical use, release, transport, toxicokinetics, and, ultimately, external and internal exposure. Exposure NAMs being developed in ExpoCast include machine learning models that draw inferences from existing data, statistical frameworks that integrate predictions from multiple models, and non-targeted analytical screening methods that generate new HT monitoring information. Here, we evaluate the landscape of exposure NAMs in the context of various chemical lists of scientific and regulatory interest, including the ToxCast and Tox21 libraries, Toxic Substances Control Act (TSCA) inventories, and larger libraries of structures recently curated within EPA's CompTox Chemicals Dashboard. We show that exposure NAMs drastically improve the coverage of the chemical landscape compared to traditional approaches. While existing HT approaches provide comprehensive coverage of many key chemical inventories for human receptors, additional work is needed to develop analogous predictions for ecological receptors. A critical bottleneck is the prediction of pathway-specific chemical releases, especially ambient releases to the environment. *In vitro* toxicokinetics information is needed for additional substances to refine exposure-dose modeling and expand the domain of *in silico* models. The utility of exposure NAMs has been demonstrated in limited case studies on household dust and consumer products, rapidly increasing the number of chemicals identified in these media. The application of exposure NAMs to additional media will be critical for the improving the scope of evaluation datasets for HT exposure predictions.

2847 Assessing the Effectiveness of a Residential Metals Abatement Program (RMAP) Using Blood Lead Levels in Children

C. Van Landingham[1], and R. A. Schoof[2]. *[1]Ramboll US Corp., Monroe, LA; and [2]Ramboll US Corp., Seattle, WA.*

The Butte RMAP program begin in 1994 and by the end of 2018 sampling of soil and dust was completed for 3,332 out of 3,646 residential parcels in the Butte Priority Soils Superfund site in Montana, with 1,152 properties and attics abated. To assess the effectiveness of the RMAP in reducing lead exposures, a 2014 study (Phase 1) evaluated blood lead levels (BLLs) in children ages 1-5 during 2003-2010. National Health and Nutrition Examination Survey (NHANES) blood lead data for the applicable years were weighted to match the Butte population for key variables known to affect BLLs and was used as a reference population. During the study period, Butte BLLs declined more rapidly than those of the NHANES reference population, and by 2009-2010 Butte geometric mean BLLs were no longer significantly different from NHANES. An update to this study (Phase 2) includes 2,330 BLL records from 2012 through 2017. The blood lead limit of detection (LOD) is 3.3 µg/dL for Phase 2, with BLLs measured using a point-of-care device, compared to the LOD of 1 µg/dL for Phase 1 data. Almost 80% of BLLs in Phase 2 are below the current LOD so remediation effectiveness is focused on evaluating the percent of children with BLLs greater than the reference level of 5 µg/dL. Among children 12 to 60 months of age, 172 of 2,330 (or 7.4%) tested between 2012 and 2017 had BLLs greater than 5 µg/dL. Older neighborhoods with more historical mining influence show a higher percentage of samples greater than 5 µg/dL in both study periods, and the percentage of BLLs above 5 µg/dL were about 20-30% higher on average in the warmer half of each year. House age was the most influential variable in the Phase 1 study, but information on house age is no longer collected as part of the more recent NHANES so could not be compared in the Phase 2 study. While this factor and the much higher detection limit for the Phase 2 Butte blood lead data prevent direct comparison of rates of elevated BLLs between NHANES and Butte, comparison of the rates of change in the elevated BLLs between the two datasets can still be conducted. Between 2003 and 2016 the percentage of the BLLs in Butte greater than 5 µg/dL descended at a faster rate than did the NHANES BLLs. Both of the Phase 1 and Phase 2 data show a leveling off in the later years (2013 to 2016) with higher rates persisting in Butte. Due to the very old housing stock and the higher poverty rate among the Butte population, substantial differences in lead risk factors between the Butte and the NHANES populations are likely to persist even when remediation is complete.

2848 Investigating Sensitization Activity of Azobenzene Disperse Dyes via the Direct Peptide Reactivity Assay (DPRA)

K. E. Overdahl, D. M. Gooden, B. G. Bobay, P. L. Ferguson, and H. M. Stapleton. *Duke University, Durham, NC.*

Azobenzene disperse dyes used to color synthetic fabrics have been characterized in literature as immune sensitizers. However, little is known about human health implications of these dyes in indoor environments. Scarcity of data is due partly to the lack of purified reference standards. Our research group and others have found that azobenzene disperse dyes are widely present in house dust, raising questions about their potential to behave as immune sensitizers at environmentally relevant levels indoors. Here, we report on sensitization activity of azobenzene disperse dyes known to be present in children's clothing and indoor environments at environmentally relevant concentrations. To address the lack of standards, individual dyes were extracted from 13 commercial dye mixtures via Soxhlet extraction, followed by purification using CombiFlash Rf+ Chromatography (Teledyne ISCO, Hexane:EtOAc). Purity and identity were evaluated using high-performance liquid chromatography (HPLC) with diode array detection (DAD), high-resolution mass spectrometry (HRMS), and nuclear magnetic resonance spectroscopy (NMR). We confirmed the chemical structures of 15 dye compounds for use as reference standards. Because covalent binding to nucleophilic proteins is a strong indicator for chemical sensitization potential, we used a spectrophotometric *in vitro* Direct Peptide Reactivity Assay (DPRA) to measure covalent protein binding via peptide depletion induced by azobenzene disperse dyes. Twenty dyes were tested: the 15 in-house purified compounds as well as commercially-available dyes Disperse Orange 25, Disperse Orange 37, Disperse Orange 61, Disperse Blue 373, and Disperse Violet 93. Results were confirmed via an HPLC-based reference DPRA to evaluate performance of the spectrophotometric DPRA for this application. Preliminary results demonstrate that dyes such as DO61 bind to nucleophilic protein residues and induce up to 41% (± 1%) peptide depletion at 0.2mM in a dose-dependent manner. This is notable when compared to characterized sensitizers such as 1-chloro-2,4-dinitrobenzene, which induces 100% peptide depletion at 10mM but induces only 16% depletion at 1mM (Wareing et al. 2017). Results suggest that exposures to azobenzene disperse dyes may present sensitization risks, warranting further detailed characterization.

2849 Dietary Lead and Phosphate Interactions Affect Oral Bioavailability of Soil Lead in the Mouse

W. C. Thayer[1], K. D. Bradham[2], C. M. Nelson[2], G. L. Diamond[1], K. G. Scheckel[3], M. Noerpel[2], K. Herbin-Davis[2], B. Elek[2], and D. J. Thomas[2]. *[1]SRC Inc., East Syracuse, NY; [2]US EPA, Research Triangle Park, NC; and [3]US EPA, Cincinnati, OH.*

Low level exposure to lead (Pb) in early life has profound and long-lasting health effects. Widespread use of this toxic metal has resulted in extensive and persistent contamination of soil and dust. Soil and indoor dust are major sources exposure of children to Pb. A critical determinant of the extent of internal exposure to Pb through ingestion of soil or dust is its bioavailability, the fraction of ingested Pb that crosses the gastrointestinal barrier and is available for systemic distribution. Effects of dietary phosphate (P) level on the oral bioavailability of Pb present in soil were examined in a mouse model. Adult female C57BL/6 mice had free access to AIN-93G purified rodent diet amended with Pb as a soluble salt, Pb acetate, or in a soil matrix (NIST SRM 2710a) with a certified Pb concentration of 5520 mg/kg. In these studies, the basal diet contained P at a nutritionally sufficient level (0.3% w/w), with approximately equal amounts of P contributed by potassium phosphate in the diet's mineral mix and by phosphoproteins in casein, the diet's protein source. The modified diets contained P at a lower (0.15%) level by omission of potassium phosphate from the mineral mix, or a higher (1.2%) level by increasing the amount of potassium phosphate in the mineral mix. Pb speciation analysis was performed for samples of diet and feces using X-ray absorption spectroscopy. Relative bioavailability was estimated as the ratio of linear regression slopes for relationships between cumulative Pb dose (mg) and tissue Pb level (mg/kg of bone or kidney, mg/l of blood). The linear regression slopes were estimated by simultaneously fitting test (NIST SRM 2710a) and reference (Pb acetate) group tissue data to linear regression models sharing common intercepts. For either dietary Pb source (Pb acetate or NIST SRM 2710a), low dietary P level markedly increased accumulation of Pb in bone, blood, and kidney. Tissue Pb levels in mice fed a high P in diet were not different from

mice fed the basal P diet. Dietary P and Pb interacted to affect body weight change and feed efficiency in mice. The relative contribution of different Pb species in diet and feces was also affected by dietary P level. Differences in Pb species between diet and feces indicated that transformation of Pb species can occur during gastrointestinal tract transit. These interactions between Pb and P that alter Pb speciation may be important determinants of the bioavailability of Pb ingested in soil.

2850 Comparisons of $PM_{2.5}$ and $BC_{2.5}$ Concentrations in the Subways of Cities in the Northeastern United States

D. Luglio[1], M. Katsigeorgis[1], R. Kim[1], J. Adragna[1], J. Hess[1], A. Raja[1], J. Fine[2], T. Gordon[1], and M. Vilcassim[3,1]. *[1]New York University Langone Health, New York, NY; [2]Norwalk Hospital, New York, NY; and [3]University of Alabama at Birmingham, Birmingham, AL.*

Subways move millions a people a day across the world, bringing people to and from work and leisure. They are essential to the working economy of many cities. More are expected to be built, globally. We know that particulate matter (PM) levels on platforms are many times higher than ambient, but we know little of the origin of this pollution. No other study has investigated intercity differences in subway air quality in the Eastern United States. Here we report the $PM_{2.5}$ and $BC_{2.5}$ concentrations in the subways in Philadelphia, Boston, Washington, and in the MTA and PATH run stations in the New York City metropolitan area. We monitored real-time concentrations with a pDR 1500 and a microaethalometer on a total of 83 platforms in 74 stations across 12 lines during the morning (6:00 - 10:30 AM) and evening (3:00 - 7:00 PM) rush hours. We also collected aerosol particles on quartz and Teflon filters at the stations with the two highest measured $PM_{2.5}$ concentrations measured in each city; we calculated the organic carbon (OC) and elemental carbon (EC) and the $PM_{2.5}$ concentrations with each form of filter, respectively. Comparisons between city, time of day, on- and off- train, and train line were made. Mean real-time $PM_{2.5}$ concentrations in underground stations were 391.91, 250.45, 144.88, 138.70, 37.91 ug/m^3, for MTA-New York, PATH-New York, Washington, Boston and Philadelphia, respectively. The average ambient PM2.5 concentration across these cities was 15.91 ug/m^3. Stations serviced by PATH had the highest $PM_{2.5}$ concentrations, as calculated by gravimetric analysis, we had observed in the world, a mean of 1204.25 ug/m^3. A measurement at the Christopher Street station was valued as high as 2773.33 ug/m^3. We also observed significant differences between on-train and on platform and AM and PM $PM_{2.5}$ concentrations. Furthermore, there was considerable variability in OC and EC concentrations between and within cities. Our results show that there is considerable variability in the $PM_{2.5}$ concentrations across cities in the Eastern United States. One train system, the PATH, is particularly polluted with gravimetric measurements calculated at almost 1000 times ambient levels. Means to reduce and to identify the sources of PM in these stations should be undertaken.

2851 Asbestos Exposure Risk from Ceiling and Other Building Materials

K. Guth, U. P. Desai, S. Godwin, J. McCluskey, and R. Harbison. *University of South Florida, Tampa, FL.*

Asbestos exposure risk was assessed from review of bulk samples collected from 27 sites from twelve states. A total of 288 bulk samples contained asbestos. Data was obtained from 18 commercial property sites and 9 residential properties. All asbestos-containing material (ACM) identified in all samples contained Chrysotile. Chrysotile content ranged from 1.25% to 70% among the various bulk samples. A total of 41 samples from popcorn or acoustical ceiling texture material were analyzed. Chrysotile content in popcorn or acoustical ceiling texture ranged from 2% to 10%. The data set contained samples from Florida, California, Colorado and other western and southeastern states. The exposure risk from textured ceiling material including popcorn and acoustical ceilings is associated with disturbance, detachment, and removal of textured surfaces. Disturbance of asbestos- containing building material may result in fiber release and mobilization of asbestos containing materials. Building materials such as duct paper contained the highest 70% ACM and roofing material exterior plaster contained the lowest 1.25% ACM. Also, caulk, wall covering, and other building materials contained asbestos. Eight personal breathing zone air samples were collected following NIOSH Method 7400 during the removal of asbestos containing textured ceiling material under negative pressure in a commercial building in Oklahoma. The personal exposures ranged from below the lab's reporting limit to 0.0201 f/cc. Area air sampling was also conducted during a large-scale (residential) asbestos removal project in Florida. A total of 400 area samples were collected during the removal of asbestos containing materials (textured ceiling, caulk, mastic and drywall) inside an active containment under negative pressure and outside of the containment structure to approximate personal breathing zone exposures. The airborne asbestos concentration ranged from below the labs reporting limit to 0.0135 f/cc. Textured ceiling material and other ACM building materials may increase the risk of asbestos exposure in commercial and residential structures.

2852 Analysis of NIOSH Health Hazard Evaluations Featuring Lead (Pb)

K. Carlson. *NIOSH, Cincinnati, OH.*

Lead (Pb) is used today in electronics, smelting, ammunition, and galvanized steel. Given this variety of possible worker exposures, evaluations summarizing occupational exposures are valuable. This analysis of 80 health hazard evaluations (HHE) with data collected by NIOSH from 1991 to 2017 found that work-related Pb exposure data has been collected in at least 32 US states. In addition, HHEs from Washington D.C., Puerto Rico, and Bolivia, were included in the analysis. Many different sectors were covered as defined by the National Occupational Research Agenda (NORA). Four (5 %) of these evaluations were from warehousing and utilities, 5 (6 %) were from public safety or healthcare, 11 (14 %) were from wholesale and retail trade, 12 (15 %) were from construction, 17 (21 %) were from manufacturing, and the majority, or 31 (39 %) were from the services sector. Given the large variety of site-specific needs and types of work covered by these NIOSH evaluations, it is not surprising that programs protecting workers from Pb were not uniformly established. Of these 80 HHE studies, 19 (24 %) reportedly had a respiratory protection program (RPP) and 16 (20 %) had a lead surveillance program (LSP). Ten (13 %) of the HHEs discussed workplaces with both a LSP and a RPP. The HHEs documented Pb exposures in regions across the United States, including Oregon, Colorado, Texas, Wisconsin, Florida, and Maine. OSHA Region 5, or the mid-western states of MN, WI, MI, IL, IN, and OH were the most represented in these HHEs. Twenty-eight percent, or 22 of 80 evaluations, were represented by Region 5 out of the ten possible OSHA regions. A wide range of exposure levels were also observed across this sample of occupational Pb exposures; air concentrations were documented in some situations as not detectable (ND), while the highest sample read 5900 µg/m^3. Blood lead levels in these participants ranged from ND to 40 µg/dL. This analysis demonstrates that occupational Pb exposures are observed in workers across the United States and throughout many different types of industries. This analysis also highlights the need for future collaborations with NIOSH as employers set up respiratory protection plans, safety programs, and medical surveillance to protect the health of workers. The wide variety of settings where Pb exposures can take place demonstrates that Pb remains a priority issue in occupational health within the United States of America. *Disclaimer: The views in this abstract are those of the authors and do not necessarily represent the views of the National Institute for Occupational Safety and Health.*

2853 Occupational Biomonitoring and Interpretation of 2,4-Dichlorophenoxyacetic Acid (2,4-D) Using Field Deployable Sensors and PBPK Modeling

A. A. Han[1], Y. Wang[2], A. D. Du[2], Y. Lin[2], and J. N. Smith[1]. *[1]Pacific Northwest National Laboratory, Richland, WA; and [2]Washington State University, Pullman, WA.*

Onsite rapid biomonitoring of occupational exposures supports safe working conditions and practices. Traditional quantification methods of chemicals in biofluids may have long turnaround times leading to delayed analysis and, if warranted, remedial action, highlighting the need for faster measurements and interpretation of measurements. In order to improve measurement and interpretation time of 2,4-dichlorophenoxyacetic acid (2,4-D), we developed a field deployable device for 2,4-D detection and a computational pharmacokinetic model for measurement interpretation. The antibody-based device features an optical-sensing platform that utilizes a smartphone to take measurements of colorimetric changes dependent on the presence of 2,4-D in biological samples. After optimizing conditions, the device detected 2,4-D in the linear range of 1 - 40 µg/L in biofluids. For measurement interpretation, we developed a physiologically based pharmacokinetic model (PBPK) to predict 2,4-D disposition in rats and humans and utilized a Transwell *in vitro* system to parameterize salivary transport of 2,4-D. The PBPK model predicted 2,4-D concentrations in urine (533 µg/L) of 2,4-D backpack applicators following an 8-hour workday exposed to 0.008-0.012 mg/kg/day of 2,4-D. At those same exposure conditions, the model predicted concentrations of 2,4-D in saliva at lower levels than urine (average 1.49 µg/L), but still within the linear range of the sensor. Since these expected levels are well within the detection

limits of the sensor, this device may be suitable for non-invasive and rapid onsite screenings in occupational settings. *Supported by CDC/NIOSH grant R01 OH011023.*

2854 Effects of Occupational Exposure to Low-Level Benzene on Oxidative Damage in Chinese Workers

K. Wang[1], Y. Zhou[1], X. Li[2], B. Wang[1], T. Wang[1], R. Sun[1], L. Yin[1], Y. Pu[1], and J. Zhang[1]. *[1]Southeast University, Nanjing, China; and [2]Yanzhou Center for Disease Control and Prevention, Yangzhou, China.* Sponsor: J. Zhang, Environmental Mutagenesis and Genomics Society

Benzene is not only a common environmental pollutant, but also a common organic solvent and chemical raw material in industry and chemical production. Because of the relevant protective measures have been taken by government and enterprises, level of the occupational benzene exposure of most Chinese workers are below the occupational limit (PC-TWA 6mg/m^3). The purpose of this study was to explore the effects of occupational exposure to low-level benzene on oxidative damage of workers. A total of 90 workers exposed to benzene and 85 non-exposed workers were enrolled in this study. The benzene monitoring data in workplace and the health examination data of workers were collected. Blood routine was examined, the S-phenylmercapturic acid (S-PMA), metabolite of benzene in urine, was measured by high performance liquid chromatography-mass spectrometry. The content of lipid peroxide malondialdehyde (MDA) in plasma and 8-hydroxy-2′-deoxyguanosine (8-OHdG) in urine were detected by colorimetry. The effects of benzene exposure on oxidative damage were analyzed by adjusting sex, age, BMI, smoking and alcohol consumption, and the correlation between S-PMA,8-OHdG and MDA was analyzed. Benzene concentrations at all workplace monitoring sites were below 0.6 mg/m^3. The blood routine results showed that the average red blood cell and platelet counts in the exposed group were significantly lower than those in the control group ($p < 0.001$), but still located within normal limits. The results of S-PMA test showed that average concentration of S-PMA in urine of exposed workers was significantly higher than that of control group (26.54μg/g Cr vs 7.84μg/g Cr, $p < 0.005$); average concentration of MDA in plasma and 8-OHdG in urine of exposed workers were also higher than that of control group ($p < 0.005$); the urine concentration of S-PMA was positively correlated with the 8-OHdG. These results suggested that occupational exposure to low-level benzene still could increase the oxidative damage in workers and the S-PMA, metabolite of benzene had a good correlation with the oxidative damage induced by benzene. *This work was supported by the National Natural Science Foundation of China (Grants no. 81872645, 81730087).*

2855 Direct Quantification Method for S-Phenyl Cysteine Benzene: Oxide Hemoglobin Adduct

T. A. Mustapha, N. Drury, Y. Liu, T. J. McDonald, and N. M. Johnson. *Texas A&M University, College Station, TX.*

Benzene oxide adducts of hemoglobin have been used as biomarkers of benzene exposure in rodent models and exposed human populations using gas chromatography mass spectrometry methods. This method entails reacting dried protein with trifluoracetic anhydride and methanesulfonic acid to yield phenyltrifluorothioacetate, the ultimate product that is quantified. In this study, we developed a high performance liquid chromatography-isotope dilution mass spectrometry method for the directed quantification of S-Phenyl Cysteine (SPC) , a benzene oxide adduct of hemoglobin cysteine, following acid hydrolysis of globin. The use of electron spray ionization on a triple quadrupole mass spectrometry system was employed to demonstrate a linear response in SPC concentration ranges from 200 fmol to 100 pmol with a 13.51% coefficient of variation between triplicates of samples. This new method showed a sensitivity of 20 pmol SPC g^{-1} globin, similar to the prior gas chromatography method, but requires no derivatization. SPC remained unchanged following hydrolysis and was determined to be stable for direct quantification. Ample precision, accuracy and sensitivity shown in this method makes it ideal for environmental exposure quantification. Validation for environmental exposure is currently in progress using human samples following hurricane related exposures in Houston.

2856 Assessment of Mineralogical Composition and Ecological Risk of Potentially Toxic Metals in Surface Sediments of a Tropical Estuary

L. B. Ibanga, A. I. Usese, and L. O. Chukwu. *University of Lagos, Lagos, Nigeria.*

The bioaccumulation in excess of natural loads and potential for remobilization of sediment bound metals in aquatic ecosystems is a major environmental concern. The study assessed the degree of contamination and risk associated with ten heavy metals in forty-five surface sediments from fifteen sites in Lagos Lagoon. Metals concentrations was determined using Agilent 7500c Inductively Coupled Plasma Mass Spectrometry (ICP-MS) while mineralogical composition was examined using X-ray diffraction (XRD) and Scanning Electron Microscopy (SEM). SEM and XRD analyses indicate that alumino-silicate and silty clay minerals influenced metals mobilization and bioavailability from sediment. The result showed that Fe with a mean concentration of 26031.96 mg/kg was the most abundant. The observed metal levels in the order; Fe > Mn > Zn > Cu > Cr > Pb > Co > Ni > As > Cd did not exceed the threshold limits for the protection of aquatic life. Estimated pollution load index (PLI), geoaccumulation index (Igeo), contamination factors and degree of contamination also indicate low to moderate environmental risks. However, the result of enrichment factor demonstrated high level of enrichment from anthropogenic sources which might still pose adverse biological effects. This calls for continuous monitoring and effective legislation in the region.

2857 Biomarker Identification for Human Exposure to Petrogenic Polycyclic Aromatic Hydrocarbons

D. Yap[1], G. Golovko[1], H. Spratt[1], H. Fernando[2], S. Ansari[1], S. Croisant[1], J. Sullivan[1], and C. J. Elferink[1]. *[1]University of Texas Medical Branch at Galveston, Galveston, TX; and [2]Prairie View A&M, Prairie View, TX.*

On April 20, 2010, the Deepwater Horizon (DWH) oil rig explosion released approximately 4.9 million barrels of crude oil into the Gulf of Mexico. Communities that rely heavily on the Gulf for their livelihood and sustenance were deeply concerned with the long-term health effects of consuming seafood laden with crude oil. Despite extensive studies on the Aryl Hydrocarbon Receptor (AHR)-mediated toxicities of pyrogenic polycyclic aromatic hydrocarbons (PAHs) such as benzo[a]pyrene, data on the human health impacts of petrogenic PAHs found in crude oil is scarce. This study aims to identify candidate biomarkers of exposure to petrogenic PAHs that can activate AHR-mediated pathways. Plasma samples were collected longitudinally from 100 volunteers in each of four partner communities (Biloxi, Mississippi; Gulfport, Mississippi; Houma, Louisiana; and Galveston, Texas) between 2012 and 2014. Extensive survey data, health assessments, and blood and urine clinical analyses were also collected. Total plasma PAH levels were measured using Gas Chromatography-Mass Spectrometry (GC-MS) and AHR-mediated activities were quantified using a modified Chemically Activated LUciferase gene eXpression (CALUX) bioassay. Results show that individual total plasma PAH levels did not correspond well with AHR activation, consistent with the presence of distinct bioactive and potentially harmful PAHs in some samples. Of the 42 PAH congeners tested, the petrogenic PAH C3-Naphthalene body burden showed significant positive correlation with AHR bioactivity and may serve as a candidate biomarker. Marked differences in total PAH levels and AHR bioactivities were seen in the subjects from Biloxi and Gulfport despite residing in the same Gulf Coast region. These indicate possible influences from other factors that may be identified using the health assessment and survey data. A general increase in total plasma PAH levels across the 3 years was also observed which may be attributed to an increase in seafood consumption in the ensuing years after the DWH oil spill. This study highlights the need for long-term monitoring of human exposure to sources of crude oil contamination. Future studies include identification and validation of biomarkers of effect to petrogenic PAHs that may aid in risk assessments. *This work is supported by NIH grants R01ES026874, U19ES020676, 1P30ES06676, and T32ES007254.*

2858 Assessment of Lead Exposure Controls on Bridge Painting Projects Using Worker Blood Lead Levels

K. Guth, M. Bourgeois, G. Johnson, and R. Harbison. *University of South Florida, Tampa, FL.*

A retrospective analysis of worker BLLs was conducted using blood lead data collected by four bridge painting contractors before and after lead exposure. The objective of the study was to evaluate the efficacy of exposure controls in preventing elevated blood lead levels (BLLs) (> 25 µg/dl) during bridge painting projects. The contractors selected for the study submitted BLL data for 289 workers representing ten work tasks and 11 bridge painting projects. In total, 842 BLL results were evaluated. The mean BLL for all workers was 10.8 µg/dl at baseline compared with 14.9 µg/dl after two months of exposure and 15.0 µg/dl after four months of exposure. 28.6 % of the painters and 35.2 % of the laborers had a 10 µg/dl incremental increase or greater in BLL two months after initial exposure. Likewise, 18.4 % of the painters and 25.9 % of the laborers had a BLL greater than 25 µg/dl during the same time. The BLLs that exceeded the 25 µg/dL threshold ranged from 30µg/dL-63 µg/dL for painters and 26 µg-56 µg/dL for laborers. All work tasks with high-intensity exposure (abrasive blaster/painter, abrasive blaster, painter & laborer) experienced an average BLL increase that ranged from 0.24 µg/dl to 8.9 µg/dl two months after initial exposure. In contrast, two months after the initial follow up blood testing, 3 out of the 4 work tasks with high-intensity exposure showed a decrease in average BLLs (range -2.6 µg/dl to -3.1 µg/dl) suggesting the reduction is associated with a modified exposure control. These results indicate the evaluated exposure controls are not effective at maintaining worker blood lead levels in some of the work tasks with high-intensity exposure to the targeted goal of 25 µg/dl. They also suggest that blood lead sampling should be conducted every month after baseline until blood lead levels are controlled to an acceptable concentration.

2859 Delta-9-Tetrahydrocannabinol (THC) Exposure from Vaporized Cannabis Concentrate in Regulated Markets Is Lower Than Smoked Cannabis

A. Fox, and E. Rufer. *PAX Labs Inc., San Francisco, CA.*

Cannabis concentrate aerosolization ("vaping") is a new and increasingly common method of cannabis consumption. A frequent criticism of cannabis concentrates is their high potency, and the implication that this increases THC exposure-related harm. However, due to the novelty of the consumption method as well as the regulatory challenges inherent in studying cannabis, the literature on THC concentrate inhalation is remarkably sparse. This presents significant challenges for public health officials and policymakers. This study aims to evaluate how delta-9-tetrahydrocannabinol (THC) exposure from aerosolized THC concentrates ("vaping") compares to that from combusted cannabis flower (joint smoking). Real world usage data demonstrate that THC exposure is lower for vaping than joint smoking for the majority of users, even though cannabis concentrates have a much higher THC concentration than cannabis flower (70-90% vs. 10-25%). Usage data from tens of thousands of regulated cannabis users that opted-in to sharing their data were collected via a mobile app connected to a digital vaporizer. Several parameters were measured (including puff timing, frequency, duration and aerosolization energy), and input into a machine-learning model to extrapolate dosages. Data collected from January 2018 through July 2019 show that daily THC exposure via aerosolized cannabis concentrates is significantly lower than exposure from smoking cannabis flower (based on consumption practices cited in the published literature). This is further supported by research showing that cannabis smokers self-titrate their puff size and puff number based on THC potency and expected effects. Consumption of unregulated (illicit) cannabis concentrates is likely higher, as these products are often diluted ("cut"); thus consumers adjust their habits and practices to achieve similar THC exposure and expected psychoactive effects. This model may be used to assess the risks of other toxicants to which consumers may be exposed.

2860 Characterization of Volatile Organic Chemicals (VOCs) in Air Collected on Synthetic Turf Fields in California

P. Wong[1], R. Woods[1], K. Sutherland-Ashley[1], R. Maddalena[2], M. Russell[2], J. Claude[1], M. Macias[1], L. Lim[1], and L. Zeise[1]. *[1]California Environmental Protection Agency, Sacramento, CA; and [2]Lawrence Berkeley National Laboratory, Berkeley, CA.*

There are more than 900 public or private synthetic turf fields in California. Synthetic turf utilizes a crumb rubber infill made from ground-up recycled waste tires, which have a complex and largely unknown chemical composition. Concern has emerged about the possible health effects of inhalation exposure to chemicals released from synthetic turf fields. Potential exposure to athletes and bystanders of all ages can occur during both sport and non-sport related activities. Diverse environmental conditions and age of the field also likely influence the release of chemicals from the turf. OEHHA sampled 35 fields of various ages across California and is assessing the potential health risks from uses of these fields. We sampled the air off-field and at on-field locations close to soccer activities at 4 heights (4 inches to 65 inches) above field surface. A total of 24 tire-related volatile organic chemicals (VOCs) and 43 common air pollutants were targeted in the air sample analysis using gas chromatography/mass spectrometry. We identified 59 VOCs from air collected on synthetic turf fields. A few tire-related VOCs (benzothiazole, methyl isobutyl ketone, and 2-methylfuran) displayed a height-dependent concentration gradient, with concentrations decreasing with increased height. Many of the common environmental pollutants, xylene, toluene, and phthalates, were present in similar concentrations at the various heights. The chemical concentration gradient noted between tire-related VOCs and common pollutants informs the extent that the synthetic turf field is the source of emission of these tire-related VOCs. This information will assist in assessing human health risks from chemicals released from the synthetic turf.

2861 Risk Assessment of Glyphosate Exposure from Consumer Application of Roundup Using a Margin of Safety Approach

D. G. Kougias, H. Reamer, M. Kovochich, A. McEwen, E. Miller, B. Roberts, C. Comerford, and J. Pierce. *Cardno ChemRisk, Chicago, IL.*

Due to the widespread application of glyphosate, a non-selective herbicide used in a variety of products, its environmental presence is common such that the general population is exposed to glyphosate in foods and in drinking water. Despite this, environmental exposures to glyphosate are considerably low in comparison to those exposed occupationally. Although previous studies have evaluated exposure to horticultural workers, no study to date has characterized the absorption and biological fate of glyphosate in consumer applicators following the use of glyphosate-containing herbicides in residential yard and garden settings. Therefore, the objective of this study was to measure glyphosate levels in urine over time following consumer application of a commercially available glyphosate-containing herbicide (Roundup®) and estimate the corresponding systemic dose in order to perform a risk assessment using a margin of safety approach. Considering that consumer applicators of glyphosate-containing herbicides are presumably exposed predominantly through inhalation and dermal routes, we evaluated each exposure route separately. In the current study, there were six study participants (i.e., "applicators") per exposure group with equal representation of each gender, for a total of 12 subjects. Each applicator sprayed approximately 16.3 gallons of a 0.96% glyphosate-containing solution (after diluting per manufacturer instructions) for 100 minutes in a gravel yard. Here, we found that, regardless of exposure route, urinary glyphosate levels generally peaked within six hours following application and were statistically indistinguishable from background levels at 24 hours post-application. In general, dermal exposure was greater than inhalation exposure. Moreover, even with the use of conservative assumptions for internal dose estimations, all 12 consumer applicators had internal doses of glyphosate below internal doses estimated from the established health-based guidance values. This pilot study demonstrates that glyphosate exposure from consumer application of a commercially available glyphosate-containing herbicide is not a health concern; however, large-scale studies are necessary to corroborate these findings.

2862 Evaluating Allergic Contact Dermatitis Risk for Organic Residuals Detected in Consumer Products

K. Morris-Schaffer[1], K. Bogen[2], and A. Gauthier[2]. *[1]Exponent, Sacramento, CA; and [2]Exponent, Oakland, CA.*

Risk of allergic contact dermatitis from consumer products is increasingly becoming a public health concern and consumer product liability risk for manufacturers. This is relevant with the increase of wearable electronic and other wearable consumer products, which can increase the leaching or dermal load of potential sensitizers. Previous research and predictive model development have shown that several well-characterized sensitizers, including nickel, chromium and acrylates, demonstrate a similar log-normal relationship between their likelihood of ACD elicitation and their dermal load. The objective of this assessment was to evaluate the previously described model's potential application to new organic sensitizers. These sensitizers are found as organic residuals in a variety of common polymer and adhesive materials. Patch test data for these organic sensitizers were compiled from regulatory and medical chemistry databases, and then selected based on data quality. The selected patch test data was then evaluated on goodness-of-fit for the previously established log-normal model. Finally, a dermal load (μg/cm^2) was calculated for each sensitizer that was correlated with an approximate 5% level of ACD elicitation risk among sensitized individuals. This 5% elicitation risk is equivalent to the calculated elicitation risk for the current nickel dermal load standard (0.5 μg/cm^2) evaluated under EN 1811 as set by the European Nickel Directive. In summary, we report that common organic sensitizers, found in modern adhesives and polymers, follow a similar relationship as sensitizers that already have regulatory oversight. This relationship can be leveraged along with patch test data from the literature to evaluate the potential elicitation risk for detected organic sensitizer residuals in consumer products.

2863 Implementation of Online Sample Extraction: the Final Step Toward Fully Automated LC-MS Urine Drug Screening

A. Filipenko. *Bruker Scientific, Billerica, MA.*

Systematic toxicological analysis (STA) using comprehensive screening approaches is a major part of everyday work in toxicology, usually involving different analytical techniques. The great benefit of immunoassays (IA) in routine screening of body fluids is the high degree of automation regarding sample preparation and reporting of results. In recent years, LC-MS has become a key technique in STA, but in contrast to IA an appropriate sample preparation is crucial for screening of biological samples. Offline liquid-liquid extraction (LLE), solid phase extraction (SPE) or protein precipitation (PP) are often laborious but mandatory steps and their integration into the analytical workflow is the missing piece towards a fully automated LC-MS screening analysis. The goal of this work was to implement an online μSPE into an existing LC-MS method to achieve a fully automated LC-MS screening of urine samples. Full integration of the online sample extraction and LC-MS screening method was achieved, and developed solution was extensively tested. Recovery Efficiency (RE), Matrix Effects (ME), Limits of Detection (LOD) and reproducible of results have been analyzed and validated with real samples in comparison to routine sample preparation and STA. All μSPE-LC-MS screening results were in good agreement with the initial routine analysis. LC-MS screening of fortified urine using online μSPE led to similar or better results than the routine sample preparation. The online extraction time of approximately 14 minutes fits well into the run-time of LC-MS analysis. Fully automated LC-MS screening eliminates the human factor in the routine analysis and not only improves productivity and reproducible, but also minimizes the exposure of the lab staff to potentially infectious samples.

2864 Estimation of MMP2 and MMP9 in the Plasma of Ill Gulf War Veterans

M. V. Brahmajothi[1], M. B. Abou-Donia[1], E. Koukkotou[2], and L. Conboy[3]. *[1]Duke University Medical Center, Durham, NC; [2]Beth Israel Deaconess Medical Center, Boston, MA; and [3]Massachusetts College of Pharmacy and Health Sciences, Worcester, MA.*

Matrix metalloproteinases are essential enzymes that degrade extracellar matrix proteins and are also known to cleave cell surface receptors. These enzymes play a dynamic role in cell maintenance, proliferation, differentiation, tissue remodeling, tissue repair, and in host defense, capable of cleaving cell surface receptors and even inhibiting cytokines under normal conditions. Aberrant activation of these MMPs can release apoptotic ligands, resulting in cellular dysregulation in various systems, including muscles and neurons, and eliciting immune responses, leading to inflammation in some. MMP2 and MMP9 are initially synthesized as inactive zymogens with pro-enzyme domain, which gets removed when the enzyme becomes active. The pro-peptide domain consists of conserved cysteine residue that interacts with zinc in the active site, maintaining an inactive form by preventing the binding and the cleavage of the substrate. Activation of pro-MMP2 and pro-MMP9 are mediated by thrombin, activated protein C and plasminogen activator/plasmin system and the activity is also controlled through TIMP-3. Since MMP2 is gelatinase A and MMP9 is gelatinase B, they are upregulated at sites of tissue damage and inflammation. It can also be activated by several cytokines and growth factors. Increased levels of MMP2 and MMP9 (Matrix metalloproteinase-MMP) are implicated in several diseases including neurological diseases. In this study, we estimated the level of MMP2 and MMP9 in the plasma of 30 Gulf War veterans with Gulf War Illness (GWI), 30 healthy controls (HC), 20 asymptomatic Gulf War veterans (aGWV), and 30 subjects with irritable bowel syndrome (IBS). We performed Enzyme Linked immunosorbent assay and a functional zymography to determine the pro and active MMP2 and MMP9. The active form of MMP2 and MMP9 were significantly increased in GWI compared to other groups ($p<0.0001$) and was increased twofold in IBS subjects when compared to aGWV and HC ($p<0.01$). Not much of a difference was observed between aGWV and HC. *This study was supported by GWIRP award GW170103 - W81XWH-18-1-0454.*

2865 Assessment of Benzene, Toluene, Ethylbenzene, and Xylene (BTEX) Contamination in Surface Water of Oil Producing Communities in Delta State, Nigeria

G. B. Akanni. *University of Pretoria, Pretoria, South Africa.*

Oil spillage and pollution of surface water bodies is commonplace in oil producing areas in Nigeria. Three major rivers namely; Obosi, Olokun and Abalaka rivers were assessed for their levels of total hydrocarbon (THC). The BTEX measurements in all the rivers exceeded National Drinking Water maximum contaminant levels (MCLs) in 90, 30, 12, and 8% of the samples, respectively. Obosi river had the highest THC values of 972 mg/l. While Olokun and Abalaka rivers recorded THC values of 757.97 mg/l and 402.52 mg/l respectively. Seasonal variation in the concentration of THC in water samples from these rivers showed that there was significant ($P<0.05$) difference in the measured concentration of THC between dry and wet seasons. The concentration of BTEX in these surface water bodies indicated a high level of environmental toxicity. Impact of decades of oil spills in the Niger delta region would have acute and long-term effects on human health. The findings in this study, makes clear indication that the composition and quality of surface water bodies around oil producing areas are being altered by hydrocarbon constituents from oil spillage. The impact of this study was to assess BTEX levels and the environmental impact on biodiversity.

2866 Assessment of Microbial Toxicity Level in Hospital Wastewater in Enugu Metropolis, Nigeria

C. Nwakanma. *Michael Okpara University of Agriculture, Umuahia, Nigeria.*

The problem of contamination of the environment by hospital and industrial effluent or wastewater has been an issue of concern to the public health of any area where these industries and hospitals are located. This study sets out to determine the level of contamination and toxicity levels caused by the discharge of wastewater from different wards at Kenechukwu Specialist Hospital Thinker's corner, Enugu, Nigeria. The microbial pathogens and toxic metal analyses of the hospital wastewater were determined using established procedures and standards. Wastewater samples were collected from three wastewater outlets of the hospital with pre-cleaned sterile and dried containers. The three sampling points were from Theatre Ward-(TWWS), Maternity ward-(MWWS) and Laboratory ward-(LWWS). The isolated pathogenic bacteria include *Staphylococcus aureus, Escherichia coli, Pseudomonas aeruginosa, Salmonella typhi, Proteus vulgaris, Shigella* sp., Bacteriodes *sp., Citrobacter* sp. and *Enterobacter* while the isolated non-pathogenic organisms were *Pseudomonas aeuroginosa, Serratia* sp. and *Bacillus* subtilis. The result also showed the presence of *Aspergillus flavus*, a pathogenic fungus as the only isolated fungi species in all wastewater samples from the different wards. High level of microbial contamination was observed in wastewater effluent from the maternity ward (MWWS). The toxic metals analysis showed the presence of Arsenic, Lead, Mercury and Chromium. Results shows that toxic metals were within the threshold of WHO permissible limit. Therefore, it was recommended that it would be necessary to properly treat all the hospital wastewater before discharging into the environment to avoid the possible

environmental health risk that might be associated with the discharged contaminated wastewater. Close monitoring of the toxic metal concentration of the discharge water is also suggested.

2867 Determining Potential Sources of Persistent Organic Pollutants in Contaminated Human and Animal Food

W. Guo[1], J. Archer[2], M. Moore[2], J. Bruce[2], M. McLain[2], S. Shojaee[2], W. Zou[1], L. Benjamin[3], A. Adeuya[4], R. Fairchild[2], and H. Hong[1]. *[1]US FDA/NCTR, Jefferson, AR; [2]US FDA Arkansas Laboratory, Jefferson, AR; [3]US FDA/CVM, Rockville, MD; and [4]US FDA/CFSAN, College Park, MD.* Sponsor: W. Tong

Persistent Organic Pollutants (POPs) present in human and animal food have been a big concern for food safety due to their persistence and toxic effects. To ensure food safety and protect human health from POPs, it is important to understand sources of POPs contamination and then minimize human dietary exposure. In the US Food and Drug Administration (FDA), to determine the sources of POPs contamination, human experts need to manually identify the congener pattern in the mass spectra data of contaminated sample and compare it with potential sources samples results. However, the visual comparison is time consuming and solely dependent on the human expert. To improve the accuracy and reproducibility, we developed a software to assist identifying sources of POPs contamination by quantifying the similarities between the contaminated sample and potential source samples data. Different types of similarities scores were computed and used to rank potential source samples based on user's need. We tested the software on a diverse set of contaminated samples by comparing the list of sources determined using the software with those from human expert analysts. The tests confirmed that the software meets user's requirement and provides results consistent with human experts' observation. In conclusion, the software improved the accuracy and reproducibility of the evaluation process by providing consistent quantifying results and reducing the need for user intervention.

2868 Biosensor Technology Applications in Galveston Bay and Houston Ship Channel: Rapid Analyses for Soils and Sediments

K. M. Camargo[1], M. A. Unger[2], A. Knap[3], T. L. Wade[3], J. L. Sericano[3], J. Horney[4], T. M. Dellapenna[5], T. J. McDonald[6], and W. A. Chiu[1]. *[1]Texas A&M University, College Station, TX; [2]Virginia Institute of Marine Science, Gloucester, VA; [3]Texas A&M University Geochemical and Environmental Research Group, College Station, TX; [4]University of Delaware, Newark, DE; [5]Texas A&M University at Galveston, Galveston, TX; and [6]Texas A&M University School of Public Health, College Station, TX.*

After Hurricane Harvey, multiple soil and sediment samples were obtained from Manchester, TX, Galveston Bay and the Houston Ship Channel (GB/HSC). Given the suite of organic analytes requested for these samples a rapid and efficient prioritization method was necessary. The purpose of this study was to prioritize samples for exposure risks of polycyclic aromatic hydrocarbons (PAHs). The Virginia Institute of Marine Science (VIMS) biosensor technology was implemented to prioritize PAH analysis for soil and sediment samples. Coupled with gas chromatography/mass spectrometry (GC/MS), individual PAH analysis found alkylated PAHs were dominant within sediments rather than EPA Priority 16 PAHs. Soil samples differed in composition as low molecular weight PAHs and the EPA Priority 16 PAHs were primarily present. Based on these patterns, soil hazard quotients (HQs) were calculated for a child's ingestion risk (range: 1.17E-4 to 6.37E-2). Both of these values are well below 1, where levels exceeding 1 would be considered samples of concern. 2016 sediment cores were analyzed to establish relevant depths to consider in future sampling trips to GB/HSC. The depths containing the highest PAH totals included 30-35cm, 35-40cm, and 40-45cm and both cores primarily consisted of perylene (0.01607-0.52559 mg/kg; 0.01821-0.48393 mg/kg) and pyrene (0.03932-0.16417 mg/kg; 0.09782-0.20832 mg/kg). Initial pore-water analysis streamlined GC/MS analytical workload by prioritizing samples; whereby the GC/MS results contextualized the data for risk characterization. Despite all samples exhibiting low risk, the prioritization and risk screening methods established by this project and a 2019 sampling trip, will afford field scientists to rapidly characterize a site for PAH gradients. *Supported by T32 ES026568; NIEHS P42 ES027704, 3R01ES024245, 2018 KC Donnelly Supplement Award.*

2869 Formulation Development and Validation of an Analytical Method for a Combination Dose Formulation of Abacavir Sulfate, Dolutegravir Sodium, and Lamivudine in Support of Rodent Toxicology Studies

J. C. Blake[1], J. Apoian[1], R. A. Fernando[1], and S. Waidyanatha[2]. *[1]RTI International, Research Triangle Park, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

Treatments for acquired immunodeficiency syndrome generally include combination therapies of antiretroviral drugs. The combination of abacavir sulfate (ABC) sodium dolutegravir (DTG), and lamivudine (3TC) is being used for the treatment of HIV-1 infection in adults. However, there is limited nonclinical safety information, specifically through maternal transfer of the agents to offspring. In this work, a procedure was developed for a combination formulation of ABC/DTG/3TC in 12:1:6 ratio (consistent with the clinical dose ratio) in aqueous 0.2% methylcellulose/0.1% Tween 80 for gavage administration in rodents. An analysis method, using ultra-performance liquid chromatography coupled with photodiode array detector, was developed and validated to determine the concentration of individual drugs in a single chromatographic run over the range 2.4/0.2/1.2 to 72/6.0/36 mg/mL (ABC/DTG/3TC). Validation parameters included linearity ($r \geq 0.9961$), accuracy (% relative error ≤ 14), and precision (% relative standard deviation (RSD) ≤ 8.0). The method was suitable for analysis of formulations with target concentrations up to 130/10.8/65 mg/mL (ABC/DTG/3TC) by diluting in to the validated range with blank vehicle. Homogeneity was successfully demonstrated on formulations containing ABC/DTG/3TC at 3.6/0.3/1.8 mg/mL (low) and 100/8.33/50 (high) with RSD $\leq$ 4.1%. Stability was evaluated at 3.6/0.3/1.8 mg/mL for up to 62 days at ambient and refrigerator temperatures. Formulations were stable when stored at ambient (88 to 104% of Day 0) or refrigerated (91 to 109% of Day 0) temperatures. Formulations were also stable for up to 3 hours under simulated dosing conditions (ambient temperature, exposed to air and light). In conclusion, a formulation and analysis method was developed to quantitate individual drugs in a combination formulation of antiretroviral therapy in support of rodent toxicology studies.

2870 Rare Earth Elements Toxicokinetics after Oral and Intravenous Administration in Rats

D. Dieme[1], J. Côté[1], M. Desrosiers[1], G. Pelletier[2], A. Nong[2], and M. Bouchard[1]. *[1]Université de Montréal, Montreal, QC, Canada; and [2]Health Canada, Ottawa, ON, Canada.*

In the past decades, there has been an increasing extraction and use of rare earth elements (REE) in several sectors. However, there is a paucity of data on their levels in the general population and their toxicokinetics. The aim of this study was to determine the biodisposition kinetics of 4 REE (neodymium (Nd), yttrium (Y), praseodymium (Pr) and cerium (Ce)) after a single oral and intravenous exposure in rats. Groups of adult male Sprague-Dawley were exposed by gavage to two different doses (100 and 1000 mg/kg bw) and by intravenous injection to a single dose (1 mg/kg bw) of $PrCl_3$, YCl_3, $NdCl_3$ and $CeCl_3$ (n = 5 per dose and per group of rats). The kinetic time courses of these 4 REE were determined in blood, urine and feces over a period of 7 days following gavage or injection; rats were sacrificed on day 7 post-dosing and tissue levels were measured. Biological levels were determined by ICP-MS. Oral results indicated that these compounds were very poorly absorbed through the gastrointestinal tract, with levels near the analytical limit of detection in blood and tissues. Urinary levels of orally administered dose were very low, with maximum percentages amounting to 0.8% when looking at individual excretion during the 0-72 h postdosing. The fecal profiles in orally exposed rats were similar for all 4 metals and indicated that the majority of the administered dose (both doses) was recovered in feces over the 72-h collection period. The mean (± SD) percentages of administered dose recovered in feces as Pr, Ce, Nd and Y were calculated to be 115 ± 13.6, 101 ± 13.5, 104 ± 22.5 and 87.5 ± 4.9% for the 100 mg/kg dose and 90.2 ± 21.8, 90.3 ± 7.0, 53.2 ± 14.8 and 67.5 ± 14.2% for the 1000 mg/kg dose during the 0-72 h postdosing. The intravenous results showed a similar rapid elimination from blood, with highest levels at 5 min post-dosing and a half-life of on average ≈ 3 h for the 4 metals. A significant tissue distribution was observed with the highest concentrations found in the liver (33.7 ± 16.8, 49.3 ± 12.3, 37.4 ± 17.5 and 10.3 ± 11.8%, respectively for $PrCl_3$, $CeCl_3$, $NdCl_3$ and YCl_3) followed in decreasing order by the spleen, kidney and lungs. Urinary excretion following intravenous injection was very low. However, fecal profiles were similar for all 4 metals and showed that excretion was not complete 7-day postdosing, asymptotic values not being reached at that time point; the mean (± SD) percentages of injected dose recovered as Pr, Ce, Nd and Y were respectively 19.2 ± 8.7, 26.7 ± 5.3, 22.1 ± 3.8 and 42.8 ± 17.6% during the 0-7-day period postdosing.

2871 Disposition of Microcystin LR in Rodents: A Potential Explanation for the Limited Toxicity Observed in Rodents following Oral Exposure

S. Waidyanatha[1], J. Pierfelice[2], J. Smith[2], E. Mutlu[1], B. Burback[2], H. Cunny[1], B. McIntyre[1], and V. Sutherland[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; and [2]Battelle Memorial Institute, Columbus, OH.*

Microcystins constitute a large class of monocyclic heptapeptides and are the most commonly found cyanotoxins worldwide. Exposure to microcystins can occur via ingestion of contaminated water and food or by inhalation of and dermal contact with contaminated water. Limited toxicity was observed in a recent study by the National Toxicology Program (NTP) following perinatal gavage exposure of CD1 mice up to 1000 µg/kg microcystin LR (MCLR). MCLR was not detected in the plasma of these animals at or above the limit of quantitation (LOQ, 1 ng/mL) of the assay. To help explain the toxicology data and to investigate species difference in disposition, we conducted studies in female CD1 mice and Hsd:Sprague Dawley® SD® (SD) rats following 5d gavage (500 µg/kg) and a single intravenous (IV, 10 µg/kg) administration, and sacrificed up to 24 h after the last dose. In mice, following gavage exposure, parent MCLR (free) in plasma was ≤LOQ of the assay. Of the administered dose, 42% was recovered in feces 24 h after the last dose with low levels in urine (~0.1%); levels in the gastrointestinal tract tissues, liver, and kidney were below the LOQ of the assay. Dose recovered as total MCLR (combined free and bound MCLR and metabolites) was 49% with the majority in feces and low levels (≤0.2%) in urine, liver, and kidney. The levels in the liver didn't change over time from 0.5 to 24 h suggesting that it was covalently bound. In rats, the pattern of disposition following gavage exposure was similar to mice based on free with 36% of the dose recovered; the recovery as total was 94% with the majority in feces and low levels (≤0.2%) in urine, liver, and kidney. Free or total MCLR was not detected in bile in rats. Following IV exposure, in mice, free or total was not detected in plasma at the earliest collection timepoint of 2 h. The dose recovered as free in aforementioned matrices was 1% and as total was 53% (liver, 48%; urine, 4%; feces, 1%). Following IV exposure in rats, low levels of free and total (≤14 ng/mL) was detected in plasma at the first collection time point of 5 min. In rats, the recovery of free was ~ 0.01% and total was 75% (liver, 64%; urine, 4%; feces, 6%). In conclusion, MCLR was very poorly absorbed following oral exposure in rodents and likely retained in the liver leading to poor systemic exposure which may in part explain the limited toxicity observed in NTP toxicology studies.

2872 Disposition and Kinetics of 2,4,6-Tribromophenol in Lactating Rats and Postnatal Day 12 Nursing Pups

G. A. Knudsen, M. Chapman, A. Trexler, C. Juberg, and L. S. Birnbaum. *NIEHS/NTP, Research Triangle Park, NC.*

2,4,6-Tribromophenol (TBP, CAS No. 118-79-6) is a widely used brominated chemical used as a flame retardant (BFR), precursor chemical, and wood antifungal agent. Due to a variety of natural and anthropogenic sources, TBP is detected in environmental matrices and biota, including human breast milk, placenta, and serum. In non-occupational exposures, serum levels of TBP correlated positively with those of polybrominated diphenyl ethers, suggesting similar sources of exposure. In addition to potential oral or dermal exposure through dust, TBP is likely to be consumed in a diet rich in wild-caught fish. To address the observations of TBP accumulation in human breast milk, studies were conducted to characterize the disposition and toxicokinetic profile of TBP in nursing Sprague Dawley rats following single oral bolus administration to the dam. Female Sprague Dawley rats (N=4-5/dose group, 14 weeks old) were used in these studies. Litters were culled and balanced to 4 males and 4 females at 4 days postpartum. Animals were maintained in an AAALAC-approved animal care facility. Dams were administered a single dose of [^{14}C]-labeled TBP by gavage on postnatal day 12 (10 µmol/kg, 25 µCi/kg, 4 mL/kg) and pups were allowed to nurse freely. Following administration of the compound, animals were euthanized between 0.25 and 24 h post dose and tissues were collected from the dam and nursing pups. Samples were analyzed in parallel for quantitative and qualitative analyses. Dams had a maximum systemic concentration (C_{max}) at 30 min (13 nmol-eq/mL) and fell through 24 h (0.2 nmol-eq/mL). In the dams, peak tissue concentrations were observed between 0.5 & 1 h post-dose where liver, kidney, and mammary tissues contained 3% (7 nmol-eq/g), 1% (20 nmol-eq/g), and 0.3% (3 nmol-eq/g) of the administered dose, respectively. The stomach contents of nursing pups increased over time, with concentrations of ~1 nmol-eq/g observed at 6 and 12 h post-dose, indicative of sustained exposure via milk. [^{14}C]-concentrations were low in pup blood and liver (<0.1 nmol-eq/g) at all time-points evaluated. Concentrations of TBP and its metabolites will be assessed in pup kidney and intestinal contents to determine the route of elimination of milk-ingested TBP. *This research was supported by the NIH Intramural Research Program [ZIA BC 011476].*

2873 Novel Mouse Lines with Humanized Glutathione *S*-Transferase Pi, Mu, and Theta Families Reveal Species Differences in Enzyme Expression and Function *In Vivo*

K. A. Behrens[1], J. N. Snouwaert[1], Z. Xiang[1], L. A. Jania[1], M. Nguyen[1], J. P. Parker[2], and B. H. Koller[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]North Carolina State University, Raleigh, NC.*

Genetic contributions to inter-individual differences in the response to a specific toxic or therapeutic substance are studied in an attempt to personalize or predict individual risk or response to a compound. The glutathione *S*-transferase (GST) enzymes, which facilitate the excretion of ubiquitous endogenous and exogenous electrophilic toxicants, have been extensively studied for their potential contributions to these gene-environment interactions, and the high frequency null alleles in the *GSTM1* and *GSTT1* genes have been linked to altered drug metabolism and increased disease risk. While experimental animal models have been used to further our mechanistic understanding of GSTs, extrapolating the results of an animal study to the human population is complicated by inter-species differences in the number and structure of these genes. Thus, although rodent models have identified a role for GSTs in metabolism, it has often been difficult to assign a specific GST or subset of GSTs to the metabolism of a compound or drug and even more so to determine how this metabolism is affected by common variants in these enzymes. To address this problem, we generated a panel of mice that express the human GST isoforms by deleting the loci carrying the 14 mouse *Gstt*, *Gstm*, and *Gstp* genes and using syntenic replacement to repopulate each locus with the corresponding segment of human DNA. These lines show quantitative and qualitative differences in the expression of the human and mouse *GSTP*, *GSTM* and *GSTP* genes. Furthermore, they reveal species-specific differences in gene induction in response to transcription factor inducers. Using the dietary toxicant acrylamide as a model substrate, we demonstrate species-specific differences in the role of GSTs in acrylamide metabolism and their ability to protect against organ damage. These humanized mouse lines provide a platform for identifying human GSTs that contribute to drug/toxin metabolism and for assessing risk imparted by common disease-associated GST polymorphisms.

2874 Prediction of Drug Hepatic Clearance Using Long-Term Sandwich-Cultured Human Hepatocytes

A. Baze[1], Z. Timár[2], P. Pádár[2], Z. Gáborik[2], S. Klieber[3], and L. Richert[1]. *[1]KaLy-Cell, Plobsheim, France; [2]Solvo Biotechnology, Szeged, Hungary; and [3]Sanofi, Montpellier, France.*

Predicting the *in vivo* pharmacokinetic characteristic of new compounds from *in vitro* studies plays an important role in the drug discovery and development processes. The prediction provides essential information for the assessment of drug-drug interaction and time dependent effects and/or toxic events. When a compound reaches the liver via the systemic circulation, hepatic elimination starts with the penetration of the drug through the sinusoidal membrane, followed by metabolism and biliary excretion. In the present project we assessed prediction of hepatic clearance using primary human hepatocytes in a sandwich configuration allowing long-term cultures, *i.e.* by renewing Matrigel overlay until bile canaliculi formation (~6-7 days after seeding), a system in which transporter and metabolic functions have been shown to be maintained [(1,2,3)], and thereafter incubated hepatocyte monolayers for a maximum of 7 days with test compounds. A total of 28 test compounds covering a large range of physicochemical and pharmacokinetic properties were considered in the study. Conventional *in vitro*/*in vivo* Extrapolation (IVIVE) methods based on the Well Stirred model were used to extrapolate the clearance 1. without taking into account any binding to proteins (*i.e.* the so-called direct method) and 2. with taking into account the concentration of albumin produced in the culture medium over the duration of incubation as recently proposed [(4)] (*i.e.* the so-called PLR adjusted method). Our result demonstrated that using the direct scaling method, 71 % of the compounds were well-predicted, within the 2/4-fold envelop (43 % in the 2-fold envelop, 25 % in the 3-fold envelop and 4 % in the 4-fold envelop). Using the PLR-adjusted method, 79 % of the compounds were also well-predicted (43 % in the 2-fold envelop, 25 % in the 3-fold envelop and 11 % in 4-fold envelop). The slowly cleared compounds, *i.e.* the 19 compounds with clearance less than 30 % of hepatic blood flow, were also well predicted, 74% in the 2/4-fold envelop with the PLR adjusted method. Our study demonstrated that by using this relatively simple and easy overlay method for prolonged hepatocyte incubation time, accurate *in vivo* clearance predictions were obtained, especially for compounds with low metabolic clearance. 1. 2875 Expression and Immunolocalization of Xenobiotic Transporters at the Human Blood-Testis Barrier

R. K. Hau, S. H. Wright, and N. J. Cherrington. *University of Arizona, Tucson, AZ.*

The blood-testis barrier (BTB) is formed by basal tight junctions between adjacent Sertoli cells of the seminiferous tubules and functions as a physical barrier to protect developing germ cells in the adluminal compartment from reproductive toxicants. Multiple xenobiotics are known to cross into the male genital tract (MGT) including male contraceptives, cancer chemotherapeutics, and environmental toxicants, although the mechanism(s) for their movement into the MGT is(are) largely unknown. Previous studies showed that several ATP-binding cassette (ABC) and solute carrier (SLC) superfamily transporters are expressed in the testes and could potentially facilitate the disposition of xenobiotics into the MGT through concurrent uptake and efflux mechanisms. This study aimed to determine the expression and localization of xenobiotic transporters that may facilitate transepithelial transport across the human BTB. We used immunofluorescence staining to determine the cellular localization of these transporters in the several cell types found in human testes. OAT1, OCTN1, and MRP3 were primarily localized to the basal membrane of Sertoli cells, whereas CNT2, OCTN2, MRP6, and MRP7 were localized to both the basal membrane of Sertoli cells and the peritubular myoid cells that surround the basal membrane of Sertoli cells. Interestingly, OCT1, OCT2, and OCT3 were localized to the peritubular myoid cells and the Leydig cells, although there was minor staining of germ cell nuclear membranes. However, definitive staining of CNT1, OAT2, OAT3, MATE1, MATE2, OATP1A2, OATP1B1, OATP1B3, OATP1C1, OATP2A1, OATP2B1, OATP3A1, OATP4A1, and OATP6A1 was not observed due to non-specific antibody staining or an absence of staining. The localization of CNT2, OAT1, OCT1, OCT2, OCT3, OCTN1, OCTN2, MRP6, and MRP7 suggests these transporters may contribute to the mechanism(s) by which xenobiotics can cross the BTB. Taken together, the localization of these pharmacologically relevant transporters provides insight into the selectivity of drug disposition across the BTB and may be useful in developing tools to understand and overcome the pharmacokinetic and pharmacodynamic difficulties presented by the BTB.

2876 Modeling Blood-Testis Barrier Characteristics with Novel CRISPR/Cas9 Functional ENT1 and ENT2 Knockout HeLa Cell Lines

S. R. Miller, X. Zhang, R. K. Hau, E. Q. Jennings, J. J. Galligan, S. H. Wright, and N. J. Cherrington. *University of Arizona, Tucson, AZ.*

Equilibrative nucleoside transporters (ENTs) transport nucleosides across the blood-testis barrier. ENT1 is located on the basal membrane while ENT2 is located on the apical membrane of human Sertoli cells, creating a transepithelial transport pathway across the blood-testis barrier. Improving drug disposition to the testis with drugs that use transepithlelial transport pathways may more effectively treat viral infections and cancer within the male genital tract. Here, we characterized uridine transport in two novel ENT cell lines and assessed the impact of nucleoside reverse transcriptase inhibitors (NRTIs) on uridine uptake to gain further insight on ENT function and substrate selectivity. ENT1 or ENT2 functional knockout HeLa cell lines were generated using CRISPR/Cas9 to determine the kinetics and selectivity of each ENT individually. We demonstrate the functional loss of each transporter through quantitation of [^{3}H]uridine uptake in the presence of the ENT specific inhibitor S-(4-nitrobenzyl)-6-thioinosine (NBMPR). At low concentrations (100nM), NBMPR inhibits ENT1; conversely, at high concentrations (100μM) NBMPR inhibits both ENT1 and ENT2. In ENT2 knockouts, >97% of [^{3}H]uridine uptake was inhibited by 100nM NBMPR, indicating ENT1 function is predominant. In ENT1 knockouts, only 5% of [^{3}H]uridine uptake was inhibited by 100nM NBMPR and 90% was inhibited by 100μM NBMPR, indicating ENT2 function is predominant. The J_{max} for ENT1 is 23.4 pmol cm^{-2} min^{-1} and for ENT2 is 34 pmol cm^{-2} min^{-1}. The K_t for ENT1 is 10μM and for ENT2 is 110μM. We next evaluated the impact of nine NRTIs (abacavir, entecavir, zidovudine, tenofovir, lamivudine, emtricitabine, zalcitabine, and stavudine) on [^{3}H]uridine uptake, revealing abacavir as the most potent inhibitor of [^{3}H]uridine uptake, with an IC_{50} of 72μM for ENT1 and 350μM for ENT2. This suggests that abacavir has higher affinity for ENT1 than ENT2. These functional knockout cell lines will allow further screening of therapeutic compounds to establish the substrate selectivity between ENT1 and ENT2, which can aid in the development of future compounds that are able to circumvent the blood-testis barrier via the ENT1-ENT2 transepithelial transport pathway.

2877 *In Vitro* Biokinetic Input of Organic Anion Transporting Polypeptide (OATP) 1B1 for Prediction of Biliary Excretion

A. Noorlander[1], E. Fabian[2], B. van Ravenzwaay[2], and I. Rietjens[1]. *[1]Wageningen University and Research, Wageningen, Netherlands; and [2]BASF SE, Ludwigshafen am Rhein, Germany.*

Application of physiologically based kinetic (PBK) modelling in quantitative *in vitro in vivo* extrapolation (QIVIVE) in human safety assessment is still in a developmental stage as far as use in regulatory frameworks is concerned. Difficulties appear to occur especially for compounds that are eliminated from the body via active excretion in either urine or bile, because *in vitro* models to quantify kinetics for this active excretion remain to be defined and validated. The aim of the present study was to develop a rat PBK model that includes biliary excretion, using estradiol-17β glucuronide (E217βG) as the model compound. E217βG is known to be preliminary excreted in bile via the organic anion transporting polypeptide (OATP) 1B1. Values for the PBK model parameters Vmax and Km required to describe OATP1B1 mediated transport of E217βG were found in literature in six different studies. These studies all used human embryonic kidney HEK-293 cells overexpressing OATP1B1 and a mock transfected cell line to obtain these kinetic parameters. Where the Km values reported were all comparable amounting to 6.3 μM - 12.85 μM, the Vmax values varied substantially between the studies, varying from 1.37 pmol/mg protein/min to 798 pmol/mg protein/min. These Vmax values were scaled to the rat liver taking into account the amount of liver protein and transporter expression in HEK-293 cells as compared to liver tissue. Use of the Km and Vmax values thus obtained in the PBK model, resulted in well-predicted time-dependent blood concentrations and cumulative biliary excretion for an intravenous dose of 81 ng/kg bw for four out of the six parameters sets. The study provides a proof of principle for how biliary excretion can be included in rat PBK models using an *in vitro* cell line to define the kinetic parameters that describe the biliary excretion thereby providing a fruitful approach in alternatives to animal testing.

2878 Altered Cisplatin Pharmacokinetics during Nonalcoholic Steatohepatitis Contributes to Reduced Nephrotoxicity

J. L. Jilek[1], E. L. Toth[1], K. L. Frost[1], K. A. Jacobus[1], W. He[1], M. Goedken[2], and N. J. Cherrington[1]. *[1]University of Arizona, Tucson, AZ; and [2]Rutgers, The State University of New Jersey, Piscataway, NJ.*

Cisplatin is an alkylating antineoplastic agent that is indicated for the treatment of solid malignancies. Cisplatin is preferentially eliminated from systemic circulation via tubular secretion, whereby it exhibits dose-limiting nephrotoxicity. Interindividual variability in xenobiotic transporter expression is a known contributor to differential cisplatin toxicity and efficacy, and may be the result of genetic, environmental, and pathological contributions. In this study, we aimed to determine if nonalcoholic steatohepatitis (NASH) alters cisplatin pharmacokinetics and if this change elicits differential nephrotoxicity. Sprague Dawley rats fed a control or methionine and choline deficient (MCD) diet to model NASH were given a single bolus dose of cisplatin and sacrificed after 72 h. The MCD diet resulted in a NASH hepatic phenotype that remained unchanged following cisplatin exposure. Drug-naïve NASH rats also displayed no evidence of differential renal pathology relative to control rats. However, renal necrosis and inflammation were reduced in NASH by 40 and 63% following cisplatin treatment, respectively, relative to healthy controls. Furthermore, kidney weights of cisplatin-treated control rats were increased by 31%, compared to an 18% increase in NASH. Plasma cisplatin clearance was reduced from 6.78 (control) to 4.04 mL/min in NASH, and cisplatin plasma AUC was significantly increased by 44% in NASH, relative to control. Cumulative urinary elimination of cisplatin was decreased from 73 to 34% of total dose and renal clearance was reduced from 4.64 to 1.49 mL/min in NASH, compared to control. Subsequently, renal intracellular accumulation of cisplatin after 6 h was reduced by 34% in NASH, relative to control. Supporting these findings, expression of proximal tubule cisplatin uptake transporters, Ctr1 and Ctr2, were reduced by 24 and 64%, respectively compared to healthy control rats, whereas expression of Oct1, Oct2, and Oct3 were unchanged. Interestingly, expression of cisplatin efflux transporters Mate1 and Atp7a were reduced by 52 and 31%, respectively, in NASH compared to control. Taken together, these data suggest that NASH alters renal uptake and efflux transporter expression, thereby attenuating cisplatin uptake and clearance in the kidney with a corresponding reduction in renal cell exposure and nephrotoxicity during NASH. As such, this study demonstrates that NASH can influence pharmacokinetics of renally-eliminated drugs which may contribute to adverse drug reactions.

2879 Differential Portal Vein versus Lymphatic Uptake of the Pyrethroids Deltamethrin (DLM) and *cis*-Permethrin (CPM) in Rats

L. G. Higgins[1], L. R. Chatham[1], S. Tomczynski[1], A. K. MacLeod[1], M. Moreau[2], M. R. Creek[3], B. G. Lake[4], and T. G. Osimitz[5]. *[1]Concept Life Sciences, Dundee, United Kingdom; [2]ScitoVation, Durham, NC; [3]Creek Consulting Services, Lincoln, CA; [4]University of Surrey, Guildford, United Kingdom; and [5]Science Strategies LLC, Charlottesville, VA.*

Little information is available on the gastrointestinal (GI) absorption pathways for the widely used pyrethroid insecticides. GI absorption typically occurs via the portal venous blood (going directly to the liver) and/or the mesenteric lymph. Absorption by one or the other pathway can significantly influence the amount of compound reaching the systemic circulation, as well as sites of tissue distribution and metabolism. Compounds entering the portal circulation are subject to first-pass hepatic uptake and metabolism, thereby reducing the quantity of pyrethroids entering the arterial circulation. Generally, absorption of highly lipophilic compounds or drugs with log P values greater than 5, such as DDT and hexachlorobenzene, occurs through lymphatic vessels. The lymphatic contribution varies depending on the fat content in diet and/or the use of different vehicles. Given the high lipophilicity of pyrethroids, with reported log P values ranging from 5.4 to 6.2 for DLM and 6.5 for CPM, a significant contribution of lymphatic absorption is likely for these two compounds. These studies employed anesthetized adult male Sprague-Dawley rats, in which the hepatic portal vein was cannulated (to collect blood), the duodenum was cannulated (to administer dose compound) and the mesenteric lymph duct was cannulated (to collect lymph). The method required careful surgical technique and a success rate for collection of lymph varied from 50-70% of the animals entering the study. Lymph and portal blood were collected pre-dosing and at various time points up to 300 minutes post-gavage dosing of either 5 mg/kg DLM or 60 mg/kg CPM in a corn oil vehicle (5 ml/kg body weight) and were analyzed for levels of either DLM or CPM. The data demonstrate that the majority of both pyrethroids are absorbed via the lymphatics with 100-1000-fold less being absorbed via portal blood for both DLM (n=5) and CPM (n=4). Additional studies are being performed with both DLM and CPM using the more polar solvent glycerol formal as the dosing vehicle. (Supported by CAPHRA).

2880 Disposition and Kinetics of 2,4,6-Tribromophenol in Pregnant Rats at Gestation Days 12 and 20

M. Chapman, G. A. Knudsen, A. Trexler, C. Juberg, and L. S. Birnbaum. *NIEHS/NTP, Research Triangle Park, NC.*

2,4,6-Tribromophenol (TBP) is a chemical commonly used as a wood preservative and a fungicide. It is also used as an intermediate in brominated flame-retardant (BFR) synthesis and is a degradation product of many of these compounds. Even though it originates from a variety of anthropogenic processes, TBP is also a naturally occurring substance in marine ecosystems, serving as a defense mechanism for a variety of organisms therein. Given its widespread use, TBP can be found throughout the environment (soil, marine organisms, mammals, birds), including in human blood, breast milk, and placental tissue. We dosed timed-pregnant HSD:Sprague Dawley rats at gestation day 12 (GD12) and 20 (GD20) with ^{14}C-radiolabeled TBP in a corn oil vehicle (10 µmol/kg, 25 µCi/kg, 4 mL/kg). We euthanized the animals following dosing at 8 different time points (15, 30 min, 1, 2, 3, 6, 12, or 24 h) and harvested tissues (whole-blood, plasma, and organ homogenates). We then oxidized tissue aliquots (~25 mg) and quantified radioactivity using a liquid scintillation spectrometer (LSC). At both gestation ages, the maximal plasma concentrations of [^{14}C]-radioactivity were observed at 15 minutes post-treatment. Plasma C_{max} was 11 nmol-eq/mL in both GD12 and GD20 rats. Plasma concentrations then steadily declined at both GE12 and 20 through 24 h, and distribution to tissues appeared to follow plasma concentrations. [^{14}C]-Radioactivity concentrations in kidneys from GD12 rats rapidly declined after 15 min (21 nmol-eq/g), while kidney concentrations in GD20 rats had a C_{max} of approx. 20 nmol-eq/g at 30 minutes, suggesting that there may be delayed clearance from the kidneys at this late stage of gestation. Furthermore, [^{14}C] in thyroid glands was notably higher in GD20 rats than in GD12 rats during the first 2 hours after exposure, suggesting that the thyroid may accumulate TBP toward the end of pregnancy. Evaluations of TBP disposition in GD12 embryos and GD20 fetuses and their associated placentae are ongoing. *This research was supported by the NIH Intramural Research Program [ZIA BC 011476].*

2881 Developing Toxicity and Pharmacokinetic Models for an *In Vitro* Integrated Organ Platform (HuDMOP)

A. Y. Efremenko[1], N. Hibbard[2], E. Hack[1], P. Mallick[1], J. A. Willoughby Sr[2], M. Anderson[1], and J. M. McKim[2]. *[1]ScitoVation, Research Triangle Park, NC; and [2]IONTOX, Kalamazoo, MI.*

In vitro methods capable of describing systemic effects of chemicals require use of multiple tissue types connected with a common perfusate (simulated blood flow). This arrangement allows integration of absorption, metabolism and toxicity data over extended times *in vitro* and provides a novel, animal-free tool for chemical, cosmetic, and pharmaceutical testing. In order to test this, a study on the uptake and distribution of acetaminophen (APAP) in a human dynamic multi-organ plate (HuDMOP™) with three tissue surrogates arranged in series: first absorption across a human 3D intestine (EpiIntestinal™, MatTek Corp), then on to a liver surrogate with human primary hepatocytes in sandwich culture and then to a kidney preparation (human renal proximal tubule cells) was developed. A common perfusate with human albumin connected the three compartments. APAP was placed on the apical side of the intestinal surrogate at 0 and 24 hr. Samples were collected from all three compartments over time and analyzed for APAP by LC/MS/MS and cytotoxicity by LDH leakage. The APAP in the uptake reservoir peaked to 60.7 µM at around 4 hours with a total uptake of 72% of the applied dose entering the first reservoir. A simple PK model was developed to describe the three cellular platforms and their physical arrangement. Mass balance equations were fit to experimental data to estimate uptake and transport characteristics. The inter-chamber flow rates and fitted experimental absorption rate constant, 0.79/hr, were consistent with a C_{max} of 62.0 µM and time of maximum concentration between 3 hr and 4 hr in the intestine compartment. With the current platform flow rates, much lower concentrations were present in the subsequent two compartments (liver and kidney) with maximum observed concentrations of 4.5 µM and 2.5 µM versus 3.1 µM and 0.9 µM predicted. The interplay between platform modeling and model-directed technical improvements will make the HuDMOP™ results more directly applicable to expected in-life behavior of various chemicals.

2882 Structural and Functional Pharmacokinetic Analogs for Physiologically Based Pharmacokinetic (PBPK) Model Evaluation

C. A. Ellison, and G. P. Daston. *Procter & Gamble, Cincinnati, OH.*

Physiologically based pharmacokinetic (PBPK) models enable simulations of absorption, distribution, metabolism, and elimination of chemicals from the body. Model evaluation is a key step in the PBPK model development processes whereby model predictions are compared to pharmacokinetic (PK) data. A prerequisite for PBPK model evaluation has always been the availability of PK data for the modeled compound, a requirement which has limited the use and acceptance of PBPK models since PK data is often limited or not available. The current work tests the hypothesis that an adequately developed PBPK model for a target chemical (chemical with no PK data) can be evaluated using PK data from a source chemical (chemical with existing PK data). Two different approaches for identifying the source chemical, a structural PK analog and functional PK analog technique, are used to evaluate a series of oral human PBPK models for approximately 100 chemical pairs. The maximum concentration in plasma (Cmax) and area under the curve (AUC) predicted by the PBPK model for a target chemical was generally within a factor of three to the experimental data from the source chemical. Results show that both analog approaches can identify PK analogs which display similar PK as the target chemical and can be used as alternative ways for evaluating PBPK models. As animal free safety assessment strategies continue to develop, it's important to develop alternative approaches for PBPK model evaluation which does not rely on generating new PK data.

2883 A Combination of a Physiologically-Based Pharmacokinetic (PBPK) Model for the Inhalational Route and an *Ex Vivo* Model for Prediction of Lung Absorption Kinetics

K. Schwarz, N. Nowak, D. Winkler, T. Hansen, K. Blümlein, S. Wilde, and S. Escher. *Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany.* Sponsor: A. Bitsch

Information on systemic available concentrations is important for the safety assessment of chemicals and the pre-clinical development of new drugs. In recent years, the inhalational route has gained particular interest. A Physiologically-Based Pharmaco-Kinetic (PBPK) model for airborne sub-

stances with focus on the uptake via the lung has been developed. The resulting IVIVE-Lung-PBPK model *(in vitro* to *in vivo* extrapolation) shall be applicable to gases, liquid aerosols and (slowly) soluble particles. The lung is divided into three sub-compartments to account for the different clearance and uptake processes in the individual lung sections. The systemic part of the model is based on a state-of-the-art design and includes the different relevant organs/tissues. For uptake through the lung epithelium, permeation values are derived using *in vitro* and *ex vivo* models, like the Isolated Perfused Rat Lung. Further relevant data and processes, such as mucociliary clearance or blood-tissue distribution coefficients are included based on literature data. To investigate the applicability of the model, pulmonary permeability coefficients were determined for ciprofloxacin and a second small molecule substance, for which many further ADME parameter are available from literature. Comparison of the data derived from the PBPK model with the permeability coefficients from the IPL as input parameters to the corresponding human data shows good agreement for the plasma concentration profile and the quantitative concentration levels. According to these investigations, the inhalation PBPK model in combination with the pulmonary absorption parameters determined in the *ex vivo* model of the Isolated Perfused Rat Lung can successfully predict the systemic uptake in humans for small molecule substances with diffusion-controlled transport mechanisms. Therefore, this model can well contribute to the safety assessment of chemicals with usually very limited availability of *in vivo* PK data, as well as for pre-clinical studies with inhalable drugs. Currently, the lung PBPK model is further improved in the project Cefic-LRI B21. This includes a more detailed description of different clearance processes, such as macrophage-mediated clearance and dissolution as well as the investigation of the applicability of other biological parameters determined *in vitro*.

2884 Physiologically Based Pharmacokinetic Modeling to Identify Upper Bound No Effect Thresholds for Human Tracheal Sensory Irritation

B. Kerger[1], and A. E. Loccisano[2]. *[1]Exponent, Irvine, CA; and [2]Exponent, Alexandria, VA.*

Exposure to sensory irritants may stimulate the trigeminal nerve receptors, eliciting sensory irritation of the eyes/nose/throat and coughing. Recent studies of human volunteers exposed to formaldehyde (FA) provide refined dose-response findings for eye and upper respiratory irritant responses controlled for negative affectivity and FA was utilized as the index compound for modeling dose-response of four other known sensory irritants: acetic acid (AA), diacetyl (DA), peroxyacetic acid (PAA), and hydrogen peroxide (H_2O_2). We applied a computational fluid dynamics/physiologically based pharmacokinetic (CFD/PBPK) model to each of these compounds to estimate no observable effect level (NOEL) thresholds for anterior tracheal sensory irritation by internal dosimetry methods. The 50% decrease in respiratory rate in mice (RD50) for each compound was used as a sensitive measure of relative potency to induce sensory irritation. The anterior tracheal epithelium was considered the primary target tissue for coughing sensation responses, and the model was run assuming no metabolism to assure upper bound estimates for a 15-min exposure duration. The human NOEL identified for FA (0.8 ppm) was used to estimate FA deposition concentration NOELs (mmol/L) in the anterior tracheal epithelium. This FA deposition NOEL was then multiplied by the RD50 ratio (e.g. AA/FA) to adjust for relative potency to estimate the molar deposition NOELs for AA, DA, PAA and H_2O_2. The model was then utilized to identify the airborne concentration of AA, PAA, DA, and H_2O_2 corresponding to the anterior trachea deposition NOEL in a human performing light exercise. Using this method and the well-defined NOEL for airborne FA controlled for negative affectivity bias, the corresponding airborne NOEL concentrations were determined for AA (61 ppm), DA (1000 ppm), PAA (1.3 ppm) and H_2O_2 (25 ppm). These model-predicted NOEL concentrations are higher than occupational standards designated based largely on animal dose-response data for upper respiratory irritation. This approach estimates an upper bound airborne NOEL value since it does not account for rapid metabolism of these example compounds, assumes both nose and mouth breathing, and may be useful for similarly assessing other sensory irritant compounds with RD50 values.

2885 Use of Toxicokinetic Data for Afidopyropen to Determine the Dose Levels in Developmental Toxicity Studies

A. E. Loccisano[1], J. Bus[1], B. Gollapudi[1], B. W. Riffle[2], E. Fabian[3], and M. Frericks[3]. *[1]Exponent, Alexandria, VA; [2]BASF Corporation, Research Triangle Park, NC; and [3]BASF Corporation, Ludwigshafen, Germany.*

Afidopyropen (AF) is an insecticide that acts as a TRPV channel modulator in chordotonal organs of target insects and has been assessed for a wide range of toxicity endpoints including developmental toxicity in rats and rabbits. The AF GLP definitive developmental toxicity study in rabbits did not produce evidence of maternal or fetal toxicity at the highest dose tested (32 mg/kg/day; NOAEL) but pharmacokinetics (PK) in pregnant rabbits exhibited onset of PK nonlinearity, as measured by plasma C_{max} and AUC, at 15, 32 and 60 mg/kg/day relative to 5 mg/kg/day. Following single gavage doses, respective C_{max} and AUC values were: C_{max}: 15.6 ± 17.3, 438 ± 23.8, 2780 ± 498, 4810 ± 721 ng/mL; AUC: 12.6 ± 9.22, 600 ± 193, 6110 ± 752, 24100 ± 3930 hr*ng/mL. The developmental NOAEL of 32 mg/kg/day is 9000X higher than the maximum expected human dietary exposures to AF; the dose range where onset of nonlinear PK was observed, 5-15 mg/kg/day, is 1400 - 4200X higher than expected human exposures. As PK nonlinearity occurred between 5 and 15 mg/kg/day, 32 mg/kg/day is a sufficiently high dose (kinetically derived maximum dose) for a prenatal developmental toxicity study. Regulatory toxicity testing dose selection guidance recognizes onset of saturated PK as evidence of excessive biological stress to test animals when well separated from human exposures, and that any effects noted at such doses have questionable relevance for human hazard identification and risk. In addition, although weak AF dopamine D2 receptor agonist activity is responsible for tumorigenicity in rats only at high metabolically saturating doses, the potent D2 agonists bromocryptine, cabergoline and pergolide mesylate are not teratogenic in rabbits, rats or mice. The *in vitro* AF concentration eliciting a 50% D2 receptor activation (594 ng/ml) is less than the C_{max} at the saturated 32 mg/kg/day AF dose, suggesting that the top rabbit NOAEL dose also presented potential pharmacological stress. Taken together, the current data demonstrate that consideration of PK is critical for improving the dose-selection in developmental toxicity studies to enhance human relevance of animal toxicity studies.

2886 Toxicokinetics of Constituents in *Ginkgo biloba* Extract Administered to Rats

T. R. Fennell[1], C. Whitaker[1], R. Snyder[1], R. Fernando[1], C. V. Rider[2], and S. Waidyanatha[2]. *[1]RTI International, Research Triangle Park, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

Investigating the toxicokinetics (TK) of the many constituents in an herbal product provides a complex investigational challenge. In this study, untargeted reverse phase ultra-high performance liquid chromatography-mass spectrometry analyses were used to generate TK profiles of the constituents of *Ginkgo biloba* extract and the data were compared with those generated using conventional targeted analysis methods. Plasma samples (3 per time point) were obtained at 0 (pre-dose) and up to 1440 min after dosing, from F344/NCrl rats administered a single 300 mg/kg dose of *Ginkgo biloba* extract by gavage and analyzed to determine their metabolic profile. Orthogonal Partial Least Squares Discriminant Analysis was used to identify the features (retention time and mass for an analyte) that differentiated between groups at 90, 480 and 1440 min, that were later identified. In plasma, bilobalide, and ginkgolides A, B, C, and J were readily detected, but isorhamnetin, quercetin, and kaempferol were not. However, conjugates of isorhamnetin glucuronide, kaempferol glucuronide and sulfate, and methylated quercetin glucuronide sulfate/isorhamnetin glucuronide sulfate were identified. Several substituted benzoic acid derivatives were also detected. Data for the top 12 constituents (peak area) were analyzed by a noncompartmental method to generate TK data. For a limited set of standards: bilobalide, and ginkgolides A, B, C, and J, quantitative analysis was conducted using a limited six-point calibration curve, and a single point calibration. All of the compounds had T_{max} values of 90 min. C_{max} and AUC values were rank ordered bilobalide > ginkgolides A > B > C > J. Half-lives ranged from 92 min (bilobalide) to 194 min (ginkgolide C). Using a one-point calibration, similar TK data were obtained except for ginkgolides C and J, which were present at the lowest concentrations. This study indicated that a limited calibration and TK analysis can be utilized to generate useful TK data for a multi-constituent mixture.

2887 Toxicokinetics of Temephos in the Rat: New Evidences of Its Potential Toxicity

F. A. Verdín-Betancourt[1], M. Figueroa[2], M. L. López-González[1], A. E. Rojas-García[3], and A. Sierra-Santoyo[1]. *[1]CINVESTAV-IPN, Mexico City, Mexico; [2]Universidad Nacional Autónoma de México Facultad de Química, Mexico City, Mexico; and [3]Laboratorio de Contaminación y Toxicología Ambiental, Universidad Autónoma de Nayarit, Tepic, Mexico.*

Temephos (Tem) is an organophosphorus larvicide used to control dengue, zika and chikungunya vector. Tem is classified as low toxicity pesticide in acute exposure. Data on the toxicity and disposition of Tem and its metabolites is limited. The aim of this study was to evaluate the disposition and metabolism of Tem in the rat. Adult male Wistar rats were administered with 300 mg/kg Tem emulsified in saline solution by gavage and were sacrificed after treatment. Blood, organs, and tissues were removed for Tem and its metabolites determination after extraction with acetonitrile by HPLC-DAD-MSD. At least twelve metabolites were detected, among them Temephos-sulfoxide (Tem-SO), Temephos-oxon (Tem-oxon), Temephos-oxon-sulfoxide (Tem-oxon-SO), Temephos-dioxon-sulfone (Tem-dox-SO_2), Temephos-sulfone-mono-hydrolyzed (Tem-SO_2-OH), Temephos-oxon-SO-mono-hydrolyzed (Tem-oxon-SO-OH), 4,4´-thiodiphenol (TDP), 4,4´-sulfinyldiphenol (SIDP), and 4,4´-sulfonyldiphenol (SODP) or bisphenol S (BPS). The liver exhibited the presence of greater metabolites number. Tem was the main compound detected in all tissues and was gradually accumulated in fat until 24 h (200.2±27.3 µg/g). Blood concentration data for Tem were fitted to a one-compartment model. After 2 h, Tem blood concentration reached the peak (10.4±1.4 µg/ml, $t_{1/2\ abs}$=0.38 h) and only trace levels were detected at 36 h ($t_{1/2\ elim}$=8.6 h). Tem-SO_2-OH levels remained relatively constant until 36 h and represented the more frequent metabolite observed in blood and kidney. Tem-oxon and -dox were detected in the brain. The clearance of the liver and kidney was 7.59 and 5.52 ml/min. The partition coefficients (organ concentration/blood concentration) of Tem for fat, liver, kidney, and brain were 20.0, 4.6, 2.5, and 1.8, respectively. These results indicate that Tem is biotransformed to reactive metabolites such as mono-oxons, di-oxons, and BPS, a well-known endocrine disruptor. In addition, Tem is well absorbed in rats, is extensively metabolized, widely distributed and preferentially accumulated in fat. These results improve the understanding of Tem toxicokinetics as well as its relationship with the organ-specific toxicity.

2888 Toxicokinetics of Bisphenol-S and Its Glucuronide Conjugate following Oral and Dermal Exposure in Volunteers

I. Khmiri[1], J. Côté[1], M. Mantha[1], R. Khemiri[1], M. Lacroix[2], N. Hagen-Picard[2], V. Gayrard[2], and M. Bouchard[1]. *[1]Université de Montréal, Montréal, QC, Canada; and [2]INRA, Toulouse, France.*

The measurement of bisphenol-S (BPS) and its glucuronide congugate (BPSG) in urine may be used for the biomonitoring of exposure in populations. However, this requires a thorough knowledge of their toxicokinetics. The time courses of BPS and BPSG were assessed in accessible biological matrices of orally and dermally exposed volunteers. Under the approval of the Research Ethics Committee of the University of Montreal, six volunteers were orally exposed to a BPS-d8 deuterated dose of 0.1 mg/kg body weight (bw). One month later, 1 mg/kg bw of BPS-d8 were applied on 40 cm^2 on the forearm and then washed 6 h after application. Blood samples were taken prior to dosing and at fixed time periods over 48 h after treatment and complete urine voids were collected pre-exposure and at established intervals over 72 h post-dosing. Following oral exposure, the plasma-concentration time courses of BPS and BPSG evolved in parallel, and showed a rapid absorption and elimination. Average peak values (± SD) were reached at 0.7 ± 0.1 and 1.1 ± 0.4 h postdosing, respectively. From the elimination phase, average apparent half-lives (t½) of 4.8 ± 0.4 and 4.5 ± 1.1 h were calculated for BPS and BPSG, respectively. Plasma concentration time-courses and urinary excretion rate profiles roughly evolved in parallel for both substances. Average peak values of BPS and BPSG in urine were reached at 2.3 ± 1.0 and 1.7 ± 1.0 h postdosing. Mean (± SD) apparent elimination t½ of BPS and BPSG derived from excretion rate profiles were 5.8 ± 1.2 and 5.0 ± 0.4 h. The average percent (± SD) of the administered dose recovered in urine as BPS and BPSG over the 0-72 h period postdosing were 2 ± 1 and 86 ± 12 %. Following dermal application, plasma levels were under LOQ or LOD at most time points. However, peak values were reached between 5 and 8 h depending on individuals, suggesting a slower absorption rate compared to oral exposure. Similarly, limited amounts of BPS and its conjugate were excreted in urine and peak excretion rates were reached between 5 h to 11 h postdosing. Excretion rate appeared similar between BPS and BPSG. The average percent (± SD) of the administered dose recovered in urine as BPS and BPSG was about 0.005 ± 0.001 and 0.09 ± 0.06 %, respectively. These data provide greater precision on the kinetics of this contaminant in humans and should be useful in developing a toxicokinetic model for a better interpretation of biomonitoring data.

2889 Role of Kinetically Derived Maximum Dose (KMD) in Repeated-Dose Toxicity Studies

J. Domoradzki[1], M. Corvaro[2], J. Henriquez[1], and C. Terry[1]. *[1]Corteva Agriscience, Indianapolis, IN; and [2]Corteva Agriscience, Rome, Italy.*

The importance of toxicokinetic (TK) data in understanding systemic exposure is included in OECD Health Testing Guidance and emphasizes that TK data can be used to improve selection of doses for repeated dose mammalian toxicity studies. The Kinetically-Derived Maximum Dose (KMD) approach selects a dose-range more relevant for risk assessment purposes. Doses based on TK data are quantitatively relevant to real-world human exposures as compared to testing at the limit dose. Since use of the KMD approach can result in doses lower than those associated with the long-standing conventional Maximum Tolerated Dose (MTD) dose selection approach, challenges have been raised that this potentially compromises identification of health hazards used in regulatory classification and labeling of chemicals. Chemicals highlighted as case studies are Sulfoxaflor (route selection), 2,4-D (saturated renal clearance and toxicity), Arylex (pharmacodynamic response), ethyl benzene (*post-hoc* study analysis), and ethyl tertiary butyl ether, and afidopyropen (mode of action) where the fold difference between the KMD dose level and human exposure is 40,000; 13,000; 123,000; 5,000; 175,000 and 4,000; respectively. For the case studies, KMD vs MTD doses are compared, values listed after the chemicals represent the KMD selected for a study vs the likely dose via the MTD approach or the KMD from *post-hoc* analysis vs the MTD used in the study: Sulfoxaflor (750, 1000 ppm), 2,4-D (26, 52 mkd), Arylex (157, 244 mkd), ethyl benzene (300, 750 ppm), ethyl tertiary butyl ether (2000, 5000 ppm), and afidopyropen (1000, 3000 ppm). Case studies associated with KMD vs MTD dose selection strategies illustrate the following: 1) Testing at KMD selected dose levels offers appropriate protection of human health (examples include chemicals where KMD dose levels are 3-5 orders of magnitude above human exposure), particularly when knowledge of human exposures is rapidly expanding; 2) KMD is consistent with current knowledge of dose-dependent transitions of toxicity responses; 3) KMD evaluations can be retroactively applied to previous classification/labeling/risk assessments based on data from MTD testing; 4) KMD approach testing honors commitments to reducing animal testing and minimizing animal stress; and 5) The opportunity to remove inter-and intraspecies uncertainty factors exists with knowledge of systemic dose. These examples will illustrate the importance of understanding systemic dose and TK of a chemical and its metabolites in top-dose selection, study interpretation and human relevance.

2890 A Parent-Metabolite Model for Predicting Human Efficacious Dose of (2R,6R)-Hydroxynorketamine, a Metabolite of Ketamine with Antidepressant Effects

M. Li, J. Boggs, and V. Walsh. *Covance Inc., Madison, WI.*

Ketamine has been used as an antidepressant in clinics but its use is limited by its side effects and abuse potential. (2R,6R)-Hydroxynorketamine (2R,6R-HNK) is one of the metabolites of ketamine and has been shown to have rapid antidepressant effects in rodents but without the adverse effects of ketamine. Major metabolites of ketamine have been analyzed in human plasma post ketamine doses; however, 2R,6R-HNK was never administered directly in humans and there is no direct pharmacokinetic (PK) data to estimate the efficacious doses needed in humans. Models reported in literature are not sufficient for prediction of 2R,6R-HNK PK in humans. Preclinical studies have resulted in very different PK properties in rodents and dogs, causing uncertainly for scaling to humans. The current work was to develop a parentmetabolite PK model to describe the PK of ketamine and its metabolites, and estimate the PK parameters of 2R,6R-HNK for prediction of exposure in humans based on the effective dose in mice. The concentration-time profiles and urine excretion data of ketamine and its major metabolites including 2R,6R-HNK were collected from literature by digitalization of the reported plots. The model development was a step-wise approach by building a model for ketamine first and adding metabolites sequentially for estimation of model parameters. Assumptions were taken based on information from literature where data was missing. The developed model was then used for predicting human PK profiles and non-compartmental analysis was used for analysis and comparison of both predicted human PK profiles and mouse PK profiles. The dose in humans was calculated which will provide the same exposure in mice at the effective dose, which was 15 mg/kg as reported in literature. The modeling re-

sults predicted the doses providing equivalent exposure in humans would be 0.05 to 0.2 mg/kg which was lower than the estimated dose using allometric scaling which was 0.4 mg/kg.

2891 Development of a Pharmacokinetic Model for Phosphine Gas Inhalation

S. A. Pierce, W. Y. Tuet, J. Tressler, L. Jennings, M. C. Racine, S. Stone, E. Peublo, B. J. McCranor, and B. Wong. *US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.*

Computational modeling has become increasingly relevant for assessing the kinetics and dynamics of potential drug candidates and toxic industrial chemicals. These models complement *in vitro* and *in vivo* experiments, creating a more comprehensive view of drug efficacy and toxicity while reducing animal use. Physiologically based pharmacokinetic (PBPK) models combine physicochemical properties with physiological data to predict concentration-time profiles within individual tissues. Despite the widespread use of PBPK models, applications involving inhalation of gaseous species remain unexplored. Phosphine gas (PH_3) is a widely used rodenticide and common reagent in chemical synthesis. Despite commercial uses, PH_3 poses a considerable threat to human health. In this study, GastroPlus, a predictive modeling software, was used to develop a PH_3 inhalation PBPK model. Given that the mechanism of action of PH_3 is largely unknown, this model was used to survey the utility of PBPK modeling for refining future studies. A PBPK model was developed to mimic PH_3 inhalation in adult female Sprague-Dawley rats. A concentration-time product of 21450 ppm × min (660 ppm for 32.5 min) was modeled, and delivered doses of PH_3 were calculated using individual subject minute volumes and average measured concentration of PH_3. In order to model exhalation of gaseous species, assumptions regarding the precipitation, dissolution, and clearance of PH_3 in pulmonary compartments were made. Precipitation was assumed to be rapid, dissolution was assumed to be negligible, and metabolic clearance was included to further mimic the exhalatory loss of PH_3. The developed PBPK model was compared to pharmacodynamic (PD) effect-time profiles of observed cardiopulmonary effects, represented as a fraction of baseline values, during and post-exposure. For PD model development, subjects were randomly separated into training and test cohorts. Direct E_{max} models were found to best fit the relationship between plasma concentrations of PH_3 and minute volume (MV) and left ventricular contractility (+dP/dt) with root mean square error (RMSE) of 0.864 and 0.266, respectively. The trained PD models were then applied to the test cohort giving an RMSE of 0.545 for MV and 0.109 for +dP/dt. These relationships imply higher concentrations of PH_3 lead to an increase in both parameters up to a maximum response, which may provide insight into pathways implicated in PH_3 toxicity.

2892 Bioactivation of Halogenated Aromatic Drugs as a Precursor to Drug-Induced Hepatotoxicity

M. A. Davis[1], S. Payakachat[2], S. Thakkar[3], T. Hughes[4], J. Swamidass[4], and G. P. Miller[1]. *[1]University of Arkansas for Medical Sciences, Little Rock, AR; [2]Hendrix College, Conway, AR; [3]US FDA/NCTR, Jefferson, AR; and [4]Washington University in St. Louis, St. Louis, MO.*

Halogens are increasingly utilized in drug development, yet their potential impacts on toxic risk through enzymatic bioactivation remain understudied. Chemical reactivity trends indicate halogenated drugs are less likely to undergo bioactivation into reactive metabolites like quinones and thus, pose a decreased toxicity risk. However, the number of hepatotoxic halogenated molecules continues to grow with the introduction of new molecular entities indicating knowledge of halogenated molecule metabolism is insufficient for toxic risk assessment. We hypothesize that the presence, type, and location of aromatic ring halogens impacts the chemical step toward reactive quinone formation (V_{max}), while enzyme affinity (K_m) determines the concentration-dependent reaction conditions. We are testing this hypothesis with a novel integration of bioinformatic, computational, and experimental approaches to assess metabolic bioactivation potential of halogenated molecular scaffolds. First, we extracted 259 halogenated compounds from the FDA DILIrank database. We utilized our Xenosite computational metabolic model to assess quinone bioactivation likelihood. Thirteen compounds were selected for further study due to high model scores and reported DILI. Meclofenamate was the highest predicted ambiguous compound and was supplemented by structurally similar derivatives such as diclofenac, lumiracoxib, and others with varied degrees of DILI risk. We have developed experimental methodologies to adduct quinone metabolites using dansyl glutathione and have established a sensitive method to fluorescently detect these metabolites. Future work will ascertain reaction kinetics and identify responsible enzymes to understand the role of halogens in metabolic clearance and bioactivation contributing to drug-induced liver injury (DILI). Additional work will be conducted using patient health records to identify trends between toxic outcomes and patient populations to stratify patient risk. These findings will provide critical insights on the impact of halogenated compound bioactivation as a precursor to DILI and thus, provide a foundation for better risk assessment in drug discovery and development. *Supported by NIGMS-T32-GM106999/NLM-R01-LM012222.*

2893 Effect of Acute Inhalation Co-exposure of Naphthalene and Carbon Particles on the Systemic Absorption of Naphthalene: Using Excretion of 1-Naphthol as a Biomarker

E. J. Arauz, M. Kozuch, and S. M. Roberts. *University of Florida, Gainesville, FL.*

Inhalation exposures to semi volatile organic (SVOC) chemicals typically include particulate matter suspended in air. There is almost no information available currently on how particulate matter in air interacts with SVOCs to influence their absorption in the lungs. We found previously that co-exposure of rats to naphthalene and carbon particles increases the naphthalene concentration in lung tissues compared to animals exposed to naphthalene alone. The objective of this study was to examine the effect of carbon particle co-exposure on the absorbed dose of inhaled naphthalene, with urinary excretion of the 1-naphthol metabolite of naphthalene used as a quantitative biomarker of systemic absorption. Male Sprague-Dawley rats were exposed nose-only for 1 h to naphthalene vapor at concentrations of 5, 10, or 20 ppm with or without carbon particles (5mg/m^3). Respiration was monitored during exposure by plethysmography. Following exposure, urine was collected over 24 h intervals for a total of 72 h. Gas chromatography tandem mass spectrometry analysis was used to measure 1-napthol concentration in urine samples. Over 90% of 1-naphthol recovered in urine was collected during the first 24 h. At each naphthalene exposure level, 1-napthol urinary excretion was significantly increased in animals co-exposed to carbon particles. These findings suggest that co-exposure of particles with naphthalene substantially increased its systemic absorption.

2895 The Extent to Which *In Vitro* Distribution Kinetics Determines Differences in Intrinsic Hepatic Clearance between Assay Setups

S. Proença, M. D. van Schijndel, T. Sinnige, and N. I. Kramer. *Institute for Risk Assessment Sciences, Utrecht, Netherlands.*

In vitro intrinsic clearance assays are used to parameterize physiologically based kinetic models for chemical safety assessment. Usually, for these assays, monolayer cultures of primary human hepatocytes and human hepatic cell lines are used. However, the biotransformation enzymes activity in such cultures is low and/or decreases over time, resulting in underestimation of hepatic intrinsic clearance as compared to *in vivo* situation. For this reason, alternative culture techniques including sandwich cultures and spheroids have been suggested to maintain optimal hepatic functionality. In addition to differences in biotransformation activity, these cultures differ from monolayer cultures in the levels of serum constituents, area and type of exposed plastic and extracellular matrix. Consequently, distribution kinetic processes between these culture models differ and thus hamper the comparison of observed intrinsic clearance across assays. The aim of this study was to quantify and compare the *in vitro* distribution kinetics of intrinsic clearance assays between HepaRG cultured as monolayers, sandwich cultures and spheroids. First, the hepatic function of the culture models was compared using transcriptomics and enzyme activity analysis with probe substrates. Second, the intrinsic clearance of cosmetic ingredients (incl. triclosan, rosiglitazone, butyl paraben) was estimated in the three different cultures. For each culture model, concentrations of chemicals over time were analytically determined in medium, cells, extracellular matrix and plastic of the microplate. Results indicate that spheroid cultures have higher levels of phase I activity, especially CYP3A4 and CYP1A1. Differences in phase II enzymes activity and transporter expression levels between culture models were less pronounced. As a result, intrinsic clearance in spheroid cultures was only higher for chemicals predominantly metabolized by phase I enzymes. Moreover, more lipophilic chemicals and/or chemicals with slower metabolism ($T_{1/2}$ larger than 4h) had lower free concentrations, influencing the measured clearance readout. This is in line with literature and partly explains the underprediction of intrinsic clearance for these classes of compounds.

2896 Variability of Blood/Gas Partition Coefficients Across Species

E. Demchuk. *CDC/ATSDR, Atlanta, GA.* Sponsor: R. Siwakoti

Blood/gas partition coefficients of volatile chemical compounds (VCC) are fundamental in inhalation toxicology, anesthesiology, pharmacokinetic modeling, and chemical risk assessment. They are available as empirical but poorly-understood quantities. In particular, their transferability across species remains unknown. In the present work, 528 blood/gas partition coefficients of 101 VCC measured in 7 mammal species were systematically compared using statistical methods. Significant differences across species were identified. On average, the blood/gas partition coefficient was found to decrease with increasing size of the species varying from rat to ox. The dependence was linear on the log scale. The observed correlation does not find a sufficient explanation in terms of water/lipid composition of the blood, but likely, signifies the importance of VCC binding to the peptide/protein component at mass-balance transfer during inhalation. The established relationship can be used for extrapolation of a blood/gas partition coefficient measured in one species to another. This way, multiple independent-study estimates of a human partition coefficient may be obtained and then transformed to a meta-analytical value. A thus-derived partition coefficient represents a meta-analytical estimate reconciled with laboratory measurements in different studies and species, which is a more reliable estimate than of a partition coefficient from a single study. Incorporated in a physiologically-based pharmacokinetic model, a meta-analytical partition coefficient is expected to be more representative of general population, reduce experimental uncertainties and, consequently, increase the accuracy of modeling and improve the effectiveness of public health decisions, for which such modeling is carried out. Thus, this methodology may facilitate public health response, especially under time-limited conditions. *Disclaimer: the findings and conclusions in this presentation have not been formally disseminated by the Centers for Disease Control and Prevention/ the Agency for Toxic Substances and Disease Registry and should not be construed to represent any agency determination or policy.*

2897 Influence of Chitosan Coating on the Oral Bioavailability of Gold Nanoparticles in Rats

A. Alalaiwe. *Prince Sattam Bin Abdulaziz University College of Pharmacy, Alkharj, Saudi Arabia.*

Gold nanoparticles (AuNPs) have been extensively studied for a range of applications, including cancer therapeutics. Gold is less toxic than other metallic nanolattices, and gold nanoparticles are excellent conductors of electrical and thermal energy, making it possible to administer non-invasive radiofrequency irradiation with sufficient heat to kill tumor cells. Nanoparticles are generally administered intravenously instead of orally due to negligible oral absorption and cellular uptake. This study evaluated the oral bioavailability of gold nanoparticles coated with chitosan (C-AuNPs), a natural mucoadhesive polymer to eventually investigate the coating agent factor on nanometals bioavailability. The classical method of comparing blood concentrations with area under the curve analysis was used to determine the oral bioavailability of 3 nm C-AuNPs following intravenous and oral doses. The C-AuNPs exhibited an average primary particle size of 3 ± 1.2 nm. Zeta potentials for the C-AuNPs in water were indistinguishable from the neutral measurement: 1.3 ± 0.9 mV. The concentrations of the C-AuNPs administered intravenously (0.8 mg / kg) were declined with half-lives ranging from 15 mins to 24 hours. The serum elimination half-life appeared to be related to the chitosan coating layer, although the half-lives were not significantly different among the treatment groups (p = 40.05). Oral administration of the C-AuNPs resulted in an absorption phase over the first 2 hours after the dose was administered during which blood concentrations increased, followed by an elimination phase. The oral bioavailability for the C-AuNPs was estimated as 2.46 %. In conclusion, even the overall bioavailability of hydrophilic, low molecule cut-off polymer, i.e. chitosan is considerably low, chitosan is a promising candidate to be an oral enhancer for medical nanometallic particles. Further investigation is appreciably needed.

2898 High NRF1 Activity Is Associated with Poor Survival and Resistance to Temozolomide Therapy

K. Bhawe, Q. Felty, C. Yoo, A. Deoraj, and D. Roy. *Florida International University Robert Stempel College of Public Health & Social Work, Miami, FL.*

Temozolomide (TMZ) has been widely used as a chemotherapeutic drug for the treatment of new cases of glioblastoma (GBM). However, the development of TMZ drug resistance in almost all cases has become a major clinical problem for the treatment of this lethal disease. The molecular mechanisms of its resistance remain poorly understood. Thus, identification of the cellular and molecular mechanisms that confer drug resistance is an important goal for the treatment of GBM. Here we report the role of nuclear respiratory factor 1 (NRF1) in resistance to TMZ therapy. To our knowledge, there are no studies reporting NRF1 transcription factor activity associated with prognosis of GBM and/or TMZ resistance. Using GBM patient data from the GSE4290 cohort, we observed that patients in the shorter survival duration group had significantly higher NRF1 TF activity (p = 2.36e-31) compared to those in the longer survival duration group. We further confirmed our findings using three independent TCGA, REMBRANDT and GSE16011 GBM cohorts. In each dataset, patients were divided into two groups based on their NRF1 gene expression levels relative to the median NRF1 expression value for that dataset (NRF1 higher than median = high NRF1 group = group 1, and NRF1 lower than median = low NRF1 group = group 2). We confirmed our findings of GSE4290 cohort in these independent studies showing that the high NRF1 group had significantly lower median overall survival (25.9 months, CI = 21 - 33.5) and mean overall survival (49.39 months, CI = 43.3-55.5) compared to the median overall survival (35.9 months, CI = 28.9 - 40.8) and mean overall survival (69.77 months, CI = 60.4 - 79.2) of the low NRF1 group. Kaplan-Meier analysis also showed that high NRF1 gene expression is a risk factor (p = 0.0016) for poor prognosis in glioma. Using TCGA data and focusing on GBM patients treated with Temozolomide, we observed that IDH1 mutation status was a statistically significant determinant of overall survival outcomes, with the longer overall survival group enriched for IDH1 mutations, but none of the other factors such as age, gender, MGMT status, original cellular subtype etc. were significantly different between the two groups by ANOVA analysis. High NRF1 cases of GBM treated with TMZ showed significantly lower survival compared to GBM cases with low NRF1 activity. Further investigation revealed that NRF1 regulated target genes are differentially over-expressed in patients that respond poorly to TMZ based therapy. Differential gene expression analysis was performed on the two groups, and the following 10 NRF1 target genes were found to be upregulated in the high risk/ poor survival outcome group: LDHA, ZMAT3, NSUN2, ARMC5, NDEL1, CLPTM1L, ALKBH5, YIPF5, PPP2CA, and TFG. In summary, our findings suggest an NRF1-based potential mechanism by which GBM patients may acquire resistance to TMZ and targeting NRF1 signature causal pathway may help in overcoming TMZ resistance.

2899 The Use of Normative qEEG Databases Increases the Accuracy of Subject Screening in Phase I Clinical Trials of Drugs with Seizure Liabilities

M. Metea[1], and J. Messenheimer[2]. *[1]Preclinical Electrophysiology Consulting, Mattapoisett, MA; and [2]John Messenheimer PLLC, Raleigh, NC.*

Electroencephalography (EEG) is added to drug safety assessments during Phase I clinical trials only when a seizure liability is suspected. In such cases, subject inclusion criteria for healthy volunteers require normal EEG which entails the absence of epileptiform discharges against a normal background EEG activity. This is usually assessed by a visual inspection of short segments of EEG collected under eyes open and closed conditions. While detection of epileptiform discharges can only be conducted visually and has high interrater reliability, this is not the case for subtle nonepileptiform EEG abnormalities, some of which are difficult to interpret even when detected. Based on qEEG (quantitative EEG) advances over the past decades, we can now generate source-correlated 3-dimensonal topographical maps reflecting anatomical integrity of Broadmann areas, modular connectivity, and effective functionality of short and long pathways underlying normal brain function. These were made possible by the development and release into the public domain of LORETA (Low-Resolution Brain Electromagnetic Tomography) EEG source correlation combined with modern tractography, commonly referred to as "brain mapping". These functional qEEG metrics (e.g. spectral, coherence and phase metrics) can be compared with a rigorously developed and validated normative qEEG database (NDB) to ensure that the subjects are within the normal range of EEG variability. The qEEG process entails generating a detailed mapping of all functional areas (cortico-cortical and cortico-thalamic) as well as the connectivity between them, within minutes. The FDA considers the NDB-based qEEG as "useful and beneficial addition to the array of medical tests used to evaluate brain structure and function". Results are statistical deviations (z-scores) displayed in topographical z-score maps. Here we present a stepwise protocol for adding z-scored (deviation from age-matched normative database) qEEG measures, with examples of normal and abnormal nonepileptiform EEG. These added EEG metrics increase the accuracy of EEG screening in Phase I when integrated with clinical exams, and can also serve as a baseline if EEG biomarkers of drug effect are required.

2900 Predicting Human Infection Risk: Do Rodent Host Resistance Models Add Value?

K. C. Wu, Y. Zhong, and J. Maher. *Genentech Inc., South San Francisco, CA.*

Use of genetically engineered rodents is often considered a valuable exercise to assess potential safety concerns associated with the inhibition of a target pathway. When there are potential immunomodulatory risks associated with the target, these genetically modified animals are often challenged with various pathogens in an acute setting to determine the risk to humans. However, the applicability of the results from infection models is seldom assessed when significant retrospective human data become available. Thus, the purpose of the current review is to compare the outcomes of infectious pathogen challenge in mice with genetic deficiencies in TNF-a, IL17, IL23, or Janus kinase pathways with infectious outcomes caused by inhibitors of these pathways in humans. In general, mouse infection challenge models had modest utility for hazard identification and were generally only able to predict overall trends in infection risk. These models did not demonstrate significant value in evaluating specific types of pathogens that are either prevalent (ie rhinoviruses) or of significant concern (ie herpes zoster). Similarly, outcomes in mouse models tended to overestimate the severity of infection risk in human patients. Thus, there is an emerging need for more human-relevant models that have better predictive value. Large meta analyses of multiple clinical trials or post-marketing evaluations remains the gold-standard for characterizing the true infection risk to patients.

2901 Carbon Monoxide Poisoning Fatalities from the National Poison Data System, 2013-2017

T. Dodd-Butera[1,2], and H. Li[3]. *[1]California State University San Bernardino, San Bernardino, CA; [2]Azusa Pacific University, San Diego, CA; and [3]Azusa Pacific University, Monrovia, CA.*

In the United States, unintentional exposure to carbon monoxide (CO) results in approximately 50,000 emergency department visits and over 400 fatalities each year (CDC, 2019; Sircar et al., 2015). The purpose of this study was to review the CO exposure and fatality cases reported to US poison control centers (PCCs). Using a retrospective descriptive design, CO exposure data in the 2013-2017 National Poison Data System (NPDS) annual reports were examined for the following variables: age, gender, intent, and the number of yearly fatalities. Analytes and carboxyhemoglobin (COHb) levels of the CO fatality cases were also reviewed when reported. There were a total of 62,205 single CO exposures in the five-year study period, including 283 fatalities (Female 43.1%). No significant annual trends in CO exposure or fatality were identified. The age reported of these fatality cases ranged from 1 to 96 years (M = 42.05, SD = 24.79). Major reasons for fatal CO exposures included unintentional-environmental (73.1%) and intentional-suspected suicide (17.0%). Unintentional environmental CO fatal exposures affected 115 males and 87 females, and the age distribution peaked at the age of 7 (N = 8), 13 (N = 6), and 64 (N = 6). A total of 25 males and 22 females who died of CO exposures were reported as intentional suicide. No children under 16 years were reported in the suicidal intent category and the two peaks in age distribution for this category were 37 (N = 3) and 53 (N =3). Carboxyhemoglobin (COHb) was logically the most frequently used analyte (97.28% of 147 analytes) and the average concentration was 45.16% at the time of autopsy (N = 40). The current study revealed no significant improvement in CO fatal or non-fatal exposures during the five-year study period. Unintentional exposures to CO in the environment accounted for the majority of fatal cases among children as well as adults. Suicides via CO exposure accounted for a noteworthy proportion of fatal cases, mostly in adults. Coupled with information from the CDC CO Poisoning Surveillance Network, these findings have important implications for identifying the scope and potential strategies for CO poison prevention. Suggested directions for continued and innovative awareness campaigns could include public health education with a focus on identified CO sources, safety promotion for National Poison Prevention Week, and partnerships between poison prevention outreach programs, emergency departments, suicide prevention programs, school districts, Women, Infant, and Children (WIC) clinics, and Federally Qualified Health Clinics (FQHC). Such efforts offer the potential for decreasing CO poisoning incidents in at-risk populations.

2903 Methionine Supplemented Diet Worsens Recovery after Stereotactic Body Radiotherapy (SBRT) in a Mouse Model

L. E. Ewing[1], C. M. Skinner[1], M. Boerma[1], A. Lumen[2], M. Hauer-Jensen[1], and I. Koturbash[1]. *[1]University of Arkansas for Medical Sciences, Little Rock, AR; and [2]US FDA/NCTR, Jefferson, AR.*

Nearly half of all cancer patients undergo radiotherapy (RT) as a treatment modality. However, up to 70% of patients develop radiation-induced gastrointestinal syndrome (RIGS). Symptoms of the latter can be exacerbated by comorbidities, as well as diet and its interaction with the gut microbiome. Methionine (Met) is an essential amino acid required for the majority of key biological processes. At the same time, we and others have shown that Met supplementation may result in a number of toxic effects. This is of particular concern as the typical Western diet contains ~3 times more Met than the daily requirements. Based on our previous studies, we hypothesized that Met supplemented diet (MSD) will exacerbate radiation-induced injury through its effect on the gut microbiome. To test this hypothesis, CBA/CaJ mice were irradiated with the small animal radiation research platform (SARRP) targeting the upper abdomen, thus mimicking SBRT. Mice receiving MSD lost more weight and maintained decreased body weights over the 10-day period compared to mice receiving Met adequate diet (MAD). While no differences were observed histologically, there were significant differences in gut microbiome profiles between the MAD and MSD mice. Furthermore, significant increases in circulating neutrophils with corresponding decreases in lymphocytes were observed in MSD mice at 7 and 10 days post-SBRT, indicating a response to infection. This was confirmed by an increase in bacterial DNA in the liver on day 10. Furthermore, changes in the expression of the tight junction-related proteins *Cldn2*, *Cldn5*, and *Cldn6* indicated a possible increase in intestinal permeability. In conclusion, MSD exacerbates SBRT-induced RIGS by altering the gut ecology and increasing intestinal permeability, thus resulting in an elevated risk of sepsis.

2904 Toxicokinetic Analysis of microRNA-122 in Hepatotoxicity Demonstrates Metabolism to isomiRs and Clearance by Kidney and Spleen

J. D. Tranter[1], L. Chahman-Vos[2], O. Matthews[1], and J. W. Dear[1]. *[1]University of Edinburgh, Edinburgh, United Kingdom; and [2]Universiteit Utrecht, Utrecht, Netherlands.*

Circulating microRNAs (miRs) are promising toxicology biomarkers. MicroRNA-122 (miR-122) is an hepatocyte-specific biomarker of drug-induced liver injury (DILI). Our first objective was to determine the tissue distribution of miR-122 after its release from the liver using a mouse model of acetaminophen (APAP)-DILI. RNA sequencing has revealed that miRs can exist in multiple isoforms ('isomiRs') that vary in length. Our second objective was to profile miR-122 isomiRs and to adapt a novel assay (Dumbbell-PCR; Db-PCR) to selectively quantify isomiRs. Male C57BL/6J mice were treated intraperitoneally with APAP (300mg/kg) or vehicle. miR-122 was measured in blood plasma and organs using PCR. The presence of miR-122 isomiRs was determined by small RNA sequencing. Synthetic canonical miR-122 (22 nucleotides) and its isomiRs underwent PCR using SYBR green and TaqMan protocols. The Db-PCR assay was optimised for the detection of miR-122 isomiRs. At 6h after APAP treatment liver miR-122 expression decreased and circulating miR-122 increased ($1.6x10^5$ and $3.2 x10^8$ median miR-122 copies/µL plasma for control and treatment groups, respectively; $P < 0.0001$). At 12h after treatment circulating miR-122 had returned to control levels. With APAP-DILI, miR-122 expression increased in the renal cortex ($2^{-dCt} = 0.04$ and 0.1 for vehicle and treatment groups, respectively; $P < 0.05$), renal medulla ($2^{-dCt} = 0.07$ and 0.1 for vehicle and treatment groups, respectively; $P < 0.05$), and the spleen ($2^{-dCt} = 0.005$ and 0.03 for vehicle and treatment groups, respectively; $P < 0.001$). FACS analysis demonstrated that miR-122 increased specifically in renal tubular cells. Small RNA sequencing demonstrated the presence of multiple miR-122 isomiRs, with 3' variants being in high concentration. The efficiency of SYBR and TaqMan PCR decreased substantially as 3' nucleotides were removed. By contrast, Db-PCR was able to discriminate equimolar isomiRs from canonical miR-122 with a difference of around 10 cycle threshold (C_T) values. In summary, DILI induces the transfer of multiple isomiRs of miR-122 from liver to the kidney and spleen that 'industry standard' PCR kits cannot accurately quantify. Db-PCR is a novel PCR-based assay that should be taken forward to full validation.

2905 Acute Toxicity Evaluation of a Novel Ceramide Analog

K. M. Bongay-Williams, M. Hill-Odom, T. Ponnapakkam, N. Goyal, and M. Foroozesh. *Xavier University of Louisiana, New Orleans, LA.* Sponsor: T. Ponnapakkam

The present study aims to determine the *in vivo* acute toxicological profile of the synthesized ceramide analog 315, (S,E)-3-hydroxy-2-(2-hydroxybenzylidene)amino-N-tetradecylpropanamide. Analog 315 is a novel ceramide which was synthesized in our laboratory for the potential treatment of breast cancer. Treatment of nude mice with 10mg/kg of the Analog, 5 days per week for 3 weeks, was shown to inhibit tumor growth, and also to reduce metastasis of triple negative breast tumors caused by MDA-MB-231cells. Hence, a subsequent study was performed to determine the toxicological profile of this compound in nude mice. In our first toxicity study, nude mice were treated with 0, 40, 80 or 120 mg/kg body weight given only once. During this 14-day acute toxicity testing period, there was no mortality or morbidity except that the calcium concentration in the serum was significantly higher in the high dose group. Therefore a second acute toxicity study was done with lower drug doses, in which mice were treated with a single dose of 0, 25, 50 or 75 mg/kg body weight. During this 14-day observation period, conventional toxicity evaluation showed no abnormal signs of toxicity (No changes in body weights, organ weights, or behavior), and all biochemical parameters evaluated including serum calcium concentration were within the normal range. Our results are expected to pave the way for developing novel ceramide drugs with more efficacy and less toxicity than conventional chemotherapies for treating breast cancer, and improve the quality of life in patients.

2906 *In Vitro* EGFR-TKI Acquired Resistance in Brain-Seeking PC-9 Cells Overcome by a Bcl-2 Inhibitor

Z. Liu, N. Shah, P. Lockman, and W. Gao. *West Virginia University, Morgantown, WV.*

A lung cancer PC-9 brain seeking cell line (PC-9-Br) was established by a repeated *ex vivo* brain extraction method. PC-9-Br showed a significant resistance to epidermal growth factor receptor-tyrosine kinase inhibitor (EGFR-TKI) gefitinib compared with parental PC-9 by *in vitro* MTT assay. Further studies on the molecular mechanisms of gefitinib resistance revealed that EGFR and phospho-EGFR (p-EGFR) significantly decreased in PC-9-Br, while Bcl-2 significantly increased in PC-9-Br compared with parental PC9. However, the expressions of E-cadherin and vimentin did not show epithelial-mesenchymal transition (EMT) in PC-9-Br compared with parental PC-9. Additionally, gene analyses showed that PC-9-Br had neither T790 mutation (T790M) nor amplifications of MET and HER2 compared with parental PC-9. Therefore, our study demonstrated that brain metastases of lung cancer cells may independently prompt drug resistance without any drug treatment. Moreover, we found that the combination of a Bcl-2 inhibitor ABT263 at low and non-toxic concentrations with gefitinib showed significant synergistic effects on overcoming the acquired resistance of PC-9-Br *in vitro*. The results suggest that Bcl-2 inhibitors may have a great potential in clinical therapeutic applications for treatments of lung cancer brain metastasis and relevant acquired resistance.

2907 Cosmetics Europe Eye Program: Application of Two Defined Approaches for Ocular Toxicity Predictions Based on *In Vitro* Bottom-Up Approach on 4 Case Studies

N. Alépée[1], A. Takayuki[2], D. Bagley[3], J. Hibatallah[4], K. Mewes[5], U. Pfannenbecker[6], and E. Adriaens[7]. *[1]L'Oreal Research & Innovation, Aulnay, France; [2]Kao Corporation, Kanagawa, Japan; [3]Colgate Palmolive, New Jersey, NJ; [4]Chanel Parfums Beauté, Neuilly-sur-Seine, France; [5]Henkel AG & Co. KGaA, Düsseldorf, Germany; [6]Beiersdorf AG, Hamburg, Germany; and [7]Adriaens Consulting, Aalter, Belgium.*

The eye irritation/severe eye damage historically played a key role in the development, validation and regulatory acceptance of *in vitro* test methods and remains an active topic for regulatory toxicology, currently within the frame of the Organisation for Economic Cooperation and Development (OECD), Test Guideline Program. Recent activities in developing defined approaches (DAs) and how those fit have been achieved for liquids chemicals (Alépée et al., 2019 a,b). From the scientific side, the DAs allow to perform predictions over the entire spectrum of United Nations Global Harmonized System for classification and labelling (UN GHS Categories 1, 2 and No Category), by strategically combining physico-chemical properties to sequential *in vitro* testing on Reconstructed human Cornea-like Epithelium (RhCE) and Bovine Corneal Opacity and Permeability Laser Light-Based Opacitometer (BCOP LLBO) in a first DA bottom-up approach; and BCOP LLBO and short time exposure (STE) test in a second DA bottom-up approach. In the present work, application of both DAs is exemplified with specific case studies on four chemicals. Among the tested chemicals, a chemical (1,3-di-isopropyl benzene) known to be No Cat. *In vivo*, is predicted as No Cat. in the first tier strategy test methods of the DAs. Concerning the positive calls on the 2 known *in vivo* Cat. 2 chemicals (2-Ethyl-1-Hexanol and 2-Methyl-1-Pentanol) and an *in vivo* Cat. 1 chemical (2-Hydroxy-Isobutyric acid ethyl ester), the second-tier step which consists of their evaluation in the BCOP LLBO test which sub categorized them as Cat 2 / Cat. 1, respectively. In conclusion, these case studies reflect 2 approaches on how to move from animal testing into an evaluation of new ingredients based on examples of application of DAs on an Integrated Approach for Testing and Assessment for safety purposes of ingredients.

2908 Testing for Cosmetics Safety Assessment: Evaluation of Results from over 70 *In Vitro* Eye Irritation Studies

E. H. Theophilus[1], V. Rana[1], D. Mihai[1], N. Habeeb[1], T. Suwa[1], B. Yasso[2], B. Varsho[2], and G. DeGeorge[2]. *[1]Shiseido Americas Corporation, East Windsor, NJ; and [2]MB Research Laboratories, Spinnerstown, PA.*

There are typically two main steps involved in cosmetics safety assessment: 1) theoretical evaluation of formulation ingredients and raw materials to determine local and systemic toxicity potential, and 2) testing to confirm local toxicity effects of final formulations. Interactions among ingredients are not always easily predicted by single-ingredient theoretical evaluations – this is where testing for safety is critical. Given the momentum regarding refinement, reduction, or replacement (3Rs) of animal-based tests with *in vitro* methods, it is important to define testing strategies that meet those requirements and provide confident safety assurance for each toxicity endpoint (e.g., eye irritation potential). When used in combination, the Chorioallantoic Membrane Vascular Assay (CAMVA) and Bovine Corneal Opacity and Permeability (BCOP) assay have demonstrated to be relevant and reliable methods to predict eye irritation potential of cosmetics. These assays aid in predicting the possible effects of mixtures in the human eye because, together, they represent the majority of the eye (i.e., conjunctiva and cornea). In the BCOP test, there are currently two suggested classifications at the low end of the irritation spectrum: 1) GHS (no category) and 2) Gautheron (mild irritant). Results from our 70 test batteries have been used to establish a prediction model for safety assessment, which can be used to guide decision-making regarding warning labels. According to our data analyses, a formulation could be confidently predicted as "practically non-irritating" to the human eye when the CAMVA RC_{50} is >70% and BCOP *in vitro* Irritancy Score (IVIS) is ≤3. Comparing *in vitro* test results predictions with post-marketing surveillance analyses allows evaluation of the accuracy of the two-test battery prediction model, and the effectiveness of safety evaluation recommendations for product market release, all to better ensure consumer safety.

2909 Toxic Effect of E-cigarette on Blood Retinal Barrier (BRB) in Diabetic Macular Edema Model

S. R. Archie, A. Bhalerao, F. Sivandzade, and L. Cucullo. *Texas Tech University Health Sciences Center, Amarillo, TX.*

Growing popularity of Electronic cigarette (E-Cig) as a safe alternative to traditional tobacco smoking has prompted the regulatory authorities and researchers towards studying the effect of E-Cig on health. Several groups including our lab have shown that E-Cig contains different potentially toxic compounds along with nicotine which may promote cerebrovascular and cardiovascular diseases. In this respect, diabetic macular edema (DME), is characterized by macular area thickening and breakdown of blood retinal barrier (BRB), plays a pivotal role in losing vision in patients affected by diabetic retinopathy. Hyper glycemia and hypoxia are the key elements behind the progression of this disease. Previous studies found that nicotine promotes blood retinal barrier (BRB) damage in an *in vitro* BRB model however, the overall impact of E-Cig vapor, on BRB integrity and function has not been investigated yet. Therefore, the aim of this study is to evaluate the effects of E-Cig on BRB by determining its impact on BRB integrity/permeability, and HIF/VEGF expression in retinal pigmented epithelial cells (ARPE-19) as a DME model. For this study, ARPE-19 cells were grown on semipermeable Transwell supports. TEER FITC-dextran permeability assays were used to assess BRB integrity. To mimic the E-cig exposure, we used freshly prepared E-Cig extracts at physiologically relevant concentrations according to a previous validated published protocol. Our preliminary results strongly suggest that E-Cig extracts alters outer BRB integrity in a hyperglycemic and hypoxic microenvironment mimicking diabetic conditions. Loss of BRB integrity was paralleled by increased

VGEF expression. From this preliminary data, we can infer that, chronic E-Cig vapers may be at risk of onset/progression of DME. Additional studies are ongoing to determine the underlying mechanisms through which E-Cig impairs BRB.

PS 2910 Ocular Side Effects of Systemic Medications: Utilization of the 3D Human Corneal Epithelial Tissue Model

Y. Kaluzhny, M. W. Kinuthia, A. Lapointe, M. Klausner, and A. Armento. *MatTek, Ashland, MA.*

Many systemic medications at high doses have a potential to induce unwanted ocular effects, including light sensitivity, pain, or corneal edema that are due to inflammation and/or cytotoxicity. Current studies utilize animal models which are not suitable for rapid drug screening, have poor species extrapolation and standardization. There is a need for physiologically relevant, human primary corneal epithelial tissue models to address ocular safety for the evaluation of new drug formulations. We have utilized the 3D human corneal epithelial tissue model, EpiCorneal, to analyze the effect of common drugs with known adverse ocular side effects. EpiCorneal tissues are comprised of normal human corneal epithelial cells, express site-specific mucins and tight junctions and attain morphology, barrier properties (TEER>900±200 Ω*cm^2), and gene expression similar to the *in vivo* human cornea. The effect of physiologically relevant concentrations of Chlorpromazine hydrochloride (CPZ), a common pshychtropic agent; Hydroxychloroquine sulfate (HCQ), an anti-inflammatory and anti-malaria drug (HCQ); and Fosamax (Alendronate Sodium, FOS), a common anti-osteoporosis agent, were investigated. Effects on tissue viability (MTT assay), barrier function (Transepithelial electrical resistance, TEER), histology, LDH and cytokine release were studied. EpiCorneal tissues were incubated in the medium containing CPZ at 6.25 - 100 µM, HCQ at 6.17 - 500 µg/ml, or FOS at 0.1 - 100 µg/ml for 24h and 48h. For CPZ-treated tissues the lowest dose to cause a significant decline in barrier function (67.4%) was 12.5 µM at 24h, and 25 µM decreased tissue viability (60.5%) at 48h. For HCQ-treated tissues, a decline in TEER (67.4%) was detected for 18.52 µg/ml at 24h, and in tissue viability (53.6%) for 55.56 µg/ml at 48h. For FOS-treated tissues, a significant TEER decrease (57.8%) was detected at 0.1 µg/ml and in tissue viability (85.7%) for 10 µg/ml, both at 48h. Treatment-specific changes in tissue morphology and dose response of LDH and cytokine release were also observed. EpiCorneal tissue model has been very useful for evaluating formulations with negligible irritation potential. It will model systemic drug exposure for extended time, will generate rapid response, avoid species extrapolation, be more cost effective and more reproducible than animal methods, and will facilitate drug discovery by allowing screening and optimization of pharmaceuticals prior to clinical studies.

PS 2911 Chronic O-GlcNAcase Inhibition Causes Lens Opacities in Dogs but Not Rats

W. Cook[1], S. Bellum[1], J. Fretton[2], L. Bernard[2], J. Darbes[2], G. Fernandez[1], S. Ferry-Martin[2], A. Galijatovic-Idrizbegovic[1], and R. Briscoe[1]. *[1]Safety Assessment and Laboratory Animal Resources (SALAR), Merck & Co. Inc., West Point, PA; and [2]SALAR, Laboratoires Merck Sharp & Dohme-Chibret, Riom, France.*

Cataracts are the leading cause of blindness worldwide and diminished proteolytic functionality in the lens may cause cataracts. O-linked β-N-acetylglucosamine (O-GlcNAc) has been proposed as an endogenous inhibitor of the proteasome and transgenic mice that over express a dominant negative form of O-GlcNAcase, GK-NCOAT, in the lens, had suppressed removal of O-GlcNAc from lens proteins, resulting in increased O-GlcNAc and decreased proteasome function in the lens, markedly larger nuclear cataracts than control mice, lens epithelial cell hyperplasia, and inhibition of lens fiber cell denucleation. These results suggested that increased O-GlcNAc in the lens could lead to cataract formation. As a potential treatment for Progressive Supranuclear Palsy (PSP), Merck investigated the potential toxicity of MK-8719, an O-GlcNAcase (OGA) inhibitor in repeat-dose general toxicology studies *in vivo* in Crl: WI(HAN) rats (up to 6 months) and Beagle dogs (up to 9 months). In dogs but not rats, upon ophthalmoscopic examination, MK-8719 produced lens changes, consisting of prominent posterior subcapsular suture lines and/or lens opacities (posterior subcapsular or subcapsular/capsular). These changes were identified in dogs following 4-6 months of dosing with MK-8719 and correlated with histomorphological findings of posterior subcapsular central lens fiber degeneration in some of the animals with ophthalmoscopic findings. To evaluate if the lens changes were mechanism based, ophthalmoscopic examinations were performed on beagle dogs receiving a structurally unrelated OGA inhibitor. This compound produced similar posterior lens changes in dogs following a similar duration of dosing, supporting the conclusion that the lens effects are mechanism based. These findings provide further evidence that increased O-GlcNAc protein posttranslational modifications in the lens can cause cataracts *in vivo* and may have implications for cataract formation as a complication of diabetes since O-GlcNAc is derived from glucose.

PS 2912 Longitudinal Imaging Reveals Patterns of Neurodegenerative Inflammation in Rotenone-Induced Retinal Neurotoxicity

J. D. Luisi, M. Motamedi, and B. Ameredes. *University of Texas Medical Branch at Galveston, Galveston, TX.*

Rotenone is a mitochondrial toxicant known to induce neurodegeneration. However, the neuroinflammatory responses following exposure to rotenone have not yet been clearly characterized. As resident immune cells of the central nervous system, microglia are known to enhance the neurotoxicity of rotenone. We postulated that non-invasive imaging of the retina can reveal neurotoxic effects of localized exposure to rotenone, including the temporal changes due to neuroinflammation. To test this, we monitored the spatial and temporal changes in retina inflammation and neurotoxicity following direct exposure to rotenone by intravitreal injection, by combining imaging techniques including optical coherence tomography (OCT) and confocal scanning-laser funduscopic (cSLO). To visualize microglia activation, we used Cx3Cr1^{eGFP} transgenic mice in which macrophages express green fluorescent protein. Accordingly, we utilized a non-invasive imaging protocol to assess neurotoxicity longitudinally, without an invasive biopsy. The OCT images were processed to characterize and quantify rotenone-induced changes in retinal morphology. We found that a 0.3µL/10mM concentration of rotenone caused retinal thinning and neurodegeneration, during the late phase of inflammation. Retinal thinning at day 7 correlated to the first appearance of hyper-florescent puncta in the photoreceptor layer. Furthermore, the puncta proliferated at day 14, indicating lipid peroxidation. The Cx3Cr1 microglia, at day 7 post treatment, were aligned with the nerve fiber tracts. Before 7 days, microglia activation in the inner portion of retina was not detected. Based on the OCT findings, neurodegeneration was 7-14 days post-injury, and photoreceptor loss was not evident until day 14. These studies showed a predominantly M1 verses M2 microglia phenotype at 7 days, suggesting transition into chronic inflammation rather than resolving phase. These studies indicated that a low dose of rotenone can facilitate development of a neurodegenerative pathology over time, and that the late phase M1 microglia activation may be the driving force of the delayed response and subsequent neurodegeneration. Furthermore, we believe that the non-invasive imaging used in the current study provides a novel approach for characterizing the inflammatory progression of neurotoxicity. *NIEHS T32ES007254.*

PS 2913 Optical Coherence Tomography (OCT) *In Vivo* Imaging Tool to Monitor Retina in Preclinical Species

S. Bellum[1], B. Bennet[2], S. Born[1], W. Cook[1], C. Lazarus[1], B. Mattson[1], N. Muniappa[1], M. Viola[1], A. Galijatovic-Idrizbegovic[1], and G. Wollenberg[1]. *[1]Merck & Co. Inc., West Point, PA; and [2]Voyager Therapeutics, Cambridge, MA.*

Optical Coherence Tomography (OCT) is a non-invasive high-resolution, 3D-imaging technique with important biomedical application in ophthalmology. OCT provides high resolution (~ 3 microns) volumetric retinal images suitable for morphologic assessment and longitudinal in-life monitoring. OCT has become a valuable tool for the study and diagnosis of retinal diseases in humans, and it may be utilized to evaluate anterior segment structures as well. In drug development, OCT can be utilized in preclinical species to provide a monitoring capability for humans. In this presentation, we report on the utility of spectral domain OCT (Envisu™ R-2200 Model, Bioptigen Inc./Leica Microsystems) to detect changes in eye structures in living rats and mice. OCT was successfully used to measure retinal thickness in-life in a light-induced retinal atrophy model and in a drug-induced (Abilify/aripiprazole) retinal atrophy model in rats. Additionally, using ritonavir-treated mice, OCT was also used to measure retinal pigmented epithelium (RPE) thickness over time. OCT was able to detect treatment-related decreases in retinal thickness and increases in the RPE thickness enabling in-life monitoring and the ability to detect the progression of lesions in the same animal, thereby enabling the use of fewer animals in some preclinical studies and demonstrating a monitoring capability for clinical studies.

2914 The Role of CYP2B6 in Sertraline-Induced Toxicity in Hepatic Cells

M. Fan[1,2], L. Guo[1], and S. Chen[1]. [1]*US FDA/NCTR, Little Rock, AR; and* [2]*Brown University, Providence, RI.*

Sertraline is an antidepressant commonly used to manage mental health symptoms relating to depression, anxiety disorders, and obsessive-compulsive disorder. The use of sertraline has been associated with rare but severe hepatotoxicity. Previous research has demonstrated that ER stress, mitochondria impairment, and apoptosis are involved in sertraline-associated cytotoxicity. It has also been demonstrated that sertraline is mainly metabolized by cytochrome P450 (CYP) 2B6. However, the role of CYP-mediated metabolism in sertraline-induced toxicity remains unclear. In this *in vitro* study, we used our established CYP2B6-overexpressed HepG2 cell line to investigate the role of CYP2B6 in sertraline-induced cytotoxicity. We found that the metabolism catalyzed by CYP2B6 significantly attenuated sertraline-induced cytotoxicity in comparison with vector control cells, as measured by LDH and MTS assays. Western Blot analysis demonstrated that less induction of γH2A.X, a hallmark of DNA damage, occurred in CYP2B6-overexpressed cells in comparison to the vector control under the same treatment of sertraline. These findings indicate that CYP2B6 plays a role in the metabolic detoxification of sertraline by preventing DNA damage. This work contributes to our overall understanding of the role that metabolic enzymes play in sertraline-associated hepatotoxicity.

2915 Gut Microbiome Critically Impacts PCBs-Induced Changes in Hepatic Transcriptome Metabolic Fingerprints

J. J. Lim[1], X. Li[2], H. Lehmler[2], D. Wang[3], H. Gu[3], and J. Y. Cui[1]. [1]*University of Washington, Seattle, WA;* [2]*University of Iowa, Iowa City, IA; and* [3]*Arizona State University, Scottsdale, AZ.*

Polychlorinated biphenyls (PCBs) are ubiquitously detected in the body and have been linked to numerous diseases. The liver serves as a central hub for the metabolism of xenobiotics and metabolites. Xenobiotics induced gut dysbiosis is recognized as a critical regulator of disease susceptibility. Although the acute toxicity of PCBs on the liver is known, the role of the microbiome in PCBs-mediated responses remains understudied. We hypothesized that PCBs-mediated changes in the metabolic fingerprints and hepatic transcriptome are regulated by enterotype and dose. Ninety-day-old female conventional (CV) and germ free (GF) C57BL/6 mice were orally exposed to the PCB Fox River Mixture (synthetic PCB mixture, 6 or 30 mg/kg) or corn oil (vehicle, 10 ml/kg), once daily for 3 consecutive days. Organs were collected 24 hours after the final dose. RNA-Seq was conducted in liver, and endogenous metabolites were quantified in liver and serum by LC-MS. Enterotype was the primary factor in clustering the transcriptomic and metabolomic signatures within the same exposure. The numbers of PCB-regulated genes were higher in CV than in GF conditions. The mRNAs and proteins of the prototypical target genes of the major xenobiotic sensing transcription factors AhR, PXR, and CAR were more readily induced by PCBs in CV than in GF conditions, indicating the effect of PCBs on the hepatic transcriptome act partly through the gut microbiome. In addition to the dysregulation of genes important for xenobiotic biotransformation and inflammation, the folding of incorrect proteins pathway was down regulated by PCBs, especially in CV conditions. At the high PCB dose, NADP and arginine, which are known to involved in the mechanism reactions of the drug-metabolizing enzymes (Cyp1-3 family, DhcR7, and Nqo1), were down-regulated in CV mice. In PCB-exposed GF groups, hepatic glucose was up-regulated, whereas fructose 6-phosphate and glucose 6-phosphate were down-regulated, indicating increased glucose utilization potentiated by lack of gut microbiota. In conclusion, our findings demonstrate that habitation of the gut microbiota drives PCBs-mediated hepatic responses, possibly due to crosstalk between gut and liver through the enterohepatic circulation.

2916 Metabolism of Naphthalene by Mouse Liver Microsomes: Glutathione Does Not Affect 1,2-Dihydrodiol Formation

E. Uwimana[1], N. Kovalchuck[1], L. Van Winkle[2], and X. Ding[1]. [1]*University of Arizona, Tucson, AZ; and* [2]*University of California Davis, Davis, CA.*

Naphthalene (NA) is a ubiquitous carcinogenic pollutant to which humans are widely exposed. A prerequisite for NA's toxicity in the respiratory tract is bioactivation by cytochrome P450 (CYP) enzymes. NA metabolic pathways to toxicity involve initial formation of NA-oxide, and subsequent formation of reactive metabolites derived from 1,2-NA-dihydrodiol (producing 1,2-naphthoquinone) or 1-naphthol (producing 1,4-naphthoquinone). However, the relative importance of these reactive metabolites and more specifically the role of reduced glutathione (GSH), which reacts with NA-oxide to form NA-GSH adducts, in modulating the abundance of 1,2-NA-dihydrodiol and 1-naphthol is unclear. In this study, we examined the effects of GSH and UDPGA (cofactor for UDP glucuronyl transferase) addition on the rates of 1,2-NA-dihydrodiol and 1-naphthol formation in reactions of NA with mouse liver microsomes. Levels of 1,2-NA-dihydrodiol and 1-naphthol were measured using UPLC-UV, whereas those of NA-GSH were measured using LC-MS/MS. We show that addition of GSH up to 10 mM, which led to maximal formation of NA-GSH, did not significantly decrease rates of 1-naphthol or 1,2-NA-dihydrodiol formation *in vitro*. On the contrary, UDPGA addition resulted in significant decreases in 1-naphthol formation, but not 1,2-NA-dihydrodiol formation. These results suggest that GSH cannot prevent formation of 1,2-NA-dihydrodiol, a reaction catalyzed by microsomal epoxide hydrolase. The implication from these findings is that levels of NA-GSH may not correlate with those of 1-naphthol or 1,2-NA-dihydrodiol *in vivo* in NA-exposed individuals, and that the risks of toxicity from the three different bioactivation pathways (via the formation of NA-oxide, 1,2-NA-quinione, and 1,4-NA-quinone) should be assessed independently. *Supported in part by NIH grant ES020867.*

2917 Crystal Structures of 2-Nitro- and 3-Nitro-4-Acetamidophenols: Significance to Mechanisms of Pharamacology and Toxicology of 4-Acetamidophenol

C. J. Deere[1], O. A. Agu[1], R. Paramkusam[1], F. R. Fronczek[2], and R. M. Uppu[1]. [1]*Southern University and A&M College, Baton Rouge, LA; and* [2]*Louisiana State University, Baton Rouge, LA.*

We have previously shown that the putative free radical products of the peroxynitrite anion-CO2 reaction (•NO2 and CO3•¯) can constitute an important source of non-CYP450-mediated oxidative biotransformation of 4-acetamidophenol (4-AP) and other xenobiotics (clozapine). In reactions of 4-AP/PN/CO2, we find that 2-nitro-4-acetamidophenol (2-nitro-4-AP) is one of the major products formed along with N,N′-(6,6′-Dihydroxy[1,1′-biphenyl]-3,3′-diyl) bisacetamide (dimer of 4-AP) and a metastable N-acetyl-1,4-benzoquinone (NBQI; demonstrated through its binding to N-acetyl-L-cysteine). It was shown recently that NBQI can react with electrophiles like the nitrite ion and form an yet another nitroproduct of 4-AP, viz., 3-nitro-4-acetamidophenol (3-nitro-4-AP). Although we did not find evidence for the formation of 3-nitro-4-AP in 4-AP/PN/CO2 reactions, we believe that 3-nitro-4-AP along with other oxidation products of 4-AP may play a role in the pharmacology and toxicology of 4-AP (4-AP overdose, either accidental or inadvertent, is the most common cause of hepatic failure in the US and elsewhere). Towards understanding this, we have synthesized the 2-nitro and 3-nitro isomers of 4-AP and examined their single crystal properties. To our surprise, we find that the two isomers have quite different molecular planarities in the solid state and also differ in their hydrogen bonding patterns. In 2-nitro-4-AP, the acetamido group is twisted out of the plane of the phenyl group by 9.0° and the nitro group is twisted out of the phenyl plane by 11.8°. The N-H group forms an intermolecular hydrogen bond to acetamido O having N···O distance 2.9079(17) Å and N-H···O angle 176.6(19)°. The OH group forms a bifurcated hydrogen bond, with intramolecular component to the adjacent nitro group (O···O 2.6093(17) Å) and a longer intermolecular component to nitro oxygen (O···O 3.1421(17) Å). In 3-nitro-4-AP, the molecule is nearly planar, with all nonhydrogen atoms having a mean deviation from coplanarity of 0.035 Å. The acetamido group has the largest deviation, with a 5.1° twist about its central N-C bond. The N-H group forms an intramolecular hydrogen bond to nitro O having N···O distance 2.6363(15) Å and N-H···O angle 139.6(15)°. The hydroxy group makes an intermolecular hydrogen bond to acetamido O having O···O distance 2.7183(14) Å and O-H···O angle 172.0(18)°, forming chains. Combined with the recent revelations of mechanisms of action of 4-AP through indirect activation of CB1 receptors by 4-aminophenol (hydrolysis product of 4-AP) and endocannabinoid reuptake inhibitor AM 404, the information presented here may provide useful insights into molecular targets for 4-AP and its metabolites.

2918 Enzyme Kinetic Parameters for Hydrogen Peroxide Generation (Auto-Oxidation) in P450-Related Microsomal Electron Transport Chains

J. E. Taylor[1], V. Mishin[2], and J. D. Laskin[2]. *[1]Eastern Michigan University, Ypsilanti, MI; and [2]Rutgers, The State University of New Jersey, Piscataway, NJ.*

It is well recognized that a microsomal electron transport chain with terminal oxidase cytochrome P450 enzymes (CYP's) generates hydrogen peroxide. This reaction requires NADPH and oxygen and proceeds via autooxidation without metabolizing substrates or by uncoupling with metabolizing substrates. Rates of hydrogen peroxide generated by this system in rat liver microsomes depend on multiple factors including the specific set of expressed CYP's. Earlier studies by our laboratory showed that the CYP3A family is one of the most active CYP's producing hydrogen peroxide. Of the CYP3A family, rat liver microsomes from male Sprague Dawley (SD) rats contain only CYP3A2; using the Amplex Red/HRP assay, we found that the Vmax for hydrogen peroxide generation by these microsomes in the absence of substrates was 4.0 nmol/min/mg protein with NADPH as the electron donor. Significantly increased hydrogen peroxide generating activity was found in liver microsomes from dexamethasone treated male rats where CYP3A1 and CYP3A2 are highly inducible (Vmax = 14-16 nmol/min/mg protein). Clotrimazole, a form-selective inhibitor of rat CYP3A1 and CYP3A2, suppressed 60% of hydrogen peroxide generation in liver microsomes from dexamethasone treated male rats. The Km for NADPH for hydrogen peroxide generation was similar (≈ 2.0 μM) in microsomes from control and dexamethasone treated male rats. These data indicate that increases in content of CYP 3A family enzyme in rat liver microsomes are largely responsible for the higher rates of hydrogen peroxide formation. Moreover, similarities in the Km for NADPH may represent similar affinities of CYP3A subfamily enzymes for the NADPH-cytochrome P450-reductase during the formation of hydrogen peroxide. *Supported by NIH grants U54AR00573 and R25ES020721.*

2919 Identifying Sites of Interdomain Interaction on Dimeric BM3 P450 Using Covalent Cross-Linking and Mass Spectrometry

D. Felker, H. Zhang, Y. Morishima, M. Lau, and Y. Osawa. *University of Michigan, Ann Arbor, MI.*

CYP102A1 (BM3) is a model P450 used to elucidate the mechanisms of enzymatic turnover in fusion P450 enzymes. BM3 is active as a homodimer, with dimerization interfaces contained within its N-terminal oxygenase and C-terminal reductase domains. While crystal structures have been successfully resolved for the heme-containing oxygenase domains in complex with a single subunit of reductase domain, the nature of interactions between full-length BM3 subunits in solution are not understood. In this study, we utilized a novel method to identify interactions between BM3 subunits by covalent crosslinking and mass spectrometry (CXL-MS). Specifically, we exposed full-length dimeric BM3 to an MS-cleavable crosslinker disuccinimidyl dibutyric urea then excised and analyzed both monomeric and dimeric BM3 from a single crosslinked sample, then validated assigned crosslinks using recent high-resolution cryogenic electron microscopy (Cryo-EM) structures of the full-length BM3 from our lab. All 13 unique crosslinks present in the monomeric BM3 band were also detected in the dimeric band and mapped to distances on the Cryo-EM structure within the spatial restraints of the crosslinker. The dimeric band yielded 32 unique crosslinking sites, 5 of which were interdomain. The interdomain crosslinks suggested extensive interaction between oxygenase and opposing reductase domains in the homodimer, which is consistent with the understood mechanism of electron transfer in the holoenzyme. These data enhance our understanding of the BM3 homodimer's structural arrangement during enzymatic turnover in solution, and identify novel target sites for enzymatic regulation. *This work was supported by NIEHS training grant T32-ES007062, NIH grants GM077430 and GM007767, NINDS grant NS055746, and the University of Michigan Medical School's Protein Folding Disease Initiative.*

2920 Single Crystal Structure of 2,5-Dinitro-4-Acetamidophenetole: Implication to Phenacetin Toxicity

S. N. Uppu[1], O. A. Agu[2], C. J. Deere[2], S. N. Murthy[2], and F. R. Froenczk[1]. *[1]Louisiana State University, Baton Rouge, LA; and [2]Southern University and A&M College, Baton Rouge, LA.*

The analgesic use of phenacetin (4-acetamidophenetole; 4-AcP) predates the First World War. 4-AcP was probably the first synthetic chemical to go on the market as a fever reducer as well. However, due to its carcinogenic and kidney-damaging properties, 4-AcP was withdrawn from the markets word over some three decades ago. In view of 4-AcP's similarity to cocaine in physical appearance and texture, in recent years, there have been several instances of 4-AcP being used as an adulterant or cutting agent, meaning that 4-AcP is still in use disguised in the form of an illicit drug. Ironically, 4-acetamidophenol, a metabolite of 4-AcP has similar analgesic properties but without any carcinogenicity or kidney toxicity. Although there has been some research on the phase I and phase II metabolites of 4-AcP, the information on metabolites of 4-AcP that could be formed in reactions with cellular oxidants such as hypochlorite ($^{-}$OCl)/hypochlorous acid (HOCl; pKa≈7.53) and the peroxynitrite ($ONOO^{-}$)/peroxynitrous acid (ONOOH; pKa≈6.2; ONOOH and $ONOO^{-}$ are collectively referred to as peroxynitrite or PN) is scanty. We have shown, for instance, that 4-AP forms nitrated and chlorinated metabolites in these systems under physiologically relevant conditions of pH and CO2 concentration (important in the case of reactions with PN). We suspect that a similar set of metabolites may be formed in reactions of 4-AcP with HOCl/OCl and PN±CO2. Towards understanding this and to shed light on molecular targets, we have synthesized 2,5-dinitro-4-acetamidophenetole (2,5-dinitro-4-AcP) using nitric acid-sulfuric acid mixtures in the cold. The single crystals of 2,5-dinitro-4-AcP from methanol were analyzed using the technique of X-ray diffraction. We find that the ethoxy group is nearly coplanar with the phenyl ring, having C-C-O-C torsion angle 1.4° and C-O-C-C(Me) torsion angle 174.6°. The acetamido group is also nearly coplanar with the phenyl ring, having C-C-N-C torsion angle 3.2°. The nitro group adjacent to acetamido is twisted out of plane by 24.2°, and the one adjacent to ethoxy is twisted out of plane by 43.0°. The N-H group forms a bifurcated hydrogen bond, with intramolecular component to the adjacent nitro group (N···O 2.6857(6) Å) and a longer intermolecular component to the other nitro group (N···O 3.4308(6) Å), forming chains. The results of the present study, together with the recent understanding of the mechanisms of action of 4-AP which proceeds through hydrolysis and subsequent formation of arachidonic acid conjugates and their binding cannabinoid receptors, may be useful in providing insights into molecular targets for 4-AcP and its metabolites.

2921 Reactions of Penicillins G and V with Peroxynitrite (±CO_2): Implications to Tyrosine Nitration in Nitric Oxide-Producing Biological Systems

O. A. Agu, C. J. Deere, R. Paramkusam, S. Kasibhatla, and R. M. Uppu. *Southern University and A&M College, Baton Rouge, LA.*

Peroxynitrite (PN) is an elusive oxidant that can be formed in nitric oxide ($^{\cdot}NO$) producing biological systems from the reaction of $^{\cdot}NO$ with superoxide ($O_2^{\cdot-}$) and oxyhemoglobin. In biological milieu, only a few substrates such as heme proteins and peroxidases react rapidly enough with PN, before it is trapped by the reaction with CO_2 forming $^{\cdot}NO_2$ and $CO_3^{\cdot-}$ free radicals in yields up to 40 mol% of the original PN. Both $^{\cdot}NO_2$ and $CO_3^{\cdot-}$ are highly reactive towards a variety of biomolecules including lipids, proteins, nucleic acids, and antioxidants. For years, our primary goal has been to elucidate the mechanisms of non-P450-mediated oxidative biotransformation of xenobiotics by $^{\cdot}NO$-derived oxidants. With this in view and also in view of the recent demonstration that certain antibiotics interference of protein nitration, we undertook studies of penicillin G (PG) and penicillin V (PV) reaction with PN, PN±CO_2, and PN±CO_2±lysozyme (lysozyme was model protein used in these studies). At pH 7.2 and 37±0.5 ^{0}C, the second-order rate constants for the PN-PG and the PN-PV reactions were found to be 101 and 135 M^{-1} s^{-1}, respectively. These rates are 3- to 4-orders of magnitude smaller than those typically found in reactions of PN with CO_2, hemoproteins, and peroxidases. Also, since the therapeutic concentrations of PG and PV are generally in the μM to sub-millmolar range, we believe that these antibiotics do not react directly with PN in competition with any of three classes of biological target molecules referenced above. To test if the products of PN±CO_2 ($^{\cdot}NO_2$ and $CO_3^{\cdot-}$) react with PG and PV, we performed the direct reactions PG and PV with PN±CO_2 and examined for the formation of nitration products with significant abortion in the visible region. While there was little or no evidence for the formation of nitro products in the case of PG, we did find that PV forms nitro products which strongly absorb in the visible region with a maximum around 464 nm. In the second set of experiments, lysozyme was allowed to PN±CO_2 for the formation of

nitrolyzyme and then examined if either PG or PV interfere with this process. There was marginal inhibition of lysozyme nitration by PV but not by PG, although the latter was employed in mM concentrations. Although the results of the present study need further confirmation with product analysis, we believe that the effects of antibiotics on protein nitration may be less significant compared to N-acetyl-L-cysteine and other reactive thiol antioxidants.

2922 Dual Mechanisms Suppress Meloxicam Bioactivation Relative to Sudoxicam

D. A. Barnette[1], M. A. Davis[1], L. R. Osborn[2], M. Matlock[3], S. Swamidass[3], and G. P. Miller[1]. *[1]University of Arkansas for Medical Sciences, Little Rock, AR; [2]Ave Maria University, Ave Maria, FL; and [3]Washington University in St. Louis, St. Louis, MO.*

Thiazoles are biologically active aromatic heterocyclic rings occurring frequently in natural products and drugs. These molecules undergo typically harmless elimination; however, a hepatotoxic response can occur due to multistep bioactivation of the thiazole to generate a reactive thioamide. A basis for those differences in outcomes remains unknown. A textbook example is the high hepatotoxicity observed for sudoxicam in contrast to the relative safe use and marketability of meloxicam despite the difference in one methyl group. Both drugs undergo bioactivation and meloxicam possesses an additional detoxification pathway due to hydroxylation of the methyl group. We hypothesized that thiazole bioactivation efficiency is similar between sudoxicam and meloxicam due to the methyl group being a weak electron donator, and thus the relevance of bioactivation and likely toxicity, depends on the competing detoxification pathway. For a rapid analysis, we modeled epoxidation of sudoxicam derivatives to investigate the impact of substituents on thiazole bioactivation. As expected, electron donating groups increased the likelihood for epoxidation with a minimal effect for the methyl group, but model predictions did not scale well among types of substituents. Through novel analytical methods, we measured steady-state kinetics for metabolic bioactivation of sudoxicam and meloxicam by human liver microsomes. Sudoxicam bioactivation was ~7-fold more efficient than that for meloxicam, yet meloxicam showed an ~12.5-fold higher efficiency of detoxification than bioactivation. Taken together, sudoxicam bioactivation was 90-fold more likely than meloxicam considering all metabolic clearance pathways. Kinetic differences likely arise from different enzymes catalyzing respective metabolic pathways for sudoxicam compared to meloxicam based on phenotyping studies. Rather than simply an alternate detoxification pathway, the meloxicam methyl group suppressed the bioactivation reaction. These findings indicate the impact of thiazole substituents on bioactivation is likely more complex than previously thought and likely contributes to the unpredictability nature of their toxic potential.

2923 Using Activity-Based Labeling to Estimate Toluene Biodegradation Rates in Soils

A. Oyarzun Mejia, and M. Hyman. *North Carolina State University, Raleigh, NC.* Sponsor: J. Bonner

Toluene is a common organic contaminant in groundwater used for drinking water. Naturally-occurring bacteria use oxygenase enzymes to initiate aerobic toluene biodegradation. Currently, detection of aerobic toluene-oxidizing bacteria in groundwater or soils is typically established by measuring the abundance of the genes encoding these oxygenases. We hypothesize that more accurate estimates of the abundance of toluene-oxidizing bacteria (and their rate of toluene biodegradation) can be derived from methods that quantify active oxygenase abundance. The objective of this project is to develop an activity-based labeling (ABL) method to quantify catalytically-active forms of toluene-oxidizing oxygenases in soil bacteria. Our ABL method uses mechanism-based inactivator probes, click chemistry and fluors to covalently label the active site of toluene-oxidizing monooxygenases. The resulting fluorescent proteins are then quantified by near-infra-red scanning after separation of total cell proteins using SDS-PAGE. We have focused on a model toluene-oxidizing bacterium (*Burkholderia vietnamiensis* G4) and have identified 1,7-octadiyne [17OD] as the most effective ABL probe based on both rates of monooxygenase inactivation and fluorescent labeling specificity. The effects of 17OD are specific for toluene-2-monooxygenase based on substrate-dependent O_2-uptake assays and we have also established a limit of detection for free-living cells using this ABL approach. To extend these studies into soils, we have also developed a whole cell extraction method using Nycodenz density gradient centrifugation that is comparably effective to methods for direct extraction of proteins from soils samples. Our future goals are to confirm the identity of the fluorescently-labeled protein using proteomic analyses of in-gel digestions of these proteins. We also plan to compare toluene-oxidizing activity and ABL responses in toluene-stimulated and control soil microcosms, and compare these responses to toluene oxygenase gene abundance measurements made using qPCR. This ABL method is also applicable to many other oxygenases that, for instance, oxidize important emerging contaminants including 1,4-dioxane and 1,2,3-trichloropropane as well as other pollutants including chlorinated solvents and fuel oxygenates. We are currently exploring the use of the ABL method to evaluate natural attenuation in water samples from fields contaminated with chlorinated solvents.

2924 Investigating the Impact of Trisomy 21 on Xenobiotic Biotransformation Using Human Dermal Fibroblasts

J. O. Marentette, A. Rauniyar, and J. Roede. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

While Down syndrome (DS, Trisomy 21) is generally associated with intellectual deficits and distinct physical features, this population of individuals experiences a host of additional comorbidities including type 1 diabetes, obesity, leukemia, inflammation and Alzheimer's disease. These comorbidities are of great significance to this study due to the fact that genetics, disease states, and cofactor levels can greatly impact xenobiotic biotransformation. To assess the impact of trisomy 21 on xenobiotic biotransformation, we investigated drug metabolizing enzyme (DME) gene expression in age- and sex-matched pairs of human dermal fibroblasts. By using Phase 1 and Phase 2 qPCR arrays, we analyzed the basal expression of 84 Phase 1 and 84 Phase 2 DME genes between control (CTRL) and DS. We detected significant differences in the expression profiles of numerous cytochrome P450s (CYPs), alcohol dehydrogenases, aldehyde dehydrogenases, glutathione transferases (GST) and sulfotransferases. Fibroblasts were then exposed to benzo[a]pyrene (BaP) to stimulate the aryl hydrocarbon receptor (AhR) and downstream drug metabolizing enzyme (DME) gene expression was analyzed. After 24 hours of BaP (10μM) stimulation, we detected variations in DME gene expression in DS compared to CTRL with ALDH3A1 (2.5 to 2 fold change in CTRL vs DS), CYP1A1 (3.8 to 0.4) and CYP1B1 (4.0 to 2.5). These studies highlight the inherent differences that having the presence of trisomy 21 has on DME inducibility via the AhR. Further, these data show that DS individuals do not metabolize xenobiotics in a manner similar to euploid individuals, indicating that additional characterizations are necessary to effectively understand drug and toxicant metabolism in this unique genetic background. Future studies will investigate gene expression downstream of additional xenosensor transcriptional factors, like the constitutive androgen receptor (CAR) and the pregnane X receptor (PXR).

2925 Novel Role of the Ah Receptor (AhR) Ligand 6-Formyllindolo[3,2-b]Carbazole (FICZ) in Cytochrome P450 (CYP)1A Induction by Hyperoxia

B. Moorthy, L. Wang, X. Couroucli, K. Lingappan, and W. Jiang. *Baylor College of Medicine, Houston, TX.*

Supplemental oxygen administration is frequently encountered in infants and adults with pulmonary insufficiency. Hyperoxia causes lung injury in experimental animals, and contributes to bronchopulmonary dysplasia (BPD) in premature infants, and ARDS in adults. CYP1 enzymes have been implicated in oxygen injury. Hyperoxia is known to induce CYP1A enzymes but the mechanisms are not fully understood. In this study, we tested the hypothesis that FICZ, formed under hyperoxic conditions, is the novel endogenous ligand of the Ah receptor (AhR) that mediates induction of CYP1A enzymes in lung and liver *in vivo* by hyperoxia. Adult male (8-10 week-old) wild type (WT) (C57BL/6J) WT, Ah receptor (AhR)-null, *Cyp1a1*_null, or *Cyp1a2*_null mice were maintained in room air or exposed to hyperoxia (> 95%) for 6 h. In some experiments, WT mice were exposed to vehicle corn oil (CO) (20 μl/mouse) or FICZ dissolved in CO (2 mg/kg), i.p., once daily for 3 days, and were maintained in room air or exposed to >95% O_2. Levels of FICZ in lungs was determined by LC-MS/MS. Hyperoxic lung injury was assessed histologically and by determining lung weight/body weight (LW/BW) ratios. FICZ was detectable in WT mice under room air conditions and after hyperoxia for 6 h, the FICZ levels were significantly increased. The AhR-null mice showed complete suppression of FICZ. In *Cyp1a1*-null and *1a2*-null mice, FICZ levels were doubled in room air compared to WT mice. FICZ caused marked induction of hepatic and pulmonary CYP1A enzymes compared to control. WT mice, pre-treated with CO showed severe lung injury after hyperoxia for 72 h, but the FICZ-treated animals were less susceptible to hyperoxic lung injury. The increases in FICZ levels after hyperoxia suggests that oxygen induces CYP1 enzymes such as CYP1A1/1A2 through formation of FICZ, an endogenous ligand for the AhR. The increased levels of FICZ in *Cyp1a1*-null or *Cyp1a2*-null mice suggests that both these enzymes play a role in metabolizing FICZ. Future studies could lead to the development of novel endogenous non-toxic ligands of the AhR in the prevention and/or treatment of BPD and ARDS in humans.

2926 Toxicological Responses in the Tongue Sole *Cynoglossus senegalensis* Naturally Exposed to Contaminants at the Ilaje Coastal Area of Ondo State, Western Niger Delta, Nigeria

E. D. Omogbemi[1], A. O. Adeogun[1], O. R. Ibor[2], and A. Arukwe[3]. *[1]University of Ibadan, Ibadan, Nigeria; [2]University of Calabar, Calabar, Nigeria; and [3]Norwegian University of Science and Technology, Trondheim, Norway.*

We have investigated toxicological (biotransformation and oxidative stress) responses in relation to contaminant burden in *Cynoglossus senegalensis* from the Ilaje coast, that receives complex mixtures of untreated effluents and run offs from oil exploration activities. Adult male and female *C. senegalensis* (n=416) were collected from October 2015- March 2017 from Araromi (putative control site), Ayetoro, Obenla and Awoye along the Ilaje coast. Hepatic mRNA expression for *cyp*1a, *cyp*1b, *ugt*2a, *gpx* and *cat*, were analyzed by qPCR, while enzymatic assays for EROD, PROD, BROD, MROD, GST, GR, GPx and CAT were also analyzed using standard methods. In addition, protein expression for CYP1A and CYP3A were measured by western blot and biota concentrations of trace metals and polycyclic-aromatic hydrocarbons were analyzed. We observed site- and gender-specific significant biotransformation and oxidative stress responses that were influenced by sampling season. These changes at mRNA and functional (enzyme and protein) levels paralleled biota contaminant burden, particularly for PAHs. Our findings suggest that contaminants (PAHs and metals) at the Ilaje coastal area may be eliciting overt physiological and health effects in *Cynoglossus senegalensis* and other marine biota at this vulnerable marine ecosystem. These effects are further confounded by negative biological consequences with significant effects on the livelihood of humans who depend on these aquatic resources as a significant source of food through fisheries.

2927 The Safener Benoxacor Is Enantioselectively Metabolized by Sprague Dawley Rat Subcellular Fractions

D. Simonsen, D. Cwiertny, and H. Lehmler. *University of Iowa, Iowa City, IA.*

Safeners (e.g. dichloroacetamide safeners) are classified as inert ingredients by the Environmental Protection Agency, but exhibit biological activity by inducing metabolic enzymes in crops to protect them from herbicide damage. Due to their "inert" classification, they are often overlooked in the literature and only limited information about their metabolites and toxicity is available. One of the most commonly applied dichloroacetamide safeners is benoxacor. The goal of this study was to elucidate the enantioselective metabolism of benoxacor *in vitro*. We studied the depletion of benoxacor in microsomes (5 µM benoxacor, 0.1 mg/mL microsomal protein, 1 mM NADPH, 37°C) and cytosol (5 µM benoxacor, 1 mg/mL protein, 5 mM glutathione, 37°C) prepared from female and male rat livers. Benoxacor levels were determined by gas chromatography-mass spectrometry. Enantiomeric fractions (EF) were determined by enantioselective gas chromatography with electron capture detection. Benoxacor was enantioselectively metabolized in both microsomal and cytosolic incubations. After 30 minutes, 48% and 45% of benoxacor remained in incubations with microsomes and only 18% and 9% remained in incubations with cytosol of female and male rats, respectively. Microsomal incubations showed an enrichment of the benoxacor enantiomer eluting first on the enantioselective column (E_1-benoxacor). A more pronounced enrichment was noted in incubations with microsomes from female than male rats (EF = 0.67 vs. EF = 0.60, respectively). Incubations with cytosol from female rats resulted in a slight enrichment of E_1-benoxacor (EF = 0.54), while incubations with cytosol from male rats displayed an enrichment of the second eluting enantiomer (E_2-benoxacor; EF = 0.43). The current results indicate that benoxacor is enantioselectively metabolized by microsomal and cytosolic enzymes present in Sprague Dawley rat subcellular fractions, and further research is needed to determine the effects of enantioselective metabolism on the toxicity of benoxacor. *[CBET-1702610/1703796.]*

2928 Exploring the Effect of Genetic Polymorphisms on Predicted High-Performance Aircraft Pilot Exposures

T. R. Covington[1], D. K. Ott[2], H. A. Pangburn[2], J. P. Jarvis[2], and J. M. Gearhart[1]. *[1]Henry M. Jackson Foundation for the Advancement of Military Medicine, on Contract to US Air Force 711th Human Performance Wing, Wright-Patterson AFB, OH; and [2]US Air Force 711th Human Performance Wing, Wright-Patterson AFB, OH.*

Previous work used high performance aircraft pilot exhaled breath samples with physiologically based pharmacokinetic (PBPK) modeling to predict in-flight concentration ranges for some possible inhalation exposures. These predictions, however, were point estimates for an "average" pilot. That work was expanded to include Monte Carlo (MC) analyses to account for interindividual variation, but did not account for complex differences in metabolism due to genetic polymorphisms that could affect the pharmacokinetics of potential exposure chemicals and, thus, the potential risk due to these exposures. Available data on known genetic polymorphisms for metabolism of volatile organic chemicals, such as frequency and impact of the polymorphism on metabolism, were compiled from the literature and analyzed as to their usefulness for predicting differences in potential exposure. Pertinent information was then incorporated into parameter distributions for use with the previously used PBPK model in MC analyses. These analyses included distributions for only the metabolism parameters and for all parameters to explore the impact of the genetic polymorphism in conjunction with individual variability. Where data were available for polymorphisms for metabolism of both the parent and metabolite, distributions for both were included in the MC analyses to assess the effect upon parent chemical predictions as well as the effect upon metabolite pharmacokinetics. Predicted area under the curve (AUC) for venous blood concentrations as well as distributions for exposure reconstructions were compared to the previously determined point estimates and exposure reconstructions to demonstrate the resulting impact of accounting for genetic polymorphisms. Differences in both predicted AUCs and exposure distributions were noted. In particular, the previous AUC estimate for simulated isopropanol exposure was below the mean AUC for 3 alcohol dehydrogenase genotypes and above for 3 others. This work demonstrates the importance of understanding the impact of genetics when assessing risk to protect a "population" as opposed to an "average" individual. The work presented here is part of an ongoing effort aimed at developing a capability to best assess true pilot physiology in a "virtual" context so that aircraft cabin exposure guidelines may be produced to ensure limited probability of contaminated cabin spaces.

2929 Predicting the Transfer of Chemicals through Lactation Using Quantitative Structure-Activity Relationship (QSAR) Modeling

N. Tahiri, L. Lévêque, and M. Verner. *Université de Montréal, Montreal, QC, Canada.*

Chemicals are regularly detected in breast milk samples from the general population, indicating that children are exposed during lactation. However, the transfer of chemicals from maternal blood to breast milk is unknown for most chemicals on the market and their metabolites. In this study, we aimed to develop a QSAR model to predict milk-plasma concentration ratios for chemicals based on their chemical structural properties. We compiled published milk-plasma concentration ratios for 183 chemicals, including 110 pharmaceutical drugs and 72 environmental chemicals (e.g., polychlorinated biphenyls, dioxins/furans, organochlorine pesticides organochlorines, phenols, parabens, perfluoroalkyl substances, and several relevant metabolites). We then used the Mordred software to calculate 1614 chemical descriptors for each chemical in the database. Multiple predictive models (e.g., random forest, k-nearest neighbor, lasso regression) were developed through 10-fold cross-validation using 80% of the chemicals (internal dataset), and tested against the remaining 20% (external dataset) using the Sklearn package in Python. We estimated the performance of each model based on the coefficient of determination (R^2), cross-validation coefficient of determination (R^2_{cv}) and external validation coefficient of determination (R^2_{ext}). Milk-plasma concentration ratios ranged from 0.01 to 20.47, with a median value of 1.25. The random forest model yielded the best results in terms of R^2 (0.94), R^2_{cv} (0.52) and R^2_{ext} (0.50). Several descriptors contributed to the random forest model, including acidic and basic group counts. QSAR modeling will help estimate the lactational transfer for data-poor chemicals, namely through the parameterization of physiologically-based pharmacokinetic models of pregnancy and lactation.

2930 Human Duodenum Intestine-Chip Model to Study Drug-Induced Toxicity

C. Lucchesi, G. Kulkarni, S. Kumar, A. Payne, K. Jang, G. A. Hamilton, K. Karalis, and M. Kasendra. *Emulate Inc., Boston, MA.*

The damage of non-steroidal anti-inflammatory drugs (NSAIDs) on gastric and duodenal mucosa has gained much attention in the last few years. A large number of people take NSAIDs each day. This number has grown significantly with increasing use of over-the-counter and prescription NSAIDs. About 30-50% of NSAIDs users present endoscopic lesions, such as erosions and ulcerations, without clinical symptoms. A lack of reliable pre-clinical models to capture critical aspects of human intestinal physiology limits our ability to dissect the exact mechanisms driving NSAIDs-induced injury of the intestinal mucosa and enable improved risk assessment. Organs-on-Chips technology can be combined with intestinal organoids to overcome some of the limitations often associated with organoids such as architecture, ability for expansion to polarized monolayers, and sampling from the epithelial side. The Duodenum Intestine-Chip contains human primary intestinal organoids derived from duodenal biopsies, along with intestinal tissue-specific microvascular endothelial cells to emulate the complex dynamic state of the native human intestine required for normal cell architecture and function, including appropriate extracellular matrix, tissue-tissue interface, and the mechanical forces that recreate both intestinal peristalsis and blood flow. In this study, we used Duodenum Intestine-Chip to model indomethacin-induced injury of human intestinal tissue. Indomethacin showed to be toxic to duodenal epithelium when administered at the epithelial side. As a result, Duodenum Intestine-Chip exposure to indomethacin led to a loss of intestinal barrier function. Consistent with the fact that the intestinal barrier function is disrupted in 60-80% of patients using NSAIDs therapy. In addition, concentration-depended increase in the release of various injury markers, such as LDH, ROS and I-FAPB, was observed in Duodenum Intestine-Chip after 24 hours of exposure, in contrast to conventional organoids that appear to fail to recreate the concentration-dependent responses. In conclusion, Duodenum Intestine-Chip provides a human-relevant model for studies to determine drug-induced toxicity that could potentially be applied into pre-clinical testing of drug safety and efficacy.

2931 Quantitative Structure-Activity Relationship (QSAR) Modeling to Predict the Transfer of Chemicals across the Placenta

L. Lévêque, N. Tahiri, and M. Verner. *Université de Montréal, Montreal, QC, Canada.*

Risk assessment of prenatal exposure to chemicals is paramount considering the potential adverse effects on the developing organism. To date, few tools are available to predict the placental transfer of chemicals across the placenta, especially for environmental chemicals. The aim of this study was to develop a QSAR model predicting cord-maternal plasma concentration ratios for environmental chemicals. We compiled cord-maternal plasma concentration ratios from published articles on multiple environmental chemicals including polychlorinated biphenyls, polybrominated diphenyl ethers, polycyclic aromatic hydrocarbons, and pesticides. We also included cord-maternal plasma concentration ratios for certain drugs to expand the domain of applicability. Only ratios from studies where cord and maternal blood samples were collected within 24 hours were kept in the dataset (n=88). We calculated 1614 descriptors for each chemical using the Mordred software. A suite of predictive models were developed through 10-fold cross-validation using 80% of the chemicals. Models were then tested against the remaining 20% of chemicals (external dataset). All statistical analyses were performed using the Sklearn package in Python. Cord-maternal plasma ratios ranged from 0.05 to 3.05 (median: 0.52), indicating that some chemicals preferentially partition into maternal or fetal plasma during pregnancy. The model developed using random forest displayed the greatest precision, with a coefficient of determination (R^2) of 0.98, a cross-validation R^2_{cv} of 0.89, and an external validation R^2_{ext} of 0.87. This level of precision was among the highest achieved for the placental transfer of chemicals and drugs. Using this QSAR model will help quantify fetal exposure to chemicals based on measured maternal plasma levels, or through the parameterization of physiologically-based pharmacokinetic models of pregnancy.

2932 Development and Application of an Interactive Physiologically Based Pharmacokinetic (iPBPK) Model Interface to Estimate Withdrawal Intervals for Penicillin G in Cattle and Swine

Z. Lin[1], M. Li[1], R. E. Baynes[2], L. A. Tell[3], J. L. Davis[4], T. W. Vickroy[5], and J. E. Riviere[1,2]. *[1]Kansas State University, Manhattan, KS; [2]North Carolina State University, Raleigh, NC; [3]University of California Davis, Davis, CA; [4]Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA; and [5]University of Florida, Gainesville, FL.*

Physiologically based pharmacokinetic (PBPK) models are a useful tool in the estimation of drug tissue residue depletion and withdrawal interval recommendations in food animals and they can be used to conduct extrapolation across species, ages, production classes, administration routes and doses. Traditional PBPK models are difficult to use by individuals with no modeling experience. Therefore, a user-friendly PBPK modeling framework and web-based interface would be beneficial. Penicillin G is a commonly used drug in food animals and was among the top three violative drug residues identified by the US National Residue Program from 2010-2018. The objective of this study was to develop a PBPK model for penicillin G in different production classes of cattle and swine and convert the model to a web-based user-friendly interactive PBPK (iPBPK) interface. Traditional PBPK models for penicillin G in market-age cattle and swine were developed and validated based on published data from the Food Animal Residue Avoidance Databank (FARAD). The model was then extrapolated to dairy cows and heavy sows. This traditional penicillin G model was converted to an iPBPK interface using R Shiny. These PBPK models can be used to predict withdrawal intervals of penicillin G after extralabel administration to cattle and swine across production classes, administration routes and doses in real time. The iPBPK framework presents proof-of-concept for developing web-based iPBPK interfaces for drug withdrawal interval estimations and animal-derived food safety assessment.

2933 Apparent Permeability Coefficients to Parameterize PBPK Models for Inhalation: Impact of the *In Vitro* Setup

N. Sonnenschein, N. Nowak, J. Knebel, D. Ritter, K. Blümlein, K. Schwarz, S. Escher, and T. Hansen. *Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany.* Sponsor: C. Dasenbrock

This study aimed at the determination of apparent permeability coefficients (P_{app}) of the inhalable antibiotic ciprofloxacin hydrochloride monohydrate (CHM) in human lung barrier models and to utilize these coefficients as input parameters for a lung PBPK model (physiologically based pharmacokinetic model). Two different cell models were used resembling different lung regions: The Calu-3 cell line expressing features of differentiated small airway epithelial cells as well as functionally immortalized human alveolar epithelial (Cl-hAELVi) cells. For both cell models, P_{app} values were measured in a submerged setting and under air-liquid interface (ALI) exposure conditions. For submerged exposures, the antibiotic CHM was dissolved in culture medium and added to the apical compartment. ALI exposures were done with CHM aerosol generated using the PreciseInhale™ device. For efficient and precise aerosol exposures, the P.R.I.T.®ExpoCube® was used. CHM concentrations in the different compartments were analysed by LC-MS/MS. In the case of ALI exposures, the CHM mass deposited on the apical cell surface had to be converted to concentration values. This was done by assuming a thickness of 2 µm for the lining fluid layer for Calu-3 and AT-1 cells and dissolving of CHM in the resulting volume. The resulting P_{app} coefficients were similar for both cell models, the levels being $1.99*10^{-8}$ cm/sec for AT-1 and $1.09*10^{-8}$ cm/sec for Calu-3, respectively. The cell models under submerged conditions showed higher P_{app} values of $6.34*10^{-7}$ cm/sec for AT 1 cells and $7.24*10^{-7}$ cm/sec for Calu-3 cells. P_{app} values obtained from both *in vitro* settings were used as input parameters for the physiologically based pharmacokinetic (PBPK) model to simulate the absorption and distribution processes in the human body. Resulting peak blood concentrations for ciprofloxacin were 5 fold higher when P_{app} coefficients obtained from submerged experiments were used. However, comparison with human literature data revealed that simulations based on P_{app} coefficients calculated for ALI exposures produced blood levels that were very close to the human *in vivo* situation. These findings suggest that the experimental setup is highly important when *in vitro* data are to be used as input parameters for PBPK models to predict the bioavailable dose after inhalation exposure in humans.

2934 Evaluation of GastroPlus Software for Predicting Toxicokinetic Parameters of Agrochemicals following Repeated-Dose Dietary Feeding

M. Chan, M. W. Himmelstein, and R. T. Mingoia. *Corteva Agriscience, Newark, DE.*

The use of *in silico* approaches for assessing the risks of chemicals in a more mechanistic and high throughput manner has become increasingly important to support human health risk assessment. Current approaches rely primarily on *in vivo* testing following intake of compounds administered by different routes and intake patterns across a day. Physiologically based pharmacokinetic (PBPK) modeling, coupled with *in silico*- and *in vitro*-derived chemical-specific parameters, provides an effective framework for improving quantitative *in vitro*-to-*in vivo* extrapolation (IVIVE). The combination of *in silico*- and *in vitro* parameter estimation with PBPK modeling can then be used to predict the *in vivo* absorption, distribution, metabolism and excretion. Current *in silico* modeling programs are not user-friendly or require extensive training to use. For example, TK modeler, a Microsoft Excel-based pharmacokinetic modeling program, can model single, multiple bolus or dietary dosing but it lacks PBPK model compartments, which are parameterized using known physiology that correspond to different organs or tissues in the body. In this research, GastroPlus™ software was evaluated to compare observed *in vivo* data with simulated results for two molecules: Penoxsulam and X11719474 (a sulfoxaflor metabolite) following repeated dose feeding in rats. These molecules were selected due to simplicity of metabolism pathway, rapid and almost complete absorption, little to no metabolism in an *in vitro* hepatocyte clearance assay, or elimination as largely unchanged parent compound following oral administration. A diurnal feeding pattern was used to model the dietary intake of the test substances and predict systemic exposure during 28 or 90-day toxicity studies. Predicted plasma concentrations and corresponding AUC values were improved by incorporation of physicochemical (i.e. LogD/P, water solubility and pH) and/or *in vitro* ADME (i.e. intrinsic clearance in primary hepatocytes and plasma protein binding) properties. Current predictions are 1 to 3-fold above the measured *in vivo* plasma concentrations. Based on this evaluation, chemical-specific parameters were critical to improving model implementation. Overall, the results demonstrated that GastroPlus™ can be used to predict toxicokinetic parameters in rats for poorly metabolized chemicals following repeated dose feeding. Simulation with other compounds is in progress to validate this approach.

2935 Development and Systematic Comparison of Pregnancy Physiologically Based Toxicokinetic Models for Bisphenols A and S

D. Filipovic, J. Gingrich, S. Bhattacharya, and A. Veiga-Lopez. *Michigan State University, East Lansing, MI.*

Physiologically based toxicokinetic (PBTK) models aid in the process of health risk assessment by incorporating *in vivo* and *in vitro* toxicokinetic data, known physiological parameters, such as fractional blood flows and organ volumes, and *in silico* tools in order to make predictions about the extent of chemical exposures. These models are particularly important in understanding exposures during vulnerable periods of life such as pregnancy and *in utero* development. Bisphenols A and S (BPA and BPS) are the first and second most abundant bisphenols detected in human blood and urine in the US. Herein, we aimed to develop physiologically sound pregnancy PBTK (P-PBTK) models for BPA and BPS using several paired maternal and fetal pregnancy toxicokinetic datasets that include parent and metabolite concentrations of BPA and BPS in sheep plasma, as well as two administration routes. Following sensitivity analysis and extensive optimization, we determined that different values of parameters produce equally good fits to the calibration datasets, for both models. After exclusion of all physiologically implausible models we were left with a set of models with narrow ranges for all estimated parameters. Among these, we picked two representative models, one for BPA and another for BPS. Both models fit most endpoints of the available datasets within one standard deviation of individual data points. The developed models provide insight into toxicokinetics of the parent compound and its metabolite in maternal and fetal tissues of interest (e.g. fetal brain), as well as gestational age, species, dose and route of exposure extrapolation. In addition, the analysis provides estimates of parameters that are difficult to measure experimentally, such as bioavailability of subcutaneous absorption and deconjugation in the fetal liver. To the best of our knowledge these are among the first P-PBTK models for BPA and BPS in sheep. Both models advance our understanding of bisphenol toxicokinetics and can assist the development of future P-PBTK models for related chemicals. Additionally, we make recommendations for future experimental toxicokinetic study designs to facilitate the construction of mechanistically sound P-PBTK models with greater translational relevance. *JG was supported by NICHD T32HD087166. 2936 INOS-Independent SNO Generation at Low Ph and SNO Prediction Using a Neural Network

Z. Liu, E. Abramova, C. Guo, and A. Gow. *Rutgers, The State University of New Jersey, New Brunswick, NJ.*

Nitrosylation is a form of post-translational modification, which provides modularity to protein function after translation, allowing cells to adapt to a variety of stimuli. However, unlike more "canonical" post-translational modifications, the motif and environmental conditions under which cysteine residues are nitrosylated are unclear. The chemistry of formation presupposes that there may be subsets of cysteines that are nitrosylated via different mechanisms. The most comprehensive database for SNO, dbSNO 2.0, indiscriminately collected literature reports for nitrosylation and thus cysteines do not follow a consistent set of environmental conditions and represent different populations of SNO. We hypothesize that different SNO populations may be generated by altering microenvironment of the cysteine residues. SNO protein formation was examined in RAW cells with and without LPS stimulation, while altering the intracellular environment using mitochondrial poisons (MP). Cells were treated with oligomycin, FCCP, or rotenone after 1 hour of stimulation with LPS. Treatment significantly increased nitrite release to the media. Both rotenone, the complex I inhibitor, and oligomycin, the ATP synthase inhibitor, significantly reduced nitrite production. FCCP did not alter nitrite production. Western blot of cell lysate confirms iNOS in LPS-stimulated cells for all treatments, with reduced banding in MP. Using Biotin Switch, we were able to show significant production of SNO proteins in response to LPS, which was unaltered by FCCP. However, rotenone completely abrogated SNO formation, while oligomycin forms SNO even in the absence of LPS. These studies indicate that nitrosylation is influenced by the intracellular environment, with cellular acidification being a major mechanism. Identification of the SNO-protein identities within cell lysate will allow one to create database for training a neural network for cysteines. To demonstrate viability of a neural network approach, an algorithm was trained on a subset of dbSNO entries, randomly selecting 20% of the trimmed sample as the validation set. A window size of 19 was discovered to return the optimal MCC for the following hyperparameters: two hidden layers, 50 neurons each layer, learning rate of 0.0005, L1 Regularization parameter of 5, and 2000 iterations. Sigmoid activation function was used for the hidden layers, TanH activation function for the output layer, and a quadratic cost function to backpropagate. A median MCC of 0.230, with a sensitivity of 0.661, a specificity of 0.569, a positive predictive value of 0.589, and a negative predictive value of 0.642 was obtained. *NIH ES005022 HL086621.*

2937 Use of a Weighted Scheme for the Interpretation and Contextualization of *In Vitro*- and *In Silico*-Derived Estrogenic Endpoints

A. M. Brinkman[1], W. D. Klaren[1], W. E. Hillwalker[1], D. J. Feifarek[1], F. A. Jones[1], K. M. Zorn[2], and S. Ekins[2]. *[1]S.C. Johnson & Son Inc., Racine, WI; and [2]Collaborations Pharmaceuticals Inc., Raleigh, NC.*

With the rise of interest in endocrine disruption by the scientific community and the general public, a clear and scientifically sound approach to evaluating potential endocrine disrupting properties is critical. Advances in *in vitro* and high throughput technologies have provided a wealth of data which provide insight into the EATS (endocrine, androgen, thyroid, steroidogenesis) modalities. A current regulatory challenge is the utilization of multiple data streams to arrive at a conclusion regarding endocrine activity. An additional challenge is that many chemicals have not been tested using existing *in vitro* approaches, thus there is a need for additional tools to provide information regarding endocrine disrupting properties. *In silico* modeling offers a robust, widely-applicable, cost- and time-effective approach to fill these data gaps. This work set out to place the development of an *in silico* predictive model into the relevant biological context to ensure the appropriate interpretation of model outputs and builds off an accompanying presentation which highlights the technical robustness of 18 models developed to predict endocrine bioactivity. Of the 18 ToxCast assays for estrogenicity, this work focuses on the five assays that describe transcription and protein production and weighs less heavily those assays that describe earlier aspects of the adverse outcome pathway, such as receptor binding. This weighting approach was validated by a selection of reference chemicals designated by the EPA and derived from *in vivo* and *in vitro* studies. Compared to the EPA *in vivo* reference chemicals, the weighted scheme of *in silico* model outputs predicts with 93% concordance. An alternate aggregation approach has gained wide acceptance in the regulatory community, but lacks the ability to evaluate novel chemicals; the approach described herein is thus advantageous in that it can predict activity for chemicals that are not already associated with *in vitro* data. This research provides the incorporation of adverse outcome pathway methodologies into the interpretation/aggregation of *in vitro* and *in silico* data sources and can

be used to predict estrogen bioactivity for novel chemicals. Such frameworks are useful for the condensation of many datapoints into a single output or conclusion for regulatory decision-making purposes.

2938 Utilization of GastroPlus Physiologically Based Pharmacokinetic (PBPK) Modeling in Nonpharmaceutical IVIVE Predictions

F. Zhang, T. Erskine, M. LaBaron, and S. Marty. *Dow, Midland, MI.*

As regulatory toxicology transitions to non-animal methods, there is a need to develop and validate *in vitro*-to-*in vivo* extrapolation (IVIVE) methods. Further, there is a recognized need to improve agricultural/industrial chemical PBPK modeling, and previous work has shown that chemical-specific *in vitro* PBPK parameters can improve PBPK predictions. In the current study, GastroPlus™ PBPK predictions were generated for four compounds - myclobutanil, oxyfluorfen, pronamide, and tricyclazole. New data were generated for the main PBPK parameters (i.e., caco-2 permeability, plasma binding, blood to plasma ratio, and rat liver microsomal half-life) and integrated into the PBPK models containing 12 organ compartments and compared using GastroPlus™ software. The fold-error (FE) of the predicted plasma AUC (area under curve) of parent pronamide without *in vitro* PBPK parameters compared with published plasma AUC values was in the range of 2.7 to 7.8; however, the FE was reduced to 1.2 to 4.2 by incorporating data for *in vitro* PBPK parameters into the model. Furthermore, the predicted plasma time course and the steady-state plasma concentration (Css) correlated well with published data when *in vitro* PBPK parameters were included in the model. In contrast, *in vivo* total radioactivity-based plasma concentrations (pronamide plus it's metabolites) had limited applicability as FEs ranged from 11 to 38 even with *in vitro* PBPK parameters applied to the model. In addition, the parent-based tissue concentrations of these four agrochemicals were predicted in rats and humans after single or 30-day repeat exposure to 10 mg/kg/day. These data indicate that GastroPlus™ PBPK predictions can be improved with chemical-specific *in vitro* PBPK parameters, and, in the cases examined, are applicable for IVIVE estimations.

2939 Evaluation of a Rapid, Multi-chemical Human Gestational Physiologically Based Toxicokinetic Model

M. Sfeir[1], D. Kapraun[1], A. Lumen[2], R. Judson[1], L. Aylward[3], D. Abrahamsson[4], T. Woodruff[4], C. Carignan[5], J. Rager[6], R. Sayre[1], R. Pearce[1], and J. Wambaugh[1]. *[1]US EPA, Research Triangle Park, NC; [2]US FDA/NCTR, Jefferson, AR; [3]Summit Toxicology, Falls Church, VA; [4]University of California San Francisco, San Francisco, CA; [5]Michigan State University, East Lansing, MI; and [6]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Human health chemical risk assessment involves consideration of potentially susceptible populations, including pregnant women with developing fetuses. It is estimated that humans encounter thousands of artificial chemicals in their environments, few of which have been characterized in terms of health risk. To assess any risk posed by a chemical, toxicokinetic (TK) information is needed to relate chemical exposure to potentially toxic tissue concentrations. As human-specific gestational exposure data are unavailable for most chemicals, physiologically-based TK (PBTK) models are needed to extrapolate knowledge from existing *in vivo* toxicological studies and/or *in vitro* bioactivity data to human pregnancy. Development of chemical-specific PBTK models is resource-intensive. As an alternative, generic PBTK approaches in which a system of ordinary differential equations (ODEs) describes a standardized physiology and chemicals are characterized with a set of standard physical and *in vitro*-measured descriptors enables expedited, high-throughput modeling and prioritization. Here we report the systematic evaluation of a generic PBTK model of a human mother and a developing fetus. Building upon a statistically plausible set of parameters with which to simulate the major physiological changes that accompany pregnancy, as well as upon the existing high-throughput toxicokinetics (httk) software package in R, we present a generic tool for estimating the disposition of many chemicals throughout a maternofetal system. In the limit of "steady state" the model assumes that the ratio of the maternal to fetal plasma chemical concentrations is a function of the relative partitioning into the placenta, which may not vary for many chemicals with exception for some ionizable compounds and chemicals that cannot reasonably reach steady-state. We compare an analytic determination of the equilibrium ratio for 25 chemicals in maternal and fetal plasma to existing measurement data on maternal-to-umbilical plasma concentration ratios at delivery. The analysis stands to be extended to the over 944 already parameterized for this model in httk. Chemical membership spans classes from organochlorine pesticides to perfluorinated compounds. With sufficient evaluation, this gestational model may allow *in vitro-in vivo* extrapolation of reproductive toxicity-relevant bioactivity to maternal chemical exposures.

2940 Physiologically Based Pharmacokinetic Modeling and Simulation of Nanoparticle Delivery to Tumors in Mice

Y. Cheng, C. He, J. E. Riviere, N. A. Monteiro-Riviere, and Z. Lin. *Kansas State University, Manhattan, KS.*

Many studies have engineered nanomaterials with different physicochemical properties to increase the delivery efficiency to solid tumors, but the mean and median delivery efficiencies are only 1.5% and 0.7% of the injected dose (%ID), respectively according to a study using a non-physiologically based approach based on published data from 2005 to 2015. In the study, we applied a physiologically based pharmacokinetic (PBPK) modeling approach to analyze 376 datasets published from 2005 to 2018, and found mean and median delivery efficiencies at the last sampling time point of 2.22% and 0.75%ID, respectively. Also, the mean and median delivery efficiencies were 2.24% and 0.76%ID at 24 h, and were reduced to only 1.23% and 0.34%ID at 168 h, respectively after intravenous injection. Although these delivery efficiencies seem to be larger than previous findings, they are still low and represent a critical barrier in the clinical translation of nanomedicines. We explore the potential causes of the low delivery efficiency from a PBPK perspective. We also propose a long-term strategy to overcome this fundamental barrier with a focus on the role of PBPK modeling and simulations.

2941 Modeling Deposition and Uptake of an Inhaled Puff Emitted from an Electronic Nicotine Delivery System (ENDS) in the Human Respiratory Tract

B. Asgharian. *Applied Research Associates Inc., Raleigh, NC.*

A puff from an electronic nicotine delivery system (ENDS) contains multi-constituent aerosols and vapors. The mixture is highly unstable and undergoes rapid thermodynamic changes. As a result, there will be significant changes in the characteristics of inhaled aerosols and vapors immediately after generation in the ENDS and while traveling through the respiratory tract. These changes need to be studied and accounted for when developing a dosimetry model to assess both vapor uptake and aerosol deposition. Hence, a coupled vapor uptake and aerosol deposition model was developed for a puff made up of water, glycerin, nicotine, propylene glycol, and flavors. The deposition model included the coagulation of airborne materials at high aerosol number concentrations and vapor exchange between liquid (aerosol) and vapor phases. The model accounted for the mixing of the puff with the dilution air at the end of mouth hold and reserve air when the puff reached the pulmonary space. The fate of all constituents in the puff was obtained at different sites of the respiratory tract. Overall, about 90% of the nicotine and propylene glycol were taken up by lung tissues whereas glycerin deposition was under 60%. Tissue dose from droplet deposition was higher than that for vapor uptake for all constituents of the puff. A software tool was developed based on the deposition model, which allows the users to study the fate of the inhaled puff under various ENDS use scenarios. The model is a powerful tool to inform the exposure and health risk evaluation of ENDS use. *This study was funded by the US FDA. This information is not a formal dissemination of information by FDA and does not represent Agency position or policy.*

2942 Generalized PBPK Model for Evaluation of Inhalation Exposure of Volatile Organic Compounds

J. Mullin[1], M. Lawless[1], E. Amini[2], V. Lukacova[1], and M. B. Bolger[1]. *[1]Simulations Plus, Lancaster, CA; and [2]University of Florida, Gainesville, FL.*

PBPK modeling is a valuable tool to evaluate inhalation exposure of volatile organic compounds (VOCs). However, many models employed in literature are ad hoc and built for a single purpose or molecule. These models generally look at a subset of major tissues and rely on experimental or fitted partition coefficients. A desirable approach would be to use a standardized PBPK model to predict exposure of VOCs rather than building ad hoc models. GastroPlus® has a physiologically based inhalation model that predicts the exposure in animals and humans for solution and dry powder doses. The goal of this work was to add a dosing route for VOCs and predict both uptake and clearance due inhalation and exhalation. The partitioning of the volatile compound between the vapor phase and the mucosal lining fluid in the lung is based on Henry's Law. Once partitioned into the mucus, the drug then diffuses though the epithelial cells to reach systemic circulation. The thickness of the mucus and epithelial cell layer is location dependent in the lung. Once VOCs have been absorbed into systemic circulation, GastroPlus has a full PBPK model to predict the systemic toxicokinetics which allows a variety of op-

tions for predicting tissue partition coefficients as well as elimination (linear clearance, non-linear metabolism, renal clearance, and metabolite tracking). Availability of physiologies for human and for animals commonly used in toxicological testing simplifies interspecies scaling and predictions of toxicokinetics in human. The VOC inhalation model was tested on several available literature datasets including ethanol, methanol, acetone, benzene, toluene, and xylene. Results show that the model does a good job at extrapolating systemic exposure from rat to human in almost all cases with the exception of ethanol where pulmonary metabolism had to be considered to fit human data; however, this is in accordance with other literature PBPK models. The average and maximum prediction error for Cmax across all compounds and datasets is 12.5 and 39.1% for rat and human. In summary, a new physiologically based VOC inhalation model has been added to the GastroPlus pulmonary module that allows prediction of toxicokinetics and interspecies scaling of exposure from animal models like rat to human. We believe this provides an improvement on current ad hoc or open source tools due to the volume of validation work on drug-like molecules in the GastroPlus platform.

2943 Physiological Parameter Values for Physiologically Based Pharmacokinetic Models in Food-Producing Animals. Part I: Cattle and Swine

M. Li[1], Y. Wang[1], L. A. Tell[2], R. E. Baynes[3], J. L. Davis[4], T. W. Vickroy[5], J. E. Riviere[1,3], and Z. Lin[1]. *[1]Kansas State University, Manhattan, KS; [2]University of California Davis, Davis, CA; [3]North Carolina State University, Raleigh, NC; [4]Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA; and [5]University of Florida, Gainesville, FL.*

Physiologically based pharmacokinetic (PBPK) models of chemicals in food animals are a useful tool in estimating depletion of chemical tissue residues and withdrawal interval recommendations. Physiological parameters such as cardiac output, organ weights and blood flows are an important component of a PBPK model. The objective of this study was to critically evaluate published PBPK-related physiological parameter data in food animals, including cattle, swine, goats, sheep, chickens, and turkeys. Literature searches were performed in PubMed and Google Scholar. Relevant literature was reviewed and tables of cardiac output, relative organ weights (% of body weight) and relative blood flows (% of cardiac output) were compiled for different production classes of cattle and swine as Part I of this series of study. The mean and standard deviation of each parameter were calculated to conduct population PBPK analysis. The results showed that the cardiac outputs were 9.09 ± 2.77, 5.45 ± 1.47, 8.70 ± 1.62 in unanesthetized calves (≤10 months old), cattle (>10 months old), and market-age swine, respectively. In cattle, the relative organ weights were 36.10 ± 11.73, 1.23 ± 0.21, 0.21 ± 0.04, and 12.27 ± 5.21 in muscle, liver, kidney, and adipose tissue, respectively. In swine, these values were 36.32 ± 2.66, 2.04 ± 0.33, 0.37 ± 0.11, and 15.44 ± 2.65, respectively. These compiled data provide a comprehensive physiological parameter database for developing PBPK models of chemicals in cattle and swine to help animal-derived food safety assessment. This work also serves a basis to compile data in other food animal species.

2944 Physiologically Based Prediction of the Impact of Nonchemical Stressors in the Aviation Environment on Xenobiotic Dosimetry in Humans: Effect of Barometric Pressure or Altitude

L. M. Sweeney. *ProSource360 Consulting Services Inc. at US Air Force 711th Human Performance, Wright-Patterson AFB, OH.*

Aircraft can be a physiologically challenging environment due to hypobaria, acceleration, low humidity, thermal variation, vibration, and other factors. The special characteristics of the military aviation operational environment and their combined impact on air crews constitute a challenge to the health risk assessment strategies used to identify situations where risk management action is needed. Among the strategies available for the quantitative comparison of risks between the general population and populations with distinctive health concerns or that experience particular environmental stressors is physiologically based pharmacokinetic (PBPK) modeling. PBPK models facilitate these comparisons by prediction of how target-tissue specific doses are altered when a stressor, such as high altitude, effects changes in physiological parameters. Cardiac output, regional blood flow, and alveolar ventilation rate for personnel acutely exposed to altitude ranging from moderate to extremely high were extracted from published data from 51 groups of human subjects and described mathematically via regression models. A scenario where a pilot could inhale organic compounds in-flight during routine training was simulated for three test chemicals. When exposed at the recommended Threshold Limit Values, arterial blood concentrations were predicted to be higher for exposure at 15,000 ft than at sea level. For example, during a series of two 1-h flights separated by a 2-h break, the peak blood toluene level was predicted to increase by 42% as compared to exposure on the ground. The predicted differences were greater for the two test compounds with higher blood: air and fat: blood partition coefficients (toluene and 1,2,4-trimethylbenzene) than the less lipophilic cyclohexane. In summary, quantitative approaches to internal dosimetry prediction that take advantage of existing knowledge of physiological changes induced by occupational stressors have potential as tools in performing human health risk assessment.

2945 Development and Evaluation of a PBTK Model for Naphthalene for Use in Human Health Risk Assessment

D. F. Kapraun[1], P. M. Schlosser[1], L. A. Nylander-French[2], D. Kim[2], E. E. Yost[1], and I. L. Druwe[1]. *[1]US EPA, Research Triangle Park, NC; and [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Naphthalene, a volatile organic compound found in moth repellants and petroleum-based fuels, has been shown to induce toxicity in the nasal epithelium of both mice and rats during chronic inhalation exposures. Any human health risk assessment for inhaled naphthalene would require the estimation of a human equivalent concentration (HEC), which is an inhaled air concentration that would produce a human internal dose equal to that occurring in an animal at a point-of-departure (POD) exposure concentration. One can estimate an HEC from an animal POD using a physiologically based toxicokinetic (PBTK) model. Confidence in an HEC estimated in this way increases if the model has been validated using both animal and human time-course internal concentration data. A published inhalation PBTK model for naphthalene was previously shown to predict rodent kinetic data well, so we sought to evaluate this model using human kinetic data. The most reliable human kinetic data available, however, were recorded during a ten-subject controlled skin exposure study and the PBTK model in question does not include a skin exposure route; therefore, we extended the model by incorporating skin compartments representing the stratum corneum (SC) and the viable epidermis. Adding these compartments required the introduction of two model parameters for which published values could not be found: diffusivity of naphthalene across the SC and the SC-to-exposure-vehicle partition coefficient. Furthermore, the human data revealed "background" blood concentrations of naphthalene in the subjects prior to exposure, so we introduced an intravenous dose rate parameter to account for baseline levels of napthalene. We calibrated these three new parameters in the modified PBTK model using data from the ten subjects of the controlled skin exposure study while maintaining the values for all other human parameters, including metabolic parameters, that were proposed for the original PBTK model. In this way, we were able to achieve reasonable agreement between the model predictions and kinetic data for all subjects. Our evaluation of the modified PBTK model using human data showed that this model can accurately predict internal doses of naphthalene and is thus a viable tool for estimating HECs for naphthalene human health risk assessments.

2946 Exploring the Application of Physiologically Based Pharmacokinetic Models in Acute Chemical Incidents: The National Toxic Substance Incidents Program

S. Boone, J. Wu, M. F. Orr, C. Welsh, and P. Ruiz. *CDC/ATSDR, Atlanta, GA.*

Chemical release incidents in the United States include a variety of different chemicals that can have negative effects on nearby communities. The Agency for Toxic Substances and Disease Registry (ATSDR) historically tracked these chemical releases from 1991-2014 in up to 16 states with the Hazardous Substances Emergency Events Surveillance (HSEES) and the National Toxic Substance Incidents Program (NTSIP) systems. With the help of surveillance data, patterns of these different chemical releases can be studied with the intent of constructing a health-protective course of action. Physiologically-Based Pharmacokinetic models (PBPK) can be utilized to simulate the chemical exposures during an acute chemical incident. We have conducted a retrospective study of one such acute chemical release occurring in 2012 with the intent of examining the components needed to integrate PBPK-modeled exposure assessments in ATSDR's Assessment of Chemical Exposure (ACE) program. We examined data from a Vinyl chloride (VC) exposure investigation to explore the utility of PBPK to assess exposures in residential populations near the release site. At the release site, immediate estimates from real-time air monitoring indicated that air levels greatly exceeded Acute Exposure Guideline Levels (AEGL) of 1,200 ppm; the corresponding PBPK modeled VC blood levels of 3.17 mg/L. "Real time" and "after action" air modeling estimated VC levels at various distances from the release site at different time

points; PBPK modeling using those air VC levels suggested elevated blood levels in community residents in areas adjacent to the release site. The PBPK modeling also provided some temporal insight on residential blood levels of VC as the event played out over several days. These results indicate that PBPK may be a useful tool for reconstructing exposures associated with acute chemical releases. *The findings and conclusions in this presentation have not been formally disseminated by [the Centers for Disease Control and Prevention/ the Agency for Toxic Substances and Disease Registry] and should not be construed to represent any agency determination or policy.*

PS 2947 Liter-Equivalence Extrapolation for Four Trihalomethanes (THMs): What Drink Would It Take to Get the Same Internal Dose?

C. R. Eklund, E. M. Kenyon, R. A. Pegram, and J. E. Simmons. *US EPA, Durham, NC.*

Due to their presence in water as volatile disinfection byproducts, THMs pose a potential health risk from exposure via oral, dermal and inhalation routes. Environmental exposure studies demonstrate that dermal and inhalation exposure to water containing THMs during showering or bathing results in more THMs being delivered to the systemic circulation than oral exposure. Using a physiologically-based pharmacokinetic (PBPK) model, we conducted a liter-equivalence analysis (Leq). We determined the concentration in one liter of water consumed orally needed to achieve the same internal dose as from a 10-minute shower for chloroform (TCM), bromodichloromethane (BDCM), dibromochloromethane (DBCM), and bromoform (TBM). Model structure and physiological parameters are the same as our published adult human BDCM model (Kenyon et al., 2016). Because human chemical-specific metabolism parameters are not available for all four THMs, rat metabolism parameters obtained from the literature were used to avoid confounding of comparisons across chemicals. For this same reason, human blood:air and rat tissue:air partition coefficients were used for all four THMs. We simulated showering for 10 minutes with water containing 8.2, 12.2, 13.5, and 8.7 µg /L for TCM, BDCM, DBCM and TBM, respectively. These are measured drinking water concentrations from a system with predominantly brominated species of THMs (Gulf coast TX, Lynberg et al., 2001). Two measures of internal dose, area under curve in venous blood (AUCv) and amount of specific THM metabolized in liver (AML) were evaluated. For AUCv, the oral Leq concentrations for the showering scenario were 20.9, 38.5, 43.8, and 29.9 µg/L for TCM, BDCM, DBCM and TBM, respectively. For AML, the oral Leq concentrations for the showering scenario were 1.3, 1.9, 1.9, and 1.4 µg/L for AML for TCM, BDCM, DBCM and TBM, respectively. These results demonstrate that dermal and inhalation exposure routes contribute significantly to internal doses of THMs reaching the systemic circulation (AUCv). In sum, consideration of the contribution of multiple routes of exposure to internal dosimetry should decrease uncertainty in dose-response characterization for water-borne THMs. *This abstract does not reflect US EPA Agency policy.*

PS 2948 An Investigation of Mirtazapine Pharamacokinetics in Cats Using Physiologic-Based Pharmacokinetic (PBPK) Modeling

R. Lake, and B. Reisfeld. *Colorado State University, Fort Collins, CO.*

The study of drug dosing and metabolic effects in cats has been under-served by a relative lack of physiologic and pharmacologic data in this species, and feline-based PBPK models have not previously been represented in the literature. Further, known genetic abnormalities in cats (e.g., UGT1A6 and ABCG2, from which alterations in glucuronidation and drug transport arise) can often lead to severe drug toxicities in this population. Thus, an unfulfilled need exists for feline-specific PBPK models to investigate the dosing and pharmacokinetic profiles of therapeutic drugs used for treating feline disease. Mirtazapine (MTZ), a noradrenergic and specific serotonergic antidepressant, was selected for study as it is commonly used in veterinary medicine as a treatment for nausea and vomiting associated with chemotherapy, pancreatitis, and chronic kidney disease in cats. An investigation of mirtazapine pharmacokinetics (PK) in cats was conducted using an eight-compartment oral dosing PBPK model, developed using MCSim, and informed by available anatomic and physicochemical data for relevant feline target tissues. Although mirtazapine exhibits linear PK in humans, a prior feline-based clinical PK study demonstrated evidence of nonlinear PK in cats, thus analytical approaches to further characterize this behavior were explored via the PBPK model. The model was parameterized using Bayesian inference via a Markov chain Monte Carlo (MCMC) methodology and population pharmacokinetics were realized using Monte Carlo simulations. Results from a typical individual simulation of 1.88mg and 3.75mg oral mirtazapine doses yielded a dose prediction curve with a Cmax=63.4 ng/ml at a tmax=1.5 hrs and 126.4 ng/ml at a tmax=1.5 hrs for the respective doses, which compares favorably to results obtained from an *in vivo* study of orally dosed mirtazapine in cats (Cmax and tmax values of 73.1 ± 45.5 ng/ml and 1.6 ± 1.3 hr, and 156.5 ± 92.4 ng/ml and 1.5 ± 1.4 hr, for the analogous doses, respectively). Additionally, Monte Carlo simulations provided prediction intervals that bounded the broad majority of available experimental data points. The results from this study further build upon the developmental computational framework for investigating drug disposition in cats, with a view toward enabling a predictive approach for better informing feline drug dosing protocols, especially for cases where drug disposition may be impacted, such as in chronic renal failure or liver disease.

PS 2949 Advantage of Read-Across and Pharmacokinetics Modeling for the Exposure Assessment of Persistent Organic Pollutants

P. Ruiz, S. Boone, and M. Mumtaz. *CDC/ATSDR, Atlanta, GA.*

Persistent organic pollutants (POPs) are highly resistant to degradation in the environment, bio-accumulate in living organisms, and can cause adverse effects. This class of chemicals include chlorinated POPs such as organochlorine pesticides, polychlorinated biphenyls, and dioxins. In this case study, we tested the hypothesis that an adequately developed, parameterized and validated human pharmacokinetic (PK) model describing a source chemical (i.e. the chemical with an existing human PK model) can be used to simulate PK data for a target chemical (i.e. the chemical with no existing human PK model). Potential single chemical surrogates for each of the organochlorinated POPs classes using analog similarity were identified. A concentration- and age-dependent dioxin pharmacokinetic model was parameterized for surrogate chemicals and coded using Berkeley Madonna software. Based on physiochemical and absorption, distribution, metabolism, and excretion (ADME) properties describing dioxin; similar chlorinated analogs were hexachlorobenzene, DDT/DDE and PCB 153. A series of PK models were parameterized to examine the utility for the surrogate chemicals. Overall, there was good agreement between the simulated and measured values. The models allow the estimation of hexachlorobenzene, DDT/DDE and PCB 153 concentrations for different exposure scenarios. Also presented is an application of the DDT/DDE model for comparison with biomonitoring data from the National Health and Nutritional Examination Survey. Hence, this series of PK models may be useful for interpreting human biomonitoring data as a part of an overall POPs risk assessment. *The findings and conclusions in this presentation have not been formally disseminated by [the Centers for Disease Control and Prevention/the Agency for Toxic Substances and Disease Registry] and should not be construed to represent any agency determination or policy.*

PS 2950 All Clinical Signs Are Important, but Some Are More Important Than Others: A Study on Associations Between Clinical Signs and Pathological Findings in Toxicity Testing

A. V. Silva[1], M. Öberg[1], U. Norinder[2], E. Liiv[3], B. Platzack[4], and E. Törnqvist[1]. *[1]Karolinska Institutet, Stockholm, Sweden; [2]Stockholms Universitet, Stockholm, Sweden; [3]Uppsala Universitet, Uppsala, Sweden; and [4]RISE Research Institutes of Sweden, Södertälje, Sweden.*

Animal testing is a legal requirement for marketing of chemicals and pharmaceuticals. These experiments must take the 3R principles (Replacement, Reduction and Refinement) into consideration and clinical signs are generally used to monitor animal welfare during ongoing studies. In this study we investigate possible associations between clinical signs, body weight change and histopathological findings observed after necropsy. It was hypothesized that clinical signs and body weight loss observed during experiments could be used as early unspecific markers of organ toxicity. Data from three sequential toxicity studies in rats were analysed using the multivariate data analysis method partial least squares (PLS). Associations were found between the increased occurrence of clinical signs and histopathological findings in the thymus, testes, epididymides and bone marrow. The derived models predicted accurately over 80% of the animals' pathological findings, when building the model using all clinical signs available. The three most important clinical signs were piloerection, stained nostrils and decreased motor activity. A 5% body weight loss was found to be a strong empirical predictor of pathological findings. In conclusion, clinical signs and body weight loss constitute early and easy to observe markers of toxicity, with empirical predictive power for pathological findings. Thus, we recommend these signs to be utilised as informative endpoints for predicting toxicity in rats, as well as a non-invasive surveillance tool for animal welfare and toxicity assessment during *in vivo* studies.

2951 Benchmark Dose Software for Toxicological Risk Assessment in Japan

H. Nishiura[1], and T. Yamaguchi[2]. [1]*Hokkaido University, Sapporo, Japan; and* [2]*Shiga University, Hikone, Japan.* Sponsor: H. Nishiura, Japanese Society of Toxicology

For toxicological risk assessment, it is fruitful to have a user-friendly software for benchmark dose (BMD) modeling, possibly with graphical user interface (GUI). Our study aimed to devise an independent software equipped with BMD method. Using statistical package R, we drafted a modeling code for quantal response data based on animal experiment. The software uses a unique package OptimCL which implements parallel computation using a package snow and helps explore likelihood surface. Results: Due to the original package, modeling results are independent of initial value for unknown parameters. In addition to comparison of penalized likelihood and lowest limit value, BMDL, the software yields model averaging results as well as the averaging of three best models, the latter we believe as yielding the most reasonable BMDL value. A GUI-based software was devised without difficulty in specifying initial values for maximum likelihood estimation. The programmed software also offers the possible best option to be used for the point of departure.

2952 A Biologically Based Model to Quantitatively Assess the Impact of Chemical Exposure on Developing Hepatic Steatosis

C. Bay[1], and H. El-Masri[2]. [1]*Oak Ridge Institute for Science and Education, Research Triangle Park, NC; and* [2]*US EPA, Research Triangle Park, NC.*

Fatty liver disease affects nearly one-third of the US population and hepatic steatosis, or excessive lipid accumulation in the hepatocyte, is the core manifestation of this ailment. Hepatic steatosis is a dysfunction of lipid homeostasis that is maintained through a complex network of biological events that include hepatic fatty acid (FA) uptake, *de novo* FA and lipid synthesis, FA oxidation, and lipid efflux. Hepatic FA *de novo* synthesis and uptake are mediated through the liver X (LXR), and pregnane X (PXR) receptors; respectively. Chemical binding to LXR modulates target genes involved in the formation of hepatic fatty acids, including sterol regulatory element-binding protein 1c (SREBP-1c), stearoyl-CoA desaturase-1 (SCD-1), and fatty acid synthase (FAS). FA uptake into liver is mediated by CD36 transporters which are regulated by PXR activation. A biologically-based quantitative model for hepatic lipid homeostasis was developed incorporating both mechanisms. Furthermore, the impact of chemical exposure on fatty acid hepatic content via LXR, and/or PXR binding was quantitively investigated by incorporating liver tissue dosimetry, using a physiologically-based pharmacokinetic (PBPK) model, with the hepatic lipid homeostasis model. The overall quantitative model was tested against three known agonists of LXR and/or PXR: T0901317 (both receptors), GW3965 (LXR only), and Rifampicin (PXR only). In agreement with literature, model predictions showed that T0901317 caused severe fatty acid build-up in the liver, with slightly less accumulation observed with Rifampicin exposure, and GW3965 caused little lipid build-up. These results highlight the importance of PXR activation while suggesting that FA *de novo* synthesis alone is not enough to cause appreciable accumulation of lipids in the liver. The chemical exposure-hepatic steatosis overall quantitative model can be used to screen chemicals for their potential to cause hepatic steatosis in view of their exposure levels and toxicological potency obtained from high throughput data for LXR and PXR binding. *This abstract does not necessarily reflect US EPA policy.*

2953 NRF2 Negatively Regulates Primary Ciliation and Hedgehog Signaling

P. Liu[1], M. Dodson[1], D. Fang[2], E. Chapman[1], and D. D. Zhang[1]. [1]*University of Arizona, Tucson, AZ; and* [2]*Northwestern University, Chicago, IL.*

Primary cilia are lost during cancer development, but the mechanism regulating cilia degeneration is not determined. NRF2 normally protects cells from oxidative, proteotoxic, and metabolic stress, with hyperactivation of NRF2 now considered oncogenic. However, the detailed molecular mechanisms by which uncontrolled NRF2 activation promotes cancer progression remain unclear. We report here that NRF2 suppresses hedgehog (Hh) signaling through Patched 1 (PTCH1), and primary ciliation via p62/SQSTM1. PTCH1, a negative regulator of Hh signaling, is an NRF2-target gene, and as such hyperactivation of NRF2 impairs Hh signaling. NRF2 also suppresses primary cilia formation through p62-dependent inclusion body formation and blockage of BBS4 entrance into cilia. Simultaneous ablation of PTCH1 and p62 completely abolishes NRF2-mediated inhibition of both primary ciliation and Hh signaling. Our findings not only uncover a mechanism by which NRF2 hyperactivation promotes tumor progression via primary cilia degeneration and aberrant Hh signaling, but also reveal a previously unidentified role of NRF2 in controlling a cellular organelle, the primary cilium, and its associated Hh signaling pathway. A better understanding of the crosstalk between NRF2 and primary cilia/Hh signaling could not only open new avenues of cancer therapeutic discovery, but could also have significant implications regarding pathologies other than cancer, including developmental disorders, where improper primary ciliation and Hh signaling play a major role. *Supported by the following NIH grants: R01 DK109555, R01 ES026845, and P42 ES004940 to D.D.Z., as well as P30 ES006694.*

2954 Estimation of Toluene Exposure in Air from BMA (S-Benzylmercapturic Acid) Urinary Measures Using a Reverse Dosimetry Approach Based on Physiologically Based Pharmacokinetic Modeling

H. G. Tohon[1], M. Valcke[2], A. Nong[3], and S. Haddad[1]. [1]*Université de Montréal, Montreal, QC, Canada;* [2]*INSPQ, Montreal, QC, Canada; and* [3]*Health Canada, Ottawa, ON, Canada.*

Biomonitoring is now an essential component of national health surveys to assess human exposure to chemical contaminants. In exposure assessment, there is evidence that the direct reconstruction of population external exposure from biological measurements (generally on parent compounds) can be done by a reverse dosimetry approach using physiologically based pharmacokinetic (PBPK) models, and steady state assumptions. The objectives of this work are to estimate individual toluene exposure in air from urinary BMA (S-benzylmercapturic acid) measurements collected in six adult Canadians by Health Canada, and to evaluate the contribution of the variability in urinary spot-sample measurements on the overall uncertainty related to toluene exposure estimates based on reverse dosimetry PBPK modeling approaches compared to the use of single 24-h urines measurements. To do so, both exposure assessment techniques were developed for each individual, namely the estimate of toluene exposure in air from a concentration of BMA measured on 24-h urines (24-h-BMA) and from a distribution of daily urinary BMA spot measurements (ds-BMA). Individual distributions of physiological parameters are described based on age, weight, size and sex. Monte Carlo simulations with PBPK models were used to generate Exposure Conversion Factor tables to convert ds-BMA (and 24-h-BMA) into toluene air levels. Based on the approach relying on ds-BMA, the ratio between the 95% probability of predicted toluene concentration and its 50% probability in the individuals studied varied between 1.2 and 1.4, while that based on 24-h-BMA varied between 1 and 1.1 (rounded values). These results point out that computing estimates of toluene air concentrations based on 24-h-BMA generates a lower level of uncertainty. They also suggest an average relative contribution of intra-individual variability in spot measurements to the overall uncertainty based on ds-BMA of about 20%. Toluene levels estimated herein (0.0078-0.0138 ppm) are similar to that previously estimated from Canadian blood measurements and well below Health Canada's maximum recommended chronic air guidelines. Concluding, PBPK modeling and reverse dosimetry can be combined to help interpret biomonitoring data on urinary metabolites of environmental volatile chemicals and assess the magnitude of the related uncertainty.

2955 Development of a Virtual Population Model of Thyroid Hormone Regulation for Safety Assessment of Endocrine Disrupting Chemicals

Z. Shi, and Q. Zhang. *Emory University, Atlanta, GA.*

Inferring human health risk of environmental exposures to endocrine disrupting chemicals (EDCs) from *in vitro* testing data is a challenging task. It requires consideration of the uncertainties and variabilities inherent to the *in vitro* to *in vivo* extrapolation (IVIVE) process and those in the human endocrine systems. To this end, a dynamic model explicitly capturing the inter-individual variability of a human population will be useful. In this study we aim to establish such a population model of the thyroid hormone system by utilizing the thyroid profile dataset in the National Health and Nutrition Examination Survey (NHANES) from 2007-2012. After eliminating individuals with thyroid cancers and on thyroid medications, we applied a rejection sampling algorithm to obtain a non-stratified sample population based on readjusted sample weights of individuals. The obtained sample population contains measured plasma levels of free T4, free T3, total T4, total T3, and TSH for over four thousand individuals; it was then used as the input to a multivariate kernel density function to estimate a continuous probability density function for a correlated distribution of these hormones. The resulting density function was then utilized to generate virtual human populations of thyroid hormone pro-

files. A dynamic hypothalamic-pituitary-thyroid (HPT) axis model describing the feedback regulation and free and total T4/T3 kinetics was then subject to parameter estimation by using the virtual human population generated. The parameter estimation process is under several mechanistic constraints imposed by the physiology of the HPT axis. To deal with the issue of parameter correlation, a modified Bayesian-like approach was used that iterates through multiple prior distributions for each parameter to obtain posterior distributions. The resulting parameter distributions are sampled to generate a virtual population model that can be perturbed *in silico* by single and mixture of thyroid EDCs. The model can take *in vitro* thyroid toxicity testing data to predict hormone alterations for a human population, bridging the IVIVE gap. The approach developed here can also generate a virtual subpopulation from the NHANES dataset, such as women at reproductive age that are susceptible to thyroid disruptions, for safety assessment.

2956 Probabilistic Physiologically Based Pharmacokinetic Model for Per- and Polyfluoroalkyl Substances (PFAS) in Beef Cattle and Dairy Cows for Food Safety Assessment

Y. Cheng, W. Chou, and Z. Lin. *Kansas State University, Manhattan, KS.*

Perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS), and perfluorohexanesulfonic acid (PFHxS) are chemicals of major concern among the family of per- and polyfluoroalkyl substances (PFAS) due to their environmental persistence and long half-lives in humans. Dietary intake of these chemicals from milk and edible tissues is considered to be the predominant route for human exposure and thus poses potential health risks. There is no available physiologically based pharmacokinetic (PBPK) model to describe the transfer and distribution of PFAS to milk and edible tissues from contaminated feed in farm animals. This study aimed to develop probabilistic PBPK models for PFOA, PFOS, and PFHxS in beef cattle and dairy cows. Based upon previously published PBPK models for PFOA and PFOS in rodents and humans, this study developed a PBPK model for lactating cows fed with naturally contaminated PFAS-contained hays and silages as well as for beef cattle following a single oral dose of PFOS and PFOA. The PBPK structure for dairy cows contained six compartments: plasma, liver, kidneys, udder, muscle, and rest of body. Preliminary results showed that the model adequately simulated available kinetic data of PFOS in plasma and milk with an estimated coefficient of determination (R^2) over 0.95. Monte Carlo simulation method is being incorporated into the model in order to estimate meat withdrawal interval and milk discard time. Extrapolation of this model to PFOA and PFHxS is ongoing. This model provides a useful tool for safety assessment of beef and milk from cattle exposed to PFOS, and serves as a foundation for extrapolation to other PFAS chemicals to improve food safety assessment.

2957 Development of Additional Workflows for Risk Assessment and Prioritization for the PLETHEM Package

K. A. Bronson, J. Fitzpatrick, M. Moreau, P. D. McMullen, and S. N. Pendse. *ScitoVation, Durham, NC.*

Over the past three years we have been developing the population life-course exposure to health effects model (PLETHEM) - the open source R package that is designed to provide tools that can be used to bridge the source-to-outcome continuum. Pharmacokinetic modeling is becoming increasingly important in chemical safety decision making, with applications in prioritizing risk assessment by establishing margins of exposure for chemicals and extrapolating hazard across different ages, population cohorts, or occupational classes. As a part of our effort to provide the community with an easy-to-use yet capable modeling tool, we have continued to develop the PLETHEM package. We have created workflows for automated reverse dosimetry and route to route extrapolation, modeling for ecotoxicology applications, and kinetically derived maximum tolerated dose estimation. The automated reverse dosimetry module implements the Discretized Bayesian Approach as described by Tan et al. (2007) along with an easy-to-use interface to run the workflow. Simulation results from existing PBPK models or from models parameterized within PLETHEM can be imported for dose reconstruction. We have also added the ability to perform automated route-to-route extrapolations within PLETHEM. The user can parameterize the model for a given route of exposure using the existing forward dosimetry interface within PLETHEM and use this parameterized model to estimate exposure along a different route using this workflow. Next, as a part of this update, we have added a fish PBPK model described by Peyret et al. (2009), physiological datasets for this model and an easy to use modeling interface to help stakeholders address ecotoxicology concerns. Lastly, we are incorporating into PLETHEM additional features to make kinetically derived maximum tolerated dose (KMD) modeling more accessible. KMD makes use of kinetic modeling to identify dose ranges that avoid saturating ADME processes, which would convolute the interpretation of the study. McFadden et al. (2012) described a statistical method to determine KMD values for toxicokinetic studies. We are adding to PLETHEM an interface that allows users to import their own toxicokinetic datasets or simulated PBPK models from PLETHEM to estimate a KMD. PLETHEM is freely available via the Comprehensive R Archive Network (CRAN). We are also hosting some of these workflows as standalone apps online to provide users with easy access to them.

2959 Combining Evidence to Assess Mutagenicity of Impurities by Supplementing QSAR, Rule-Based, and Read-Across Predictions with Expert Opinions

A. Mostrag-Szlichtyng[1], B. Bienfait[2], E. Fioravanzo[3], T. Magdziarz[2], J. Marusczyk[2], J. Park[4], J. F. Rathman[1,5], P. Russell[3], O. Sacher[2], C. Schwab[2], A. Tarkhov[2], and C. Yang[1,2,4]. *[1]MN-AM, Columbus, OH; [2]MN-AM, Nuremberg, Germany; [3]ToxNavigation Ltd., East Molesey, United Kingdom; [4]MN-AM, Seoul, Korea, Republic of; and [5]Ohio State University, Columbus, OH.*

In silico toxicity predictions have been established as alternative methods for evaluating the genotoxic potential of chemical impurities or metabolites in safety assessment of pharmaceuticals (ICH M7) or agrochemicals (EFSA). Quantitative structure-activity relationships (QSARs) and expert knowledge-based rules are commonly employed for *in silico* models and are well-suited for DNA-reactive mutagenicity where modes of chemical reactivity are well characterized. While much effort has been dedicated to the *in silico* modelling of one particular endpoint, bacterial reverse mutagenesis, there remains a need to establish a systematic method to consider and incorporate other relevant pieces of evidence including, for example, experimental results from mechanistic analogs to improve confidence in predictions, or the need to evaluate such experimental data with further knowledge in metabolism or reactivity. This study was performed to demonstrate the full workflow necessary in this process using pharmaceutical impurities as examples. Experimental Ames assay results, QSAR and Rule-based predictions, and expert's rationales are lined up in an assessment table, and these data are then combined for the final outcome along with uncertainty estimation. Three studies were included for cases when QSAR and Rule-based results 1) are all in agreement; 2) show equivocal results (e.g., 1,2-diformylhydrazine); 3) are in conflict (e.g., 1,2-diphenylhydrazine). Expert reviews were also included for each case to decide whether to overrule the predictions or recommend the weight-of-evidence final conclusion. This approach pushes the envelope of *in silico* methods to be combined with expert opinions in a weight of evidence mode to achieve reproducible and robust assessments.

2960 Calculated Solvation Energies Predict the Elimination Half-Lives of Perfluoroalkyl Substances in Mammals

A. J. Prussia, M. C. Buser, and C. Welsh. *CDC/ATSDR, Atlanta, GA.*

Some perfluoroalkyl substances are highly stable and bioaccumulative contaminants in mammals. The elimination half-lives for some analogs in humans measures in years, not hours. However, the half-lives can vary dramatically based on the analog and species in question. In general, longer-chain perfluoroalkyl analogs have lengthened half-lives in larger mammals. This complicates risk assessment because the points of departure are often serum levels in rodents that cause a health effect. The human equivalent dose (HED) that would result in an equivalent serum level is calculated using estimates for half-life, volume of distribution, and absorbed fraction. Because the half-life may differ drastically between rodents and humans, it has a large effect on the final HED. Relatively few perfluoroalkyls have elimination half-lives measured in multiple species. This data gap is exacerbated by increasing use of shorter-chain analogs that are less persistent and therefore perceived to be less toxic. Because most perfluoroalkyls are not modified metabolically, we hypothesized that the half-life is driven by the physical properties of the substances. However, standard prediction tools (EPIsuite, ACD/Labs) for these properties may lack parameterization for their unique chemistry. Therefore, *ab initio* quantum mechanical calculations with the Poisson-Boltzmann solvation model were performed on perfluoroalkyls with experimental half-lives. The resulting solvation energies for water and cyclohexane are able to explain more than 80% of the variance in experimental half-lives in a simple multiple least squares regression model that includes human, monkey, mouse, and rat species. The model can be viewed as a first step toward establishing elimination half-lives based on a structure activity relationship for perfluoroalkyls and may allow for a rough estimate of the bioaccumulative potential of alter-

native perfluoroalkyls. *Disclaimer: the findings and conclusions in this presentation have not been formally disseminated by [the Centers for Disease Control and Prevention/the Agency for Toxic Substances and Disease Registry and should not be construed to represent any agency determination or policy.*

2961 Drug-Induced Liver Injury Severity and Toxicity (DILIst): Binary Classification of 1303 Drugs by Human Hepatotoxicity

S. Thakkar[1], T. Li[1], Z. Liu[1], L. Wu[1], R. Roberts[2], and W. Tong[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]ApconiX, Alderley Edge, United Kingdom.*

Drug-induced liver injury (DILI) is one of the primary challenges for drug development in part because of the limited success with existing preclinical models. This concern has led to significant efforts in evaluating alternative methods, particularly animal-free approaches, for predicting DILI in humans. Most of these methods requires a large drug list with known DILI severity and toxicity that distinguish DILI positives from negatives. Previously, we reported DILIrank that consisted of 775 drugs and their DILI classifications, assessed using FDA approved drug labeling information. In this study, we augmented DILIrank with four large literature datasets (N>350 drugs) using a statistical approach to generate DILIst (DILI severity and toxicity). The augmentation was carried out separately for each DILI class (i.e., positive or negative) and resulted in a DILIst database of 1303 drugs of which 789 were DILI positives (increased 69% from DILIrank) and 514 were DILI negatives (increased by 66%). DILIst is an invaluable resource for the community to improve DILI research in the areas of elucidation of mechanisms, predictive model development and biomarker identification, and provides additional opportunities to exploit the potential of emerging technologies. *Disclaimer: The views presented in this paper do not necessarily reflect current or future opinion or policy of the US FDA. Any mention of commercial products is for clarification and not intended as endorsement.*

2962 3D-SDAR Classification Models for Large and Diverse Sets of Opioid Receptors Binders: Structural Factors Affecting Binding to Mu, Kappa, and Delta Opioid Receptors

S. Slavov, W. Mattes, and R. Beger. *US FDA/NCTR, Jefferson, AR.*

Addiction is a complex behavioral phenomenon in which naturally occurring or synthetic chemicals through their binding to a variety of neuroreceptors, modulate the response of the reward system, resulting in compulsive substance-seeking (Can. Med. Assoc. J. 164.6, 2001, 817). Among these, the opioid receptor family (OR) plays a critical role in the addiction to powerful prescription and illicit drugs. As more than 700 new psychoactive substances were illegally sold between 2009 and 2016, most of them lacking basic toxicological and pharmacological profiles, molecular modeling approaches that could quickly and reliably fill in the gaps in our knowledge are highly desirable. A grid-based, alignment independent technique utilizing fingerprints constructed from NMR chemical shifts and interatomic distances (named 3D-SDAR) was used for model building, validation and interpretation. To generate balanced modeling and "blind" prediction subsets, all chemicals from the initial sets of 3594, 2942 and 2420 MOR, KOR and DOR binders were sorted according to their molecular weight and every 3rd compound from these three lists was moved out to form the prediction subsets. The remaining 2/3 of the chemicals constituted the modeling subsets which were then split repeatedly into training and hold-out test set pairs used for model building and internal validation. After 100 randomizations the aggregated predicted values for the training, hold-out and prediction subsets were averaged individually for each compound and each subset and a cut-off value of 0.5 was used to classify the chemicals as either binders (>0.5) or non-binders (≤0.5). The accuracy, sensitivity and specificity for the "blind" prediction subsets consistently exceeded 0.8 and were significantly higher after the removal of the inconclusive predictions near the cut-off. The AUC values for all prediction subsets exceeded 0.88. 3D-SDAR mapping identified the morphinan and benzomorphan backbones as universal and non-selective components of OR binders, whereas specific functional groups such as 3,4-dimethyl-4-(3-hydroxyphenyl) piperidine, 3-pyrrolidinol and benzamide were found to result in substances that are selective to MOR, KOR and DOR, respectively. Furthermore, a cyclopropylmethyl moiety linked to the basic nitrogen atom of both morphinan and benzomorphan derivatives was found to enhance the affinity towards all OR subtypes.

2963 Improving the Read-Across Assessment Framework (RAAF) for Better Assessing Read-Across Predictions

A. Abe, T. Sezaki, Y. Tahara, and K. Kinoshita. *Mitsui Chemicals Inc., Chiba, Japan.* Sponsor: Y. Tahara, Japanese Society of Toxicology

From the viewpoint of animal welfare, alternative methods for the safety assessment of chemicals is becoming more vital. Among the alternative methods, read-across is importantly used to fulfil the requirement for information under regulatory frameworks, such as the registration, evaluation, authorization and restriction of chemicals (REACH) regulation. As a systematic framework to assess the read-across cases under REACH, the Read-Across Assessment Framework (RAAF) was developed by the European Chemicals Agency (ECHA). The validity and reliability of the read-across is judged according to the Assessment Elements (AEs) in the RAAF. Basically, the RAAF is not created for a specific endpoint and its AEs are scientific aspects commonly required for all read-across cases (e.g. data quality, category boundary, underlying mechanisms, etc.). However, for the read-across of a specific endpoint, more specific AEs would be more useful for users to assess their read-across predictions. Therefore, in this study, we tried to improve the original RAAF for more practical applications and developed a RAAF for skin corrosion/irritation read-across (RAAF-SCI) by setting more specific assessment procedures based on the original AEs. For example, category boundaries were determined on the basis of octanol-water partition coefficient, melting point, boiling point and molecular weight, the common underlying mechanisms were evaluated based on the profiling results by the OECD QSAR Toolbox, and source data quality was assessed by referring to the publically available reliability scores. In order to evaluate the effectiveness of our improved RAAF-SCI, we applied it to the read-across predictions of 4 chemicals whose skin irritation data already existed. Initially the category of the target chemical was created by the predefined procedure using the OECD QSAR Toolbox [SAR QSAR Environ Res, v30, 2019 p279]. The category was then assessed by the RAAF-SCI and improved if necessary. For example, if the target chemical was outside the boundary of the category, analogues were added so that the target chemical fell into the category. Finally, the read-across from the improved category members could reproduce the skin irritation potential of the target chemicals. As a result, our RAAF-SCI with improved AEs gave more reliable read-across predictions.

2964 Quantitative Systems Toxicology (QST) Reproduces Species Differences in PF-04895162 Liver Safety Due to Combined Mitochondrial and Bile Acid Toxicity

V. V. Lakhani[1], G. Generaux[1], Y. Yang[1], S. Nadanaciva[2], L. Qiu[2], K. Riccardi[2], L. Di[2], B. A. Howell[1], S. Q. Siler[1], P. B. Watkins[3], H. A. Barton[2], M. D. Aleo[2], and L. K. Shoda[1]. *[1]DILIsym Services Inc., Durham, NC; [2]Pfizer Inc., Groton, CT; and [3]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

PF-04895162 (ICA-105665), a drug in development for the treatment of epilepsy, was terminated after transaminase elevations (up to grade 3) were observed in healthy volunteers (NCT01691274). Human hepatotoxicity was unexpected, because liver safety concerns had not been raised in preclinical safety studies (Aleo et al. 2019). The purpose of our investigation was to better understand the mechanisms underlying the apparent species differences, between rat and human, in liver safety. We retrospectively analyzed PF-04895162 using a computational representation of drug induced liver injury, DILIsym, which integrates *in vitro* data of hepatotoxic mechanisms with *in vivo* predictions of liver exposure to mechanistically simulate hepatotoxicity. The *in vitro* data include drug inhibition of bile acid (BA) transporters (human BSEP, NTCP, MRP3 and MRP4, as well as, rat Bsep, Mrp3 and Ntcp) and drug-induced mitochondrial dysfunction (using the Seahorse XF Analyzer). PF-04895162 weakly interacted with BA transporters (IC_{50} values >100μM) and mildly reduced mitochondrial function. Physiologically based pharmacokinetic (PBPK) models were fit to pre-clinical and clinical plasma concentrations and used to predict *in vivo* liver concentrations. DILIsym integrated the *in vitro* data and PBPK models to predict hepatotoxicity in both species. Simulations were conducted in SimPops, which represent population variability, including pathways that regulate sensitivity to certain hepatotoxic mechanisms. The simulations reproduced the observed human hepatotoxicity and the lack of rat hepatotoxicity. Simulated hepatotoxicity was multifactorial. Simulations showed higher liver exposure in humans than in rats. Elimination of drug effects on either mechanism wholly abrogated simulated injury; thus, both mechanisms were required. The interaction of two hepatotoxic mechanisms explains how the mild effects observed *in vitro* could plausibly translate to hepatotoxicity *in vivo*. Importantly, the mechanistic interaction is not readily foreseeable given the *in vitro* data alone. This study reproduces species differences using a QST approach and supports the contention that QST tools have the potential to identify latent hepatotoxic risks.

2965 Application of the CiPA *In Silico* Model in Early Drug Research: Validation Results for Different Drug Development Phases

M. Schaefer[1], F. Schmidt[1], A. Czich[1], J. Guillon[2], V. Ballet[2], D. Rampe[3], J. Kang[4], A. Bohme[2], H. Matter[1], and A. Amberg[1]. *[1]Sanofi, Frankfurt, Germany; [2]Sanofi, Paris, France; [3]Sanofi, Bridgewater, NJ; and [4]Sanofi, Framingham, MA.* Sponsor: D. Keller

The CiPA (comprehensive *in vitro* Proarrhythmia Assay) initiative proposes a novel screening paradigm for the assessment of proarrhythmic liabilities. The core element is an *in silico* cellular simulation model (O'Hara/Rudy type) combining ion channel *in vitro* data to reconstruct the cardiac action potential. The CiPA paradigm is intended to refine the ICH S7B/E14 guideline and the clinical thorough QT (TQT) study in development. This study investigated if the CiPA model is also applicable in the research drug optimization phase to early eliminate drug candidates with proarrhythmic risk before entering development. We first evaluated the 28 drugs (9 low, 11 intermediate, 8 high risk) that were also used to validate the CiPA model. Various simplification steps were applied to simulate the early research phase when limited data sets are available for decisions. So we predicted the proarrhythmic risk by reducing the number of originally 7 down to the 3 main ion channels hERG, Cav1.2 and Nav1.5 (peak) typically screened in early research. Then we excluded the dynamic binding parameters and just used IC50 values for simulation. With these settings, the correct classification of almost all high and low risk drugs of the 28 CiPA compounds could be confirmed using qNet values at 4x Cmax. However, both false negatives and false positives were observed. The CiPA model was also applied to internal drug candidates and proarrhythmic risk was validated against results from the Purkinje fiber assay as an important follow up assay in early research. Finally, since many drugs in early optimization are first theoretically designed, the IC50 values of hERG, Cav1.2 and Nav1.5 were also predicted based on their chemical structure using in-house QSAR models. So when using predicted IC50 values for the CiPA simulation, depending on the QSAR model's applicability domain and chemical series, most of the positives were correctly predicted with sensitivities up to 80-90% (average prediction accuracy was 70%). The accuracy could be increased when predicted IC50 values were replaced by measured data. These validation results show that a combination of the CiPA model using predicted or measured ion channel data and confirmation by the Purkinje fiber assay can successfully be applied in R&D to rank and early eliminate drug candidates with proarrhythmic liabilities but cannot be currently used for quantitative safety margin evaluation.

2966 Data-Driven Selection of Biologically Diverse Cell Lines for Chemical Bioactivity Screening Using Content Maximization

J. A. Harrill[1], C. Willis[1], S. Malcomber[2], A. White[2], R. Thomas[1], N. Sipes[3], and R. Setzer[1]. *[1]US EPA, Research Triangle Park, NC; [2]Unilever Safety and Environmental Assurance Centre, Colworth, United Kingdom; and [3]NIEHS/NTP, Research Triangle Park, NC.*

Many research organizations are exploring the use of high-throughput profiling (HTP) assays for *in vitro* hazard evaluation. HTP assays can be used to characterize the response of many human-derived cell types to chemicals. However, no single cell type will express all the potential molecular targets and pathways that are present in the human body. Therefore, an envisioned approach for HTP assays in bioactivity screening involves panels of cells that express complimentary (i.e. partially non-overlapping) sets of molecular targets to address a broad swath of human biological diversity. Here, we present a data-driven approach for selection of biologically diverse cell lines for HTP screening based on basal gene expression. First, the cancer cell line encyclopedia (CCLE) Affymetrix transcriptomics dataset was RMA-normalized and a pair-wise Euclidean distance matrix was calculated. Three cell lines of programmatic interest (MCF-7, U-2 OS, HepG2) were selected as anchors (i.e. initial vertices) and ten more biologically diverse cell lines were selected by identifying the group of cells within CCLE that maximized the content (i.e. Cayley-Menger determinant) of a multidimensional simplex. This approach identified cell lines with a variety of tissue origins (immune, fibroblast, lung, upper aerodigestive tract, skin, CNS and kidney) that were non-redundant with the tissue origins of the anchor lines (breast, bone, liver). These cell lines, along with a set of thirteen hTERT-immortalized primary cell lines from various tissues and 2-D HepaRG cells were profiled using whole transcriptome TempO-Seq. The data was used to map the diversity of molecular targets and pathways expressed across the 30 total cell lines. Cell lines from similar tissues tended to have more similar gene expression profiles than cell lines from disparate tissues. The hTERT cell lines had less diversity in gene expression than the cancer cell lines. The content maximization algorithm was applied to the TempO-Seq data to generate ranked lists of cell lines that progressively increases the amount of biological diversity given a particular set of anchor cell lines. This data-driven method can be used in an unbiased manner for populating cell line panels for HTP-based toxicity screening. *This abstract does not reflect US EPA policy.*

2967 Comparison of CATMoS Acute Oral Toxicity GHS Classifications with Historical *In Silico* Estimates and *In Vivo* Test Data

C. Owens, and L. Milchak. *3M, Saint Paul, MN.*

Computational toxicology has rapidly progressed in capability in the last decade as alternative methods have become more widely available to attempt to reduce reliance on animal testing while providing equivalent or more accurate information for human health risk assessments. As part of this effort, significant resources have been dedicated to developing comprehensive tools to aid those conducting *in silico* assessments, including the development of the Open Structure-Activity/Property Relationship App (OPERA) by the National Toxicology Program (NTP). To evaluate the performance of the OPERA Collaborative Acute Toxicity Modeling Suite (CATMoS) Acute Lethality Consensus model, the model's predictions were compared to historical acute oral lethality computational assessments conducted by a 3M weight of evidence (WoE) approach (n=81) that included analysis of (Q)SAR predictions and read-across from structural analogs. When comparing the results, the CATMos predicted GHS class agreed with the 3M WoE prediction for 78% of the substances (63/81). In instances where there was disagreement (n=18), the 3M WoE prediction was more conservative (a lower GHS class was predicted) for 17/18 of those substances. Additionally, the CATMoS model's performance was compared to a set of proprietary 3M chemistries with experimental *in vivo* oral LD_{50} values and corresponding GHS classifications (n=70). When testing CATMoS against the experimental test set, the model correctly predicted the GHS classification for 77% of the substances (54/70). For substances that were misclassified by the model (n=16), 7 of the predictions were more conservative (a lower GHS class was predicted) compared to the experimental data. Substances where the lethality was under-predicted most often contained metals or double or triple-bonded nitrogen. Overall, the CATMoS Acute Lethality consensus model performed well when tested against a diverse test set that included hydrocarbons, fluorocarbons, and structures will a wide variety of phosphorous, sulfur and some nitrogen-containing functional groups that can often pose challenges for statistical models that rely on a single prediction rather than a consensus approach. However, the consensus model was less conservative in some instances compared to a WoE approach that considered (Q)SAR predictions and read-across from structural analogs. Further evaluations will include attempts to identify the types of chemical classes or functional groups that CATMoS was not able to correctly classify.

2968 ToxSIBAR: Predicting Toxicity with Similarity-Based Descriptors

B. Zdrazil[1], B. Khalil[1], S. E. Escher[2], and G. F. Ecker[1]. *[1]Universität Wien, Vienna, Austria; and [2]Fraunhofer Institute of Toxicology and Experimental Medicine, Hannover, Germany.* Sponsor: C. Dasenbrock

The concept of similarity is broadly implemented in predictive toxicology, assuming that chemical compounds with similar chemical structure, similar pharmacological target profiles, similar metabolic, toxicodynamic and or toxicokinetic profiles will exert similar toxicological effects. Being widely known as read-across approaches, such concepts can aid as alternative tools to animal testing for hazard assessment. In addition to a concept aiming to group (or position) compounds based on some sort of similarity measure, compounds with known toxicity can also be used to build a predictive computational model in order to forecast the toxicity of a compound with unknown adverse effect. A prerequisite however, is the availability of enough chemical data as well as the employment of relevant features (describing/encrypting the chemical compounds) being able to sufficiently capture the essentials of that toxic event. The latter, is one of the biggest challenges in computational toxicology nowadays since mechanistic information of the toxic event under study can seldomly sufficiently be encrypted in the chemical structures and derived descriptors. We are proposing a new methodology, utilizing the concept of read-across in the framework of a predictive modeling approach. The ToxSIBAR concept is based on previous work where (euclidean) distances of the training set compounds to a set of reference compounds were utilized as input features for building QSAR models for predicting e.g., transport inhibition. We applied this concept to an *in vivo* dataset of >1000 diverse compounds measured as positive or negative for hepatic steatosis in rodent studies with repeated oral exposure by using different reference compound sets (e.g., randomly chosen; based on maximum diversity) and by applying different basic descriptors and classifiers. Interestingly, the models utilizing the ToxSIBAR descriptors as input outperformed the baseline models highlighting the potential of the method to be developed and optimized further.

This work has received funding from the EU-TOXRISK, a project running under the European Union's Horizon 2020 research and innovation programme, grant agreement No 681002.

2969 Quantitative Systems Toxicology Modeling of Cisplatin Nephrotoxicity Using *In Vitro* Assays of Proximal Tubule Epithelial Cells for Mechanistic Toxicity Pathways

Y. Gebremichael, N. Hamzavi, J. Woodhead, S. Tallapaka, S. Siler, and B. Howell. *DILIsym Services Inc., Research Triangle Park, NC.*

Cisplatin-induced nephrotoxicity results in acute kidney injury (AKI) and is caused by various cellular mechanisms, including mitochondrial dysfunction, oxidative stress, and others. AKI mechanisms of cisplatin and several other nephrotoxic drugs remain incompletely understood. Quantitative system toxicology (QST) offers promise for better understanding of drug induced AKI through mechanistic representation of the underlying toxicity pathways. We developed a QST model of cisplatin induced AKI using *in vitro* assay data to characterize injury pathways. We employed RENAsym, a QST model of drug-induced AKI, to quantify cellular toxicity and injury mechanisms of nephrotoxicants. RENAsym represents aspects of renal proximal tubule epithelial cells (RPTEC) including cell life cycle, bioenergetics, drug-induced cell death pathways, and biomarker (αGST) responses. For mechanistic representation of cisplatin induced AKI, we analyzed data from a 2D *in vitro* system (collected by Cyprotex, Inc.) of RPTEC. Seahorse XF analyzer and high content imaging (HCI) were used to quantify cisplatin-induced mitochondrial dysfunction and oxidative stress. Seahorse mitochondrial dysfunction assays show a substantial decline in oxygen consumption rate at 24 hours, suggesting dose-dependent ETC inhibition by cisplatin. Similarly, HCI data depicts a dose-dependent rise in oxidative stress, both at 24 hours and 9 days. Simulations using RENAsym predict dose-dependent toxicity as quantified by elevations in αGST, a biomarker that marks RPTEC death. A simulated single high dose of 533 mg/m^2 i.v. cisplatin results in 14 fold change in αGST, while a simulated clinical dose of 100 mg/m^2 shows 1.4. This result is in qualitative agreement with 3.4 fold change observed in a clinical study where patients administered 100 mg/m^2 i.v. cisplatin exhibited 20% incidence of AKI [1]. RENAsym simulations predicted dose-dependent AKI in human exposed to cisplatin, in qualitative agreement with clinical data. RENAsym shows promise in combining QST modeling and *in vitro* assay data to provide a unique tool for drug-induced AKI prediction. *Funding: NIDD SBIR grant [1] Ummer et al. International journal of Bioscience, Biochemistry and Bioinformatics, Vol. 2, No. 4, July 2012.*

2970 Updated Dermal Sensitization Thresholds Derived Using an *In Silico* Expert System and an Expanded Local Lymph Node Assay Dataset

M. L. Chilton[1], D. S. Macmillan[1], A. M. Api[2], G. F. Gerberick[3], M. Lavelle[2], M. Na[2], D. O'Brien[2], and R. J. Safford[4]. *[1]Lhasa Limited, Leeds, United Kingdom; [2]Research Institute for Fragrance Materials, Woodcliff Lake, NJ; [3]GF3 Consultancy LLC, West Chester, OH; and [4]B-Safe Toxicology Consulting, Rushden, United Kingdom.*

When toxicologists need to conduct a Quantitative Risk Assessment (QRA) of a potential skin sensitiser lacking *in vivo* toxicity data, one available approach is the Dermal Sensitisation Threshold (DST). The DST acts as a surrogate point of departure within the QRA when exposure to the chemical is expected to be low, representing a worst-case scenario based on the known skin sensitisation potency of hundreds of chemicals. Two values have previously been published: a non-reactive DST of 900 µg/cm^2 based on Local Lymph Node Assay (LLNA) data for 38 sensitisers judged to be non-reactive by human experts, and a reactive DST of 64 µg/cm^2 based on LLNA data for 233 reactive sensitisers. This study sought to update these DST values using an expanded LLNA dataset, and to investigate whether the chemical reactivity could be assigned *in silico*. An expanded LLNA dataset containing 1,175 chemicals was collected from the public domain and curated in-house. The potency values in this dataset fitted a similar gamma distribution to the original dataset. The skin sensitisation structural alerts within Derek Nexus, an *in silico* expert system for predicting toxicity, were used to assign each chemical as reactive or non-reactive. The 454 reactive sensitisers resulted in a reactive DST of 59 µg/cm^2, whilst the 109 non-reactive sensitisers led to a preliminary non-reactive DST of 290 µg/cm^2. The updated reactive DST (59 µg/cm^2) was remarkably similar to the original value (64 µg/cm^2) despite being based on almost twice as many chemicals, indicating the robustness of the reactive DST. However, the updated non-reactive DST (290 µg/cm^2), based on almost 3 times as many chemicals, was approximately 3 times smaller than the original value (900 µg/cm^2). A review of the 109 non-reactive sensitisers highlighted chemicals requiring autoxidation, questionable dose-response data and possible false positive irritant responses. As an example of the impact these data points can have, removal of the LLNA data for 3 salicylate esters (which are likely to be irritants rather than sensitisers) would cause the non-reactive DST to increase to 320 µg/cm^2.

2971 Developing Semantic Technology for Toxicology Applications: Interdisciplinary Collaborations and Community Development

A. E. Thessen[1], T. J. Callahan[2], L. Chan[1], N. Vasilevsky[3], R. Boyles[4], R. Kulkarni[5], C. J. Grondin[6], M. Willis[1], and M. Haendel[1]. *[1]Oregon State University, Corvallis, OR; [2]University of Colorado Anschutz Medical Campus, Aurora, CO; [3]Oregon Health and Science University, Portland, OR; [4]RTI International, Durham, NC; [5]NIEHS, Research Triangle Park, NC; and [6]North Carolina State University, Raleigh, NC.*

Modern toxicology is evolving to leverage data science methodologies to better address complex public health concerns. Understanding the health impacts of environmental exposures requires working across a variety of domains and data types that are often siloed and require manual curation and extraction. Ontologies and semantic engineering can facilitate meaningful data integration, but existing semantic standards have not been widely used in toxicology. Development of semantic standards for toxicology requires sustained interdisciplinary collaborations. One place where the community came together to discuss this need is the "Computable Exposures" workshop, held at Oregon State University in September 2019. Ontologists, toxicologists, epidemiologists, exposure scientists, ecotoxicologists, clinicians, computer scientists, computational biologists, and data scientists from academia, government, and industry were in attendance. Here we describe community-building efforts, standards development, and plans for future work. Objectives include building a semantic exposure data model using the Environmental Conditions, Treatments, and Exposures Ontology (ECTO), developing toxicology-driven use cases and competency questions, creating a mailing list, and planning a larger computable exposures conference. Fifteen use cases were developed during the workshop, including the use of semantic technology to complete Adverse Outcomes Pathway (AOP) and Aggregate Exposure Pathway (AEP) given the initiating and terminal key events. Broader adoption of ontologies, together with increased data sharing, has the potential to improve a toxicologist's ability to integrate, navigate, and analyze vast amounts of heterogeneous data—allowing for more rapid safety assessment of chemical and environmental exposures, and increased understanding of underlying biological mechanisms.

2972 Toward Mechanistic-Based Assessment: Rapid Elucidation of the Key Molecular Pathways Underlying Diketone-Induced Bronchiolitis Obliterans Using Phenotypic and Transcriptomic Profiling

S. S. Htwe, K. W. Kong, S. O. Fu, J. J. Lee, J. C. Kong, V. Limviphuvadh, B. P. Smith, S. Maurer-Stroh, S. Hoon, and L. Loo. *Agency for Science, Technology and Research (A*STAR), Singapore, Singapore.*

New approach methods based on mechanistic reasoning have the potential to provide more human-relevant information for chemical safety assessment. In particular, genome-wide transcriptomics may be used to rapidly elucidate the molecular pathways underpinning the key events of an adverse outcome. Recent advances in transcriptomic technology have enabled more cost-effective and higher throughput assays. However, the relevancy of the identified molecular pathways is still largely limited by the biological models used, and their specificity to an adverse outcome. We have developed a platform called Toxicity Mode of Action Discovery (ToxMAD) Platform to overcome these challenges. To demonstrate the application of ToxMAD, we performed a case study on diketone-induced bronchiolitis obliterans (BO). Diketones are flavoring additives shown to be associated with BO in popcorn factory workers. *Firstly,* we performed a literature review to identify the key events associated with the progression of BO under *in vivo* diketone exposures. *Secondly,* we identified *in vitro* human cell models sensitive to a chemical of interest using high-throughput imaging-based phenotypic profiling (HIPPTox). Among the three tested human cell models, a lung bronchial epithelial cell line, BEAS-2B, was found to be the most sensitive to *diketones,* including diacetyl and 2,3-pentanedione. Thirdly, we used high-throughput transcriptomics (HTTr) to identify differentially expressed genes (DEGs) induced by the two chemicals, and 849 and 533 DEGs (Adj P-value<0.05) were found to be induced by them, respectively. Interestingly, the gene expression profiles induced by these two diketones are positively correlated (r=0.929, p=2.2x10^{-16}) suggesting the same modes of action were induced. Furthermore, many of the DEGs

were also found in a previous rodent transcriptomics study of 2,3-pentanedione. Finally, we developed bioinformatic methods to identify key pathways and their corresponding DEGs that are relevant to the key events of BO. These genes may be used as markers to compare the potency and evaluate the potential hazards of other diketones or related compounds that may cause BO.

2973 Predicting Subchronic and Chronic Animal Toxicity from *In Vitro* High Content Imaging Data Using PBTK and Machine Learning

T. Antonijevic[1], and I. Shah[2]. *[1]ToxStrategies Inc., Katy, TX; and [2]US EPA, Durham, NC.*

A major challenge in toxicity testing in the 21st century is to predict animal toxicity from *in vitro* studies. Here, we utilized physiologically based toxicokinetic (PBTK) modeling and machine learning (ML) to predict mouse, rat, and dog liver toxicity from high content imaging (HCI) data obtained by measuring HepG2 cell responses to 967 chemical treatments across 10 endpoints and 3 time points (1h, 24h, and 72h). First, the HCI data were normalized to generate z-score data for p53, c-Jun, H2A.X, PH3, α-tubulin, mitochondrial membrane potential, mitochondrial mass, cell cycle arrest, nuclear size, and cell number. Second, lowest-observed adverse effect level (LOAEL) values for chemicals from subchronic/chronic studies in mouse (75/154), rat (161/160), and dog (69/113) were obtained from the ToxRef database. Third, LOAEL values were converted to average venous concentrations using PBTK to match the *in vitro* treatment protocol. Fourth, each *in vitro* treatment was associated with a toxicity class as follows: nontoxic if the venous concentration corresponding to LOAEL was greater than *in vitro* concentration, and toxic otherwise. Finally, 5 ML algorithms (k-nearest neighbors (kNN), Random forest (RF), support vector machine (SVM), decision trees (DT) and naïve Bayes (NB)) were used to evaluate the accuracy for predicting toxicity in each study type and species by each *in vitro* time point. Lastly, we created balanced data using B-splines to interpolate the HCI concentration-response data at untested concentrations. The mean area under the receiver operating characteristic curve (AUC) for chronic and subchronic imbalanced data were 0.7 (SD 0.01) and 0.72 (SD 0.01), respectively. The predictive performance was greater for balanced datasets with a mean AUC of 0.73 (SD 0.01) and 0.79 (SD 0.01) for chronic and subchronic toxicity, respectively. RF was the best algorithm to predict subchronic liver toxicity with AUC 0.96 (SD 0.005) for mice, 0.9 (SD 0.004) for rat and 0.84 (SD 0.01) for dog. For chronic studies, the most accurate classifiers were RF for mice 0.87 (SD 0.01), kNN for rat 0.82 (SD 0.005) and dog 0.79 (SD 0.01). The best prediction for mouse subchronic/chronic liver toxicity was obtained from 1h/24h HepG2 data, whereas for rat and dog, the highest score was obtained at 24h/1h. Our findings suggest the utility of a new approach for linking *in vitro* data to *in vivo* outcomes using machine learning. *This abstract does not reflect EPA policy.*

2974 Toxicants Associated with Spontaneous Abortion in the Comparative Toxicogenomics Database

S. M. Harris[1], Y. Jin[1], R. Loch-Caruso[1], I. Y. Padilla[2], J. D. Meeker[1], and K. M. Bakulski[1]. *[1]University of Michigan, Ann Arbor, MI; and [2]Universitario de Mayagüez, Mayagüez, PR.*

Up to 70% of all pregnancies result in either implantation failure or spontaneous abortion (SA). Adverse pregnancy outcomes are particularly challenging to evaluate in any one *in vitro* or *in vivo* model, thus we lack a comprehensive understanding of how chemicals exposures affect the risk of SA. Our goal was to identify chemicals with a high number of interactions with SA genes, based on known toxicogenomic responses. We used reference SA and chemical gene lists from the Comparative Toxicogenomics Database in human, mouse, and rat. We prioritized chemicals (n=25) found in Superfund sites. For chemical-disease gene sets of sufficient size (n=13 chemicals, n=20 comparisons), chi-squared enrichment tests and proportional reporting ratios (PRR) were calculated. Among the SA genes, we assessed enrichment for Gene Ontology defined biological processes. In humans, all chemicals tested were highly enriched for SA gene overlap (all $p<0.001$; parathion PRR=7, cadmium PRR=6.5, lead PRR=3.9, arsenic PRR=3.5, atrazine PRR=2.8). In mice, highest enrichment ($p<0.001$) was observed for naphthalene (PRR=16.1), cadmium (PRR=12.8), arsenic (PRR=11.6), and carbon tetrachloride (PRR=7.7). In rats, we observed highest enrichment ($p<0.001$) for cadmium (PRR=8.7), carbon tetrachloride (PRR=8.3), and dieldrin (PRR=5.3). SA genes were overrepresented in the following biological processes: inflammatory response (q=0.001), collagen metabolic process ($q=1x10^{-13}$), and vascular development (q=0.005). We observed chemical gene sets (parathion, cadmium, naphthalene, carbon tetrachloride, arsenic, lead, dieldrin, and atrazine) were highly enriched for SA genes. Our findings have critical public health implications for successful pregnancies and the interpretation of environmental pregnancy cohort analyses. These findings also have implications for the design of toxicology studies investigating the end point of spontaneous abortion.

2975 Weight of Evidence Assessment of Genotoxicity Based on a Battery of Genetic Toxicity Assays: Improvement of Decision Making for Genotoxic Carcinogens

J. F. Rathman[1,2], M. T. Cronin[3], D. Ebbrell[3], S. Escher[4], J. Firman[3], A. Mostrag-Szlichtyng[1], and C. Yang[1,5]. *[1]MN-AM, Columbus, OH; [2]Ohio State University, Columbus, OH; [3]Liverpool John Moores University, Liverpool, United Kingdom; [4]Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; and [5]MN-AM, Nuremberg, Germany.*

Determining whether a compound is mutagenic and/or genotoxic is an important decision point in regulatory risk assessment workflows. In addition to the obvious need to differentiate genotoxic and non-genotoxic modes of carcinogenicity, the early decision steps in the Threshold of Toxicological Concern (TTC) framework require knowledge of genotoxicity, with a separate decision tree for suspected genotoxic carcinogens. Which assays should be used and how many need to be positive before a chemical is termed "genotoxic" are common questions. The issue is complicated by the long-held understanding that genotoxic carcinogens are more potent than those acting by non-genotoxicity mechanisms. Thus, there is a need to define and identify genotoxic carcinogens. Regulatory guidance, e.g. from the US Environmental Protection Agency (EPA), recommends a hierarchical data preference method with a weight of evidence (WoE) approach. As a result, decisions on mutagenicity or genotoxicity are often made by expert opinion utilizing and interpreting multiple streams of data from *in vitro* and *in vivo* assays through WoE. The aim of this study was to define genotoxic carcinogens from publicly available genetic toxicity data applying WoE approaches. From the updated CPDB (Carcinogenicity Potency Database), 549 selected compounds were identified, for which BMDL10 and TD10 calculations were possible to be used for Cancer-TTC analysis. Genetic toxicity data for these putative carcinogens were sourced from diverse sources including NTP, FDA, ECHA, EFSA and the open literature as well as ChemTunes.ToxGPS. The dataset was evaluated to rate study reliability, and the available data were then combined to define whether a compound is a genotoxic carcinogen. Two WoE approaches were compared, the first based on rationales by experts using both experimental, when available, and (quantitative) structure-activity relationship ((Q)SAR) predictions. The second employed training a Bayesian Network to define a latent variable for "genetic toxicity" given a battery of assay data and *in silico* predictions. Validating the identification of genotoxic and non-genotoxic carcinogens was performed utilizing available data from the EFSA and ECHA databases. This approach to systematically define "genotoxicity" empowers and extends the value of (Q)SAR in safety/risk assessment.

2976 NICEATM Computational Tools and Resources Supporting Alternative Test Method Development and Evaluation

S. Bell[1], K. Mansouri[1], J. Phillips[2], X. Chang[1], J. Abedini[1], A. L. Karmaus[1], I. Lea[1], R. Rai[1], D. G. Allen[1], W. Casey[3], and N. C. Kleinstreuer[3]. *[1]Integrated Laboratory Systems Inc., Research Triangle Park, NC; [2]Sciome LLC, Research Triangle Park, NC; and [3]NIEHS/NICEATM, Research Triangle Park, NC.*

The NTP Interagency Center for the Evaluation of Alternative Toxicological Methods (NICEATM) develops and evaluates alternatives to animal use for chemical safety testing. To support these activities, NICEATM has developed a set of computational tools and resources in partnership with federal agencies, industry, and academia. This presentation highlights two resources that make data and computational tools more accessible to our stakeholders: the Open Structure-activity/property Relationship App (OPERA) and the Integrated Chemical Environment (ICE). OPERA is a suite of QSAR models to predict physicochemical and pharmacokinetic properties often needed in modeling. OPERA also includes a set of models built using global collaborative crowdsourcing approaches to construct consensus models for various toxicity endpoints. CERAPP and CoMPARA are consensus models that predict estrogen and androgen receptor pathway activity, respectively. The newest model, CATMoS, is a consensus model providing predictions for acute oral systemic toxicity (LD50) and hazard categories. OPERA is available as a standalone downloadable program with graphical user interface and command line options. ICE is an online database that provides users access to *in vivo*, *in vitro*, and *in silico* data for a range of toxicity endpoints, including curated Tox21 high-throughput screening data for >9,000 chemicals and OPERA predictions for >700,000 chemicals. ICE also includes a growing suite of tools such as a web-based *in vitro* to *in vivo* extrapolation tool allowing users to

compare predicted exposures from *in vitro* bioactivity concentrations to doses from *in vivo* animal studies. For test method developers and evaluators, curated lists of reference chemicals with known effects are available along with their supporting data. Features of both tools and example use cases in the context of chemical evaluation will be presented. *This project was funded in whole or in part with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C.*

2977 Automated Applications of Ontologies to Standardize Developmental Toxicology Study Extractions

C. Foster[1], J. Wignall[1], S. Kovach[1], J. Trgovcich[1], A. Varghese[1], J. Rochester[1], M. Stout[2], and N. Kleinstreuer[2]. *[1]ICF International Inc., Durham, NC; and [2]NIEHS/NTP, Durham, NC.*

Extraction of toxicological endpoints from primary sources is a central component of systematic reviews in human health risk assessment. For extracted data to be comparable and therefore useful for analyses such as calculating chemical-specific effects, establishing reference datasets for validation of new approaches, and computational modeling purposes, consistent language should be used for endpoint descriptions. However, primary source language describing treatment-related effects can vary greatly, resulting in large labor efforts to manually standardize extractions before data is fit for use. To minimize these labor efforts, we developed Python code that automates application of pre-existing ontologies and controlled vocabularies to extracted endpoints. Our approach was initially developed to apply a subset of Unified Medical Language System (UMLS) codes (i.e., those used previously in ToxRefDB as described in Watford et al. 2019) along with German Federal Institute for Risk Assessment (BfR) DevTox ontology codes and OECD endpoint vocabularies to roughly 36,000 extractions from developmental toxicology studies conducted by the National Toxicology Program. Extractions were recorded based on the original study report language. Our code was able to automatically apply standardized ontologies to 82% of these extractions. The code was then applied to 6,400 extractions from ECHA developmental toxicology studies and was able to automatically standardize 79% of the extractions. Of extractions that were standardized, about 6% required additional manual curation to correct inaccurate matches (e.g., "missing tail" tagged as "double-tipped tail"). This low error rate is due to optimizing the code for precision. Extractions from both datasets that were not standardized tended to be out of scope of developmental toxicology endpoints (e.g., "number of litters"). We estimate that we reduced time spent standardizing the language for these two datasets from 350 to 50 hours, assuming 30 seconds per extraction. We would predict similar results if this approach was applied to other legacy developmental toxicology extraction datasets. In addition, the design of the code ensures that it can be easily expanded beyond developmental toxicology endpoints for application to other study types, which would improve the utility of legacy datasets for use in modeling or other analyses.

2978 Improving Identification of Neuroactive Compounds Using Temporal Information from Microelectrode Array Recordings of Cortical Neural Networks and a Semi-Supervised Classification Algorithm

S. Davila-Montero[1], T. J. Shafer[2], K. Wallace[2], J. Fink[2], and A. J. Mason[1]. *[1]Michigan State University, East Lansing, MI; and [2]US EPA/ORD, Research Triangle Park, NC.*

Human exposure to environmental chemicals can result in acute neurotoxicity (NT), negatively impacting brain activity. *In vitro* microelectrode array recordings of neural network function following chemical exposure can be used to screen chemicals for NT hazard. These recordings capture temporal (from min to days) and spatial aspects of action potential activity as described by a set of network parameters (NPs). To determine if a compound is neuroactive, global NPs are extracted from 40 min neural recordings resulting in loss of temporal information (TI). The TI could improve identification of compound fingerprints and/or provide information on the mechanisms of action that mediate a neural network response after acute exposure of a compound. Here, data from 384 previously tested compounds were used to explore the properties of the TI to screen for acute neuroactive compounds using the response from a single high concentration (nominally 40 μM) and a window analysis technique. From recordings on day *in vitro* 12, a total of 19 NPs were extracted for each 1-min window of time with 50% overlaps, resulting in one time series (trajectory) per NP. Extracted NP trajectories were normalized per well and per window of time, and a moving median filter was applied to reduce outliers. A *k*-means trajectory clustering technique was used to find 10 clusters of trajectories for each NP and to assign cluster IDs to the trajectories of each compound. Then, for each compound, a vector with a total of 19 cluster IDs (one per NP) was assigned and used to classify the compounds as neuroactive or negative compounds using a Support Vector Machine (SVM) classifier. The entire classification model was trained with 73 compounds (42 neuroactives, 31 negatives) and yielded a classification accuracy of 93.2%. When using the model to classify the 384 compounds, 257 were identified as neuroactives and 127 as negatives. By comparison, when TI was excluded from the SVM classifier, classification accuracy of the same 73 neuroactive/negative compounds decreased to 86.3%. The higher classification accuracy of the SVM model that uses TI data demonstrates including TI is more effective for identifying acute neuroactive compounds when performing single-point screening. *This abstract does not reflect policy of the US EPA.*

2979 Updates to the Cramer et al. Decision Tree and Thresholds of Toxicological Concern to Improve Safety Assessment and Prioritize Chemicals for Testing

S. Stice, R. Kolanos, and T. Adams. *US FDA, College Park, MD.* Sponsor: S. Choudhury

The Cramer *et al.* (1978) Decision Tree (CDT) prioritizes chemicals according to their toxic potential using a sequence of 33 mainly structure-based yes or no questions, to which the answer either refers the user to another question or assigns the substance to one of three structural classes of toxic potential. Each question was designed based on information on chemical structure, reactivity, metabolism, toxicokinetics, biochemistry, and animal toxicology existing over 40 years ago. The concept of the Threshold of Toxicological Concern (TTC) refers to the establishment of a level of exposure for chemicals in each TTC class below which there would be no appreciable risk to human health. Each of the three CDT classes has a corresponding TTC level. Once a chemical is assigned to a CDT class, its consumption is assumed to be reasonably safe provided its intake is below its class TTC. Given the scientific knowledge accumulated since 1978, the CDT has been long overdue for an update. More than 18,000 scientific studies were reviewed to determine the effects of species, strain, sex, and target organ on toxicity and metabolic fate. These studies provided no-observed-effect-levels for 1,900+ substances that were then organized according to their structure, metabolic fate, and toxic potential. Analysis of this database resulted in the development of more refined questions, leading to a better separation between classes and an increased number of classes of toxic concern along with a broader scope of chemicals that are addressed by the Expanded Decision Tree (EDT). The toxic potential of each of the six classes was quantified by determining the EDT class TTCs. During the last seven decades, scientific advancements have led to an exponential increase in the number and types of chemicals to which humans are exposed, leading to an ever increasing need to screen and prioritize these substances according to their relative toxicity. Furthermore, calls for reducing the use of animals for safety testing has been increasing. Hence, updating of the scientific underpinnings of the CDT and TTC is timely and their expansion to allow for the screening of a broader scope of substances present in food, food contact materials, cosmetics, dietary supplements and elsewhere is desirable. This session will provide insight into the current use of the CDT and TTC, efforts to modernize them, and to increase their applicability.

2980 A Baseline Measurement for Endpoint Consistency across Zebrafish Laboratories

A. E. Thessen[1], M. Haendel[1], K. Ryan[2], L. Truong[1], J. Hamm[3], N. Klüver[4], S. Scholz[4], and D. M. Reif[5]. *[1]Oregon State University, Corvallis, OR; [2]NIEHS, Research Triangle Park, NC; [3]Integrated Laboratory Systems Inc., Research Triangle Park, NC; [4]Helmholtz Centre for Environmental Research, Leipzig, Germany; and [5]North Carolina State University, Raleigh, NC.*

Toxicology as a discipline is moving toward increased standardization of methods for testing and reporting end points in model organisms for improved, cross-laboratory data integration. Labs engaged in high-throughput analyses have established handbooks to internally standardize results, but these standards are rarely applied across laboratories. This poses a problem for integrating and comparing data across labs, which could support more robust corroboration in the confidence of results from toxicological assessments. To set a baseline, an informal survey was created asking participants to score 24 lateral images of zebrafish larvae for chemical-induced malformations (i.e., abnormalities) according to their laboratory practices and standards. Participants were allowed to answer using free text. Eighteen researchers from fourteen different labs participated. The free text results included 1748 terms which were mapped to 48 traits from the Zebrafish Phenotype Ontology (ZP) for comparison. Both the reported endpoints and the terms used to describe them were very heterogeneous and had little agreement - even the most straightforward of endpoints, normal and dead embryos,

were not consistently identified. Abnormalities of the heart and yolk were the most consistently identified (67% and 63% agreement, respectively) while abnormalities of the pectoral fin and the gut were least consistently identified (6% and 11% agreement, respectively). Abnormalities of the gut, pectoral fin, and otic vesicles were the most heterogeneously described while abnormalities of the trunk, snout, and heart were the most homogeneously described. Participants were able to score every image. All images were lateral views at stage 96 hours post fertilization (hpf) which were taken with the VAST (Vertebrate Automates Screening Technology) System. It is clear from these results that the community requires improved standards for defining and scoring toxicological endpoints. Future work will include conducting a study that includes a controlled vocabulary with textual definitions for scoring embryo images, to determine if this improves consistency.

PS 2981 High-Throughput Phenotypic Profiling (HTPP) to Discern Putative Mechanism of Action (MOA) for Environmental Chemicals

J. Nyffeler, C. Willis, G. Patlewicz, I. Shah, and J. Harrill. *US EPA, Research Triangle Park, NC.*

HTPP is an imaging-based profiling method that combines automated microscopy and image analysis to measure a large variety of morphological features at the single cell level. The USEPA is currently exploring the use of HTPP for rapid bioactivity screening and hazard characterization of environmental chemicals. Here, we investigate the use of HTPP data for identifying chemicals with similar bioactivity profiles and discerning putative MOA. We screened a set of 120 reference chemicals to compare against 462 environmental chemicals selected from the ToxCast collection. Human U-2 OS cells were plated in 384-well format and treated with 8 concentrations (0.03 - 100 µM) of test chemicals. At 24 h, cells were fixed and labeled with fluorescent probes to visualize multiple organelles, including nucleus, nucleoli, endoplasmic reticulum, golgi, cytoskeleton, plasma membrane and mitochondria. Confocal images were acquired and 1300 phenotypic features were extracted at the single cell level. Cell-level data was normalized to the median and variance of the solvent control and aggregated to a well-level median. Well-level data was averaged across replicates (n = 4). Profiles for each chemical were obtained by retaining the largest effect size observed at non-cytotoxic concentrations. Signatures were computed by flooring values < 1.5 to 0 and biological similarity of chemicals was evaluated using Pearson correlation. Structural similarity was evaluated by comparing Morgan fingerprints using Tanimoto similarity. Within the reference chemical set, 16 distinct profile clusters were observed. Reference chemicals with various DNA damaging mechanisms clustered and demonstrated similarity with a subset of environmental chemicals. Different classes of pesticides also had distinct profiles. Five structurally-related organochlorine pesticides affected DNA texture and had biological similarities between 0.5 and 0.7. A group of strobilurin fungicides had similar profiles based on changes in mitochondrial features, consistent with the ability of strobilurins to inhibit fungal mitochondrial respiration. In summary, HTPP facilitated identification of chemicals with similar bioactivity profiles and potentially similar MOA, both among structurally-related and structurally diverse chemicals. *This abstract does not reflect US EPA policy.*

PS 2982 Quantitative Integration of Dose-Response Data for Relative Potency Estimates of Dioxin-Like Chemicals

C. Ring[1], S. Fitch[2], L. Haws[1], M. Harris[3], and D. Wikoff[4]. *[1]ToxStrategies Inc., Austin, TX; [2]ToxStrategies Inc., Dallas, TX; [3]ToxStrategies Inc., Katy, TX; and [4]ToxStrategies Inc., Asheville, NC.*

Toxic equivalency factors (TEFs) for dioxin-like chemicals (DLCs) are informed by an underlying database of relative potency (REP) estimates composed of heterogenous data from various study types, species, duration, dose, methods for deriving REPs, etc. The objective herein was to update the REP database and combine these heterogeneous data to infer quantitative dose-response (DR) distributions of REPs for each of 28 DLCs. Using a systematic search approach, > 50 studies were added to the database, doubling the size to >1200 datasets with DR and/or REP data. Individual DR curves were fitted to each dataset with DR data. Then, each DR curve was standardized by normalizing to the reference DR curve for each dataset. For each congener, from the set of study-specific standardized DR curves and/or study-specific REP values, an "average" standardized DR curve was inferred using a hierarchical Bayesian model. By comparing each congener-specific average standardized DR curve to the TCDD average standardized DR curve, a TEF value for each congener was inferred, along with uncertainty in the inferred value. Quantitative weighting based on study quality was incorporated by modeling increased heterogeneity of study-specific DR curves for lower-quality studies. For many data-rich congeners (e.g. 2,3,4.7,8-PeCDF), predicted TEF values are on the order of 2005 WHO TEF values; TEF 95% credible intervals are less than 1 order of magnitude wide. For congeners with little data (e.g. 1,2,3,7,8,9-HxCDF), TEF 95% credible intervals are 2 or more orders of magnitude wide. By modeling standardized DR curves, our approach harmonizes heterogeneous DR and REP data, and allows full consideration of shape and parallelism of DR curves — collectively demonstrating integration of dose-response data across study types and endpoints, including quantitative consideration of individual REP quality and relevance.

PS 2983 EU-ToxRisk Guidance for New Approach Methods (NAM)-Supported Read-Across

EU-ToxRisk Guidance for New Approach Methods (NAM)-Supported Read-Across

S. Hougaard Bennekou[1], A. Bitsch[2], S. Escher[2], D. Kroese[3], M. Mone[4], G. Ouedraogo[5], S. Stuart[6], and H. G. Kamp[7]. *[1]Danmarks Tekniske Universitet, Lyngby, Denmark; [2]Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; [3]Nederlandse Organisatie voor Toegepast Natuurwetenschappelijk Onderzoek, Zeist, Netherlands; [4]Universiteit Leiden, Leiden, Netherlands; [5]L'Oréal, Paris, France; [6]Procter & Gamble, Cincinnati, OH; and [7]BASF SE, Ludwigshafen, Germany.*

Read-across (RAX) is a valuable approach to fill data gaps for complex toxicological endpoints without the use of *de novo in vivo* studies. Toxicological data from compounds with certain structural/physicochemical properties can be extrapolated to similar compounds that lack these data. For RAX to be reliable, however, biological similarity has to be accounted for as well. NAMs that describe toxicokinetic and toxicodynamic properties can be deployed to verify this biological similarity, and to establish a scientifically reliable and robust RAX. The use of NAMs goes hand in hand with new challenges like scope of *in vitro* testing, use of AOPs, interpretation of conflicting results, description of uncertainty, and reliability of test methods. More guidance is needed to assure transparent and accurate use of NAMs and by this promote acceptance of these new data within RAX assessments. In May 2019, the Horizon 2020 European collaborative project EU-ToxRisk - An Integrated European 'Flagship' Programme Driving Mechanism-based Toxicity Testing and Risk Assessment for the 21st century - together with European agencies (ECHA, EFSA, SCCS), US agencies (NTP, EPA), and global organizations (OECD), hosted the workshop "New Approach Method (NAM)-supported read-across: from case studies to regulatory guidance in safety assessment". Based on case studies that targeted different regulatory applications, the use of NAMs was discussed with a special focus on the regulatory context and the associated regulatory requirements that these approaches have to fulfil. Furthermore, some of the cases have also been reviewed by the OECD IATA working group. This poster highlights the main learnings from the feedback on the NAM-based read-across reports, such as the requirements for data and method descriptions, the application of AOPs in terms of IATAs, the use of positive and negative controls to proof fitness-for-purpose of testing strategies, and uncertainty assessment.

PS 2984 Physiologically Based Pharmacokinetic Modeling of Impact of Nonalcoholic Fatty Liver Disease on Toxicokinetics of Perchloroethylene in Mice

C. Dalaijamts, C. A. Joseph, L. Yu-Syuan, I. Rusyn, and W. A. Chiu. *Texas A&M University, College Station, TX.*

Nonalcoholic fatty liver disease (NAFLD) is a major cause of chronic liver disease in the Western population and steadily increasing in worldwide populations with metabolic syndrome, which is becoming more common due to the Western diet. The physiological changes associated with the disease substantially affect chemical toxicokinetics, which in turn modulate chemical toxicity. This study aims to use physiologically-based pharmacokinetic (PBPK) modeling to characterize the impact of diet-induced NAFLD on toxicokinetic variability of perchloroethylene (PERC) in mice. Quantitative measures of physiological and biochemical changes associated with the presence of NAFLD induced by high-fat or methionine/choline-deficient diets in C57B1/6J mice are incorporated into a previously developed PBPK model for B6C3F1, Swiss, and C57B1/6J male mice on normal diets. For instance, C57B1/6J mice having various stages of diet-induced NAFLD showed changes in fat and liver volumes and blood:air and liver:air partition coefficients, which are incorporated into the model. Hierarchical Bayesian population analysis using Markov chain Monte Carlo simulation is conducted to characterize uncertainty and inter-diet and inter-strain variability in PERC toxicokinetics and metabolism. The updated population model accurately predicts *in vivo* toxicokinetics of PERC oxidative and glutathione conjugative metabolites in all tissues across all diets and strains of mice. Parent compound toxicokinetics is well-predicted

in healthy mice, but model predictions of PERC toxicokinetics in blood and fat are underestimated in mice fed NAFLD-inducing diets. Toxicokinetic variability across strains and diets is evident, with mice on NAFLD-inducing diets showing greater oxidative and lower conjugative metabolism as compared to healthy mice of all strains. Moreover, the variation across three diets in C57B1/6J mice is at least as great as the variation across three strains on normal diets. These results suggest that non-genetic factors such as diet and pre-existing disease conditions may be at least as influential as genetic factors in altering chemical toxicokinetics, and thus are likely to be a substantial contributor to population variation in susceptibility to chemical exposures. *This work was supported by a grant from NIH/NIEHS (P42 ES027704).*

PS 2985 Exploring the Use of Compound-Induced Transcriptomic Data Generated from Cell Lines to Predict Compound Activity toward Molecular Targets

B. Baillif, O. Mendez Lucio, and D. Rouquie. *Bayer SAS, Sophia Antipolis, France.* Sponsor: R. Bars

Pharmaceuticals or phytopharmaceuticals molecules rely on the interaction with one or few specific molecular targets to induce their anticipated biological responses. Nonetheless, these compounds also are prone to interact with many other biological targets, also known as off-targets. This fact is particularly critical when some (or a combination) off-targets are associated to adverse effects. Unfortunately, off-target identification is extremely difficult and expensive. Consequently, QSAR models predicting the activity of a molecule on a particular off-target have gained importance in the de-risking process of chemicals. For example, QSAR models have been designed to predict the risk associated with mutagenicity, oral acute toxicity or endocrine related toxicity. However, only few off-targets are well characterized and with enough data to build such *in silico* models. A good alternative to individual off-target evaluations is the use of integrative evaluations such as transcriptomics obtained from compound-induced gene expression derived from *in vitro* cell cultures. The advantage of this strategy is to inform about the consequences of the interaction of compounds on many possible molecular targets and biological pathways, without having any constraints concerning the chemical space. In this work, we assess the value of compound-induced transcriptomic data to build machine-learning models that can predict molecular targets (or off-targets) causally associated to known toxicity. For this, we trained random forest models using data from the cMAP L1000 dataset, which contains a large number of compound-induced gene expression profiles. Transcriptomic-based machine learning models were able to predict off-targets using data generated from appropriate cell lines; even in some cases, outperforming QSAR models. We also provide a simple framework to determine in which cases the use of transcriptomics data exploring biological spaces can help to overcome the limitations derived from a restricted chemical space.

PS 2986 A Deep Generative Model Predicts Tissue Response to Chemical Perturbation

Y. Yang, and S. Bhattacharya. *Michigan State University, East Lansing, MI.*

Predictive computational toxicology plays an essential role in safety testing and has the potential to reduce animal usage. A central goal of predictive computational toxicology is to predict tissue responses to perturbation across domains, such as doses, tissues, organs, or species. In contrast to mechanistic, pathway-based models, the recent rise of deep generative modeling techniques provides an alternative approach to modeling the underlying structure of experimental data. Here we have developed a deep learning-based variational autoencoder model to predict dose responses of the mouse liver to 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) perturbation using transcriptomic datasets. After training the model with liver transcriptome data from control groups, the model was used to encode transcriptome data into a compressed latent space. Following vector arithmetic operations in latent space, the results were decoded back to transcriptome space as the predicted response. We demonstrated here that the variational autoencoder can predict responses of new tissue samples to various doses of 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) perturbation. Deep generative computational models can potentially add to the set of predictive toxicology tools and help reduce the need for expensive *in vitro* and *in vivo* experiments.

PS 2987 An Open-Source *In Silico* Prediction Model of Hepatic Intrinsic Clearance for *In Vitro* to *In Vivo* Extrapolation

J. Fitzpatrick, P. Mallick, K. Bronson, and P. McMullen. *ScitoVation, Research Triangle Park, NC.*

Chemical risk assessment is moving away from animal testing with the goal of incorporating predictive approaches, including computational modeling and simulation into risk assessment. A tiered testing approach has the potential to provide new risk assessment information within lower tiers of testing focused on rapid prioritization of chemicals using high-throughput techniques. Dosimetry, by determining the amount, rate, and distribution of a chemical in the body, is thus essential for the use of new approach methodologies in risk-based decision making. Use of models such as high-throughput *in vitro* to *in vivo* extrapolation (HT-IVIVE) has allowed dosimetry considerations to be more readily incorporated earlier in safety decision making processes. To keep pace with *de novo* computational approaches for estimating hazard, new tools are needed that can provide reasonable estimates of chemical clearance without requiring wet-lab experimentation and analytical chemistry. To this end we have developed a free tool using published intrinsic clearance data that uses physicochemical information to estimate intrinsic clearance. This tool allows a user to input a novel structure by hand or a series of structures using a chemical structure file such as a SMILES or SDF file. A prediction is then generated using a variety of machine learning algorithms along with a confidence metric. The descriptors used in our model are structural as well as predicted physical chemical. In our initial development, the most successful algorithms were the neural network and nearest neighbors algorithms. In the case of the nearest neighbors, this tool also displays structurally similar neighbors from the training set. A total of 433 compounds were used in training set and 100 as test set. Predictions on an independent test set showed that our best performing models could predict the clearance value within one log unit of the known value 65% of the time, and 81% were within one and a half log units of the known value.

PS 2988 An Interactive Online Database for Mining Information on Tobacco Products

Z. Hassan[1], C. Hua[1], E. Omaiye[1], C. Khachatoorian[1], M. Williams[1], R. Behar[1], T. Martinez[1], W. Luo[2], J. Pankow[2], K. Mc Whiter[2], and P. Talbot[1]. *[1]University of California Riverside, Riverside, CA; and [2]Portland State University, Portland, OR.*

Our lab has obtained large amounts of data on flavor chemicals and metals in electronic cigarette fluids and aerosols, the cytotoxicity of these products, and the specific ingredients that cause cytotoxicity using various assays and cell types, including stem cells. In order to manage, search, and work with these data and make them available to others in a useful form, we have developed a searchable online database. The centralized database is being created using Microsoft SQL Server 2017, which is an intelligent relational database management system that runs on the SQL programming language. The SQL Server was chosen since it optimizes the storage of data and ensures security, integrity, and consistency. SQL also gives various ways to present the data analytically, making it convenient for a user to mine and extract useful information. A layout of the database was designed to store data in tabular form with appropriate naming conventions and necessary columns. The master tables are formed by identifying and assembling subjects from experiments and each tabular row is assigned a unique ID. These unique IDs help distinguish subjects across the database and serve as foreign keys to join related tables to retrieve complex information. The database has an interactive web interface that can be leveraged by users worldwide to perform various functions that include searching on keywords (e.g. specific metals and elements, specific flavor chemicals, product names, cell types), visualizing graphs, constructing statistical tables, and navigating to the published papers. Multiple cell types have been used in the cytotoxicity experiments enabling direct comparisons between the responses of stem cells and differentiated cells. The database is scalable and additional information can be added to the database as it becomes available, by conveniently importing and exporting data and modifying the database schema to add new columns and constraints.

2989 Robust Workflows for the Analysis of High-Throughput Transcriptomics Data in Chemical Safety Screening

L. J. Everett[1], J. A. Harrill[1], D. Haggard[2], I. Shah[1], R. Judson[1], T. Sheffield[1], and W. Setzer[1]. *[1]US EPA, Research Triangle Park, NC; and [2]Oak Ridge Institute for Science and Education, Research Triangle Park, NC.*

High-Throughput Transcriptomics (HTTr) is emerging as a chemical toxicity screening method that allows for broad assessment of many target pathways and modes of action in a single assay, which can inform both hazard identification and potency estimation. Steady decreases in cost have made HTTr feasible for screening hundreds to thousands of chemicals, while capturing expression profiles of over 10,000 genes per sample. To date, US EPA has generated HTTr screening data using the TempO-seq platform and MCF-7 cell line for ~2,200 chemicals, and is actively expanding this screening effort into additional cell types and chemicals. Batches of chemicals were tested in 8-point concentration series in triplicate using a 384-well plate format, with multiple types of reference samples per plate for evaluating technical and biological variability. The resulting data is substantially more complex than previous univariate high-throughput screening assays in terms of dimensionality, noise, and correlation structure. Thus, critical open questions remain regarding best practices for HTTr data analysis. Our recent work on this growing collection of data has included: 1) development of an open-source pipeline for rapid and robust processing of TempO-seq data; 2) comparison of multiple analytical methods for estimating differential expression and dose-response models; 3) quantification of reproducibility across platforms and methods; and 4) pathway-level analysis methods to summarize results and link findings to interpretable biology and known hazards. Specifically, we have developed novel quality control metrics to ensure accurate and reproducible hit calls and point-of-departure estimates. We have also rigorously analyzed reference samples across our screening efforts to demonstrate the overall reliability of the TempO-seq platform and quantify uncertainty resulting from multiple sources of experimental variation. We have tested multiple dose-response modeling approaches, including BMDExpress2 software and a novel pipeline that combines DESeq2 differential expression analysis with the ToxCast Pipeline (tcpl). Notably, the results show that aggregating signal at the pathway level improves reproducibility and reduces uncertainty in screening results. *This abstract does not necessarily reflect US EPA policy.*

2990 Deciphering Heterogeneity in Hepatic Responses to 2,3,7,8-Tetrachlorodibenzo-*p*-Dioxin in Mouse Using Single-Nuclei RNA Sequencing

R. Nault, K. A. Fader, S. Bhattacharya, and T. Zacharewski. *Michigan State University, East Lansing, MI.*

Differences in cell type, spatial organization, and epigenetic regulation in a tissue can affect chemical- or drug-elicited responses. Bulk RNA-sequencing (RNAseq) involving tissue homogenization does not distinguish between cell-specific responses and only provides an average gene expression response across all cell types in a tissue. In contrast, single-cell RNA sequencing (scRNAseq) can assess cell-specific responses within the context of its resident tissue. We performed single-nuclei RNA-sequencing (snRNAseq) using nuclei isolated from frozen liver samples from male mice gavaged with sesame oil or 30 µg/kg TCDD every 4 days for 28 days. Approximately 17,921 expressed genes were detected across 16,711 sequenced nuclei isolated from control and TCDD treated samples. Overall, 11 cell (sub)types were identified including distinct pericentral, midzonal, and periportal hepatocyte sub-populations. Cell type clusters from nuclei expression data were similar to published expression profiles from fresh liver single-cell RNA sequencing (scRNA-seq) datasets generated using diverse technologies. Notably, cell type annotation from scRNA-seq was predictive of snRNA-seq clusters. TCDD treatment altered the proportion and composition of hepatic cell types was changed in response to TCDD treatment. Specifically, macrophage representation increased from 0.6% to 23.5%, while neutrophils were only evident in treated samples. The number of differentially expressed genes in each cell type ranged from 178 (B-cells) to 1,212 (pericentral hepatocytes). AhR battery genes such as *Cyp1a1*, *Cyp1a2*, and *Tiparp* were induced 8.8-, 10.5-, and 8.6-fold, respectively, in hepatocytes and endothelial cells. Other differentially expressed genes reported in bulk RNAseq analyses were also found to be specific to a cell type such as the 21.6-fold induction of *Gpnmb* only in macrophages, and the ~3-fold induction of *Col1a2* and *Col1a3* only in stellate cells. Functional analysis identified the hepatocyte-specific repression of oxaloacetate and bile acid metabolism, and the enrichment of B- and T-cell IL-7 signal transduction. Overall, snRNA-seq can be used to investigate cell-specific responses to TCDD within the context of whole tissue using frozen samples. *Funded by NHGRI R21HG010789.*

2991 Mechanism of Action Prediction Using High-Throughput Transcriptomics

D. Mav[1], D. Phadke[1], M. Balik-Meisner[1], C. E. Wimberley[1], A. Ross[1], W. Gwinn[2], R. Shah[1], B. A. Merrick[2], and M. DeVito[2]. *[1]Sciome LLC, Research Triangle Park, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

High-throughput transcriptomics (HTT) has been proposed as alternative cost-effective screening approach that covers a vast array of biological space of expression responses to chemical exposure. The Division of the National Toxicology Program (DNTP) is currently evaluating HTT as an approach to provide estimates of chemical exposure that may pose minimal human risk. HTT was evaluated in a 5-day (repeated dose) rat model with the objective to study and characterize the transcriptional changes in the liver and kidney. This approach will be useful to prioritize chemicals for further testing while providing actionable data in a timely and cost-effective manner. Twenty chemicals, most having been tested by the NTP in 2-year bioassays, were chosen for this study. The 20 chemicals are Acrylamide, Bisphenol AF (BPAF), Bromodichloroacetic Acid, Coumarin, Di(2-ethylhexyl) phthalate (DEHP), Pentabromodiphenyl Ether Mixture (DE-71), Ethinyl Estradiol, Fenofibrate, Furan, Ginseng, Hexachlorobenzene, Methyl Eugenol, Milk Thistle Extract, Perfluorooctanoic Acid (PFOA), Pulegone, Triclosan, Tris(chloropropyl)phosphate (TCPP), Tetrachloroazobenzene, Thujone and Tetrabromobisphenol A. Male Sprague Dawley rats were exposed daily for 5 consecutive days by oral gavage to 8 to 10 dose levels of each chemical. Liver and kidney were collected 24 hours after the final exposure for HTT using the Biospyder rat S1500+ platform. Using GENIE's network analysis module we (1) find groupings within the 20 chemicals and (2) perform transcriptomics read across to predict the mechanism of action (MOA) of each chemical. We obtained the following clear groups within the chemicals: Group #1 - PFOA, Fenofibrate, DEHP and Triclosan, Group #2: BPAF and ethinyl estradiol, Group #3: Coumarin and TCPP, Group #4: Pulegone, Furan and Methyl Eugenol. The rest of the chemicals do not group with any other chemical in the study. GENIE Network analysis module was used to compare the gene expression profile of each of these chemicals to thousands of gene expression signatures compiled from large curated databases such as Drugmatrix and TG-GATES rat database. For each of these chemicals, the top hits from the GENIE Rat database match the known MOAfor the chemical. For example, all the top hits with pvalue<0.005 for PFOA and Fenofibrate in this study are fibrates (bezafibrate, fenofibrate, pirinixic acid, clofibric acid, gemfibrozil etc.) in the Drugmatrix/TG-GATES database. This illustrates that proposed approach is applicable to any chemical of interest for MOA characterization.

2992 Physiologically Based Pharmacokinetic Modeling Improves *In Vitro* to *In Vivo* Extrapolation of Transcriptional Points of Departure

E. Bianchi, K. Johnson, S. Davis, E. Costa, and J. LaRocca. *Corteva Agriscience, Indianapolis, IN.*

In vitro (cellular) approaches are promising alternatives to current *in vivo* methods for chemical risk assessment. In particular, transcriptome-based *in vitro* methods could provide a powerful tool for regulatory decision-making. However, the use of such models brings new challenges associated with translating *in vitro* concentrations to corresponding *in vivo* internal exposures. Physiologically-based pharmacokinetic (PBPK) modeling provides an effective framework for conducting quantitative *in vitro* to *in vivo* extrapolation. Given that previous results suggested apical and transcriptomic endpoints show similar points of departure (POD) *in vivo*, we tested the hypothesis that an *in vivo* transcriptional POD could be accurately predicted from an *in vitro* POD using PBPK modeling. Transcriptional profiles from rat liver samples and rat primary hepatocytes exposed to different chemicals from the Toxicogenomics Project-Genomics Assisted Toxicity Evaluation system (TG-GATEs) database were used to generate transcriptome PODs using BMDExpress software. Because *in vitro* concentrations may not accurately reflect *in vivo* internal exposures, we integrated PBPK software (GastroPlus) to calculate blood Cmax and liver Cmax from *in vivo* data using measured or predicted plasma protein binding and hepatic clearance data. Our findings suggest a stronger correlation between *in vitro* and *in vivo* transcriptional PODs using measured plasma protein binding and hepatic clearance data instead of GastroPlus-predicted values (R^2=0.45 vs R^2=0.08). These findings suggest that *in silico* PBPK modeling may improve the prediction of *in vivo* PODs from *in vitro* transcriptome data.

2993 Whole Transcriptome Extrapolation, Mechanism of Action Analysis, and Network Visualization: Tunicamycin Case Study

R. Shah[1], M. Balik-Meisner[1], D. Mav[1], D. Phadke[1], M. Shah[1], A. Ross[1], J. Phillips[1], B. van de Water[2], M. Niemeijer[2], S. Auerbach[3], B. A. Merrick[3], and R. Paules[3]. *[1]Sciome LLC, Research Triangle Park, NC; [2]Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands; and [3]NIEHS, Research Triangle Park, NC.*

Targeted transcriptomic analyses decrease the time and resources associated with obtaining whole transcriptomic data in high throughput screens. The TempO-Seq S1500+ platform(s), now available for human, mouse, rat and zebrafish, measures a carefully selected subset of the transcriptome such that it provides adequate representation of the biological responses, functional pathways and coregulate gene modules in the transcriptome. While measurement of these S1500+ genes provides a valuable assessment of gene expression activity, extrapolating expression values to the whole transcriptome (~26 K genes in humans) increases the power of pathway analysis algorithms. Here we use a human S1500+ Tunicamycin dataset to explore the improved downstream analysis achieved by extrapolating expression to the remaining transcriptome. Extrapolation increased the number of significant genes by 49%, bringing to the forefront many genes and pathways that have been established to be differentially expressed by Tunicamycin exposure without significantly changing the sample variability. We demonstrate that gene- and pathway-level biological interpretations were improved by extrapolating from the ~3K measured genes to approximately 26K genes before performing a variety of downstream applications, including differential expression analysis, gene set enrichment pathway analysis, and DAVID keyword analysis. The extrapolated data highlight the role of metabolism/metabolic pathways, the endoplasmic reticulum, and the unfolded protein response, each of which are key activities associated with Tunicamycin exposure that were underrepresented prior to extrapolation. Furthermore, when including extrapolated genes, Tunicamycin rose from third to first upstream regulator in Ingenuity pathway analysis, from sixth to second most correlated compound in Nextbio analysis, and Tunicamycin exposure is identified as top three signatures in GeniE Network Analysis. Our case study suggests that whole transcriptome extrapolation of data from the S1500+ platform provides improved insight into biological mechanisms and functional outcomes.

2994 Expression of Copper Transport Protein-2 (CTR2) in the Blood-CSF Barrier: Effect of Lead Exposure *In Vitro*

D. Y. Du[1], L. Liu[2], and W. Zheng[2]. *[1]Park Tudor School, Indianapolis, IN; and [2]Purdue University, West Lafayette, IN.*

Copper (Cu) is an essential metal for living organisms; either deficiency or overload of Cu can cause cellular dysfunctions. Thus, the Cu homeostasis is tightly regulated by multiple copper transport proteins. Copper transport protein-2 (CTR2) has recently been suggested to regulate the function of copper transport protein 1 (CTR1) so to maintain the stable intracellular Cu level. However, the existence of CTR2 in the blood-cerebrospinal fluid (CSF) barrier (BCB) in brain choroid plexus, which regulates material movements between the blood and CSF, was virtually unknown. This study was designed to explore the existence of CTR2 in the BCB; furthermore, the effect of *in vitro* exposure to lead (Pb), a toxic metal abundantly accumulated in the choroid plexus, on the expression of CTR2 was investigated. Immortalized choroidal epithelial Z310 cells and freshly isolated mouse plexus tissues were used to identify the expression of CTR2. Both qPCR and confocal immunofluorescent data demonstrated the presence of CTR2 in Z310 cells as well as in plexus tissues; in Z310 cells, CTR2 appeared to be localized in cytoplasm and stored in vesicles, while in plexus tissues, CTR2 signals were primarily present in the cytosol between nuclei and brush boarder facing the CSF. When Z310 cells were incubated in a Pb-containing medium at 2, 5, and 10 μM for 24 hrs, the levels of CTR2 expression, as quantified by immunofluorescence, were reduced by 35.50%, 37.14%, and 52.10%, respectively, as compared to controls ($p<0.05$, $n=4$). The confocal data also revealed that incubation of plexus tissues in a Pb-containing artificial-CSF significantly reduced the fluorescent signals associated with CTR2. Moreover, CTR2 signals in Pb-treated plexus tissues appeared to be concentrated in areas beneath the epithelial microvilli, suggesting an intracellular trafficking of CTR2 towards the CSF-facing epithelial surface. These observations provide the first-hand evidence that CTR2 exists in the blood-CSF barrier, and Pb exposure not only reduces the expression of CTR2, but also causes it to translocate toward the epithelial microvilli. Mechanistic studies to investigate the function of CTR2, in coordination with CTR1, in regulating Cu transport by the BCB, and the consequence of Pb exposure are currently in progress. *Supported in part by NIH/NIEHS R01 ES027078.*

2995 Neuroprotection by Luteolin and Gallic Acid against Cobalt Chloride-Induced Behavioral, Morphological, and Neurochemical Alterations in Wistar Rats

O. E. Adebiyi, and A. S. Akinrinde. *University of Ibadan, Ibadan, Nigeria.*

Cobalt (Co) intoxication arising from occupational exposures and ion release from metal implants has been associated with neurological alterations such as cognitive decline, incoordination and depression. The present study evaluated the mechanisms of neuroprotection exerted by Luteolin (Lut; 100 mg/kg) and Gallic acid (GA; 120 mg/kg) in Wistar rats exposed to cobalt chloride (CoCl2) at 150 mg/kg for 7 consecutive days. Results indicate that CoCl2 induced neuro-behavioural deficits specifically by decreasing exploratory activities of CoCl2-exposed rats, increased anxiety, as well as significant reduction in hanging latency. Co-treatment with Lut or GA,however, restored these parameters to values near those of normal controls. Moreover, Lut and GA prevented CoCl2-induced increases in hydrogen peroxide (H_2O_2), malondialdehyde (MDA) and nitric oxide (NO) in the brain, while also restoring the activities of acetylcholinesterase, glutathione-S-transferase (GST) and superoxide dismutase (SOD). In addition, Lut and GA produced significant reversal of CoCl2-induced elevation in levels of serum Interleukin 1 beta (IL-1β) and Tumor necrosis factor (TNFα). Meanwhile, immunohistochemistry revealed increased astrocytic expression of glial fibrillary acidic protein (GFAP), with intense calbindin (CB) D-28k staining and pronounced dendrites in the Purkinje cells. In contrast, the CoCl2 group was characterized by decreased number of neurons expressing CB and dendritic loss. Taken together, mechanisms of luteolin and/or gallic acid protection against Co toxicity involved restoration of Ca2+ homeostasis, acetylcholinesterase and antioxidant enzyme activities, as well as inhibition of lipid peroxidation in the brain.

2996 Effects of Methylmercury on Excitatory Amino Acid Transporters Expression in Cortical Astrocytes and Motor Neuron-Like Cells

K. M. Santiago Colón[1], G. M. Rivera Lopéz[2], and W. D. Atchison[2]. *[1]Universidad de Puerto Rico Cayey, Cayey, PR; and [2]Michigan State University, East Lansing, MI.*

Excitatory amino acid transporters (EAATs) have the important role of removing extracellular glutamate from the synaptic cleft. They have been characterized as critical in protecting neurons against glutamate-induced excitotoxicity. Methylmercury (MeHg) is an environmental neurotoxicant identified as excitotoxic which induces excessive release of glutamate. MeHg induces EAAT impairment by reactive oxygen species generation. Consequently, this disrupts glutamate homeostasis, glutathione synthesis (an important antioxidant for toxicity) and eventually induces excitotoxic neuron death. EAAT1 and EAAT2 are primarily expressed in astrocytes and EAAT3 in neurons. Because of the established importance of EAATs, we hypothesized that MeHg exposure could exacerbate expression of EAATs in both astrocytes and motor neuron-like cells (NSC-34). To assess the effects of MeHg in the transporters, cortical astrocytes, extracted from mice, and NSC-34 cells were cultured and exposed to 1, 2 and 5μM MeHg for 3 hours. The capacity of EAAT expression after MeHg exposure, was examined using immunocytochemistry and the images were analyzed by the mean fluorescence intensity to quantify the expression of the proteins. We observed that MeHg induced EAAT3 overexpression which increased with the increases in the concentration of exposure. In addition, cortical astrocyte EAAT1 and EAAT2 expression were not affected by MeHg after 3 hours of exposure. Modulating EAATs function may be a therapeutic target to attenuate excitotoxicity-induced pathogenesis in diseases such as Amyotrophic Lateral Sclerosis. *This research was supported by NIH grant R01ES024064, and R25NS090989- NINDS ENDURE Program, and the Bridge to the Ph.D. in Neuroscience Program.*

2997 Methylmercury-Induced Excitotoxcity in Forebrain Astrocytes and Pharmacological Mediation by ω-conotoxin GVIA and Nimodipine

M. Flores[1], A. Miller-Maldonado[2], G. M. Rivera-Lopez[3], and W. D. Atchison[3]. *[1]St. Mary's University, San Antonio, TX; [2]Universidad de Puerto Rico Cayey, Cayey, PR; and [3]Michigan State University, East Lansing, MI.*

Methylmercury (MeHg) is a contemporary neurotoxicant that affects both neurons and supporting glial cells including astrocytes. In the Amyotrophic Lateral Sclerosis (ALS) humanized transgenic mouse model, which over-expresses the human superoxide dismutase1 mutant- SOD1 G93A, MeHg ex-

posure hastened the onset of ALS-like phenotype. On a cellular level, MeHg toxicity causes a spontaneous release of glutamate, which then increases intracellular [Ca2+], damages mitochondria, causes reactive oxygen species formation, and ultimately leads to cell death. Calcium channel blockers have been shown to delay the onset of MeHg-induced increases in intracellular [Ca2+], and reduce the incidence of cytotoxicity induced by MeHg. In this study, we used astrocytes derived from SOD1G93A mice to test for the contribution of voltage-gated Ca2+ channels to cytotoxicity induced by MeHg. In particular, antagonists of the N-type (Cav2.2) and L-type (Cav1.3) channels were tested, as these types of Ca2+ channels have been reported to exist in astrocytes. In effort to mediate MeHg-induced cytotoxicity, calcium channel blockers, ω-conotoxin GVIA (which blocks N-type) and nimodipine, (which blocks L-type channels) were used as a pretreatment of isolated astrocytes from SOD1 mice which were then exposed to 2μM and 5μM MeHg. A calcein viability assay and fluorescence microscopy was performed to analyze the extent of protection that the calcium channel blockers provided to the astrocytes. Viability percentages were calculated from average cell counts from control and experimental assays. It was hypothesized that treatments of ω-conotoxin and nimodipine would reduce extracellular Ca 2+ from entering the cell. Results concluded that the calcium channel blockers increased cell viability with the lower concentrations of MeHg (1, 2μM), but lost effectiveness at 5μM MeHg. Thus voltage-gated Ca2+ channels contribute to entry of Ca2+ inducing cytotoxicity in SOD1 mouse-derived astrocytes. *This research was supported by NIH grant R01ES024064, and R25NS090989- ENDURE Program, as well as an SOT Summer Toxicology Internship to MF.*

PS 2998 Neurotoxic Effect of Manganese and Vanadium Co-exposure in Animal Models of Parkinson's Disease

A. Bargues Carot, N. Kondru, M. Haller, H. Jin, V. Anantharam, A. Kanthasamy, and A. G. Kanthasamy. *Iowa State University, Ames, IA.*

Chronic environmental exposure to a mixture of two or more heavy metals, often from occupational or industrial sources, has been implicated in Parkinson's disease (PD). Vanadium pentoxide (V_2O_5) typically presents along with manganese (Mn), especially in welding rods. The neurotoxic consequences of chronic Mn/V_2O_5 co-exposure on key pathological features of PD such as α-synuclein protein aggregation remains to be investigated. In this study, we examined the neurotoxic effects of Mn/V_2O_5 co-exposure in a transgenic animal model of PD. Wild-type mice (naïve C57 black strain) and transgenic mice expressing A53T alpha-synuclein were intranasally co-exposed to 100 μg $MnCl_2$ and 75 μg V_2O_5 five times a week, representing a 5-day work week of occupational exposure, for up to three months, and all mice were subjected to a battery of behavioral tests at monthly intervals. Exploratory locomotor activity in an open-field test declined significantly in Mn/V_2O_5-treated A53T male mice and female mice, but not in Mn/V_2O_5-treated C57 black mice. Motor coordination during forced locomotor activity, in contrast, was not significantly affected by Mn/V_2O_5 treatments in either A53T or C57 black mice. Effects of chronic intranasal co-exposure to Mn/V_2O_5 on olfactory discrimination of social cues were significant starting the second-month post-treatment. Mn/V_2O_5-treated A53T mice and C57 male mice exhibited olfactory deficits while C57 female mice did not. Treatment with Mn/V_2O_5 did not induce depression-like behavior in any group as measured by tail suspension or forced swim tests. Taken together, our results suggest that co-exposure to Mn and V_2O_5 can adversely affect α-synuclein-overexpressing A53T mutant mice when compared to naïve C57 black mice. These results highlight a possible role of neurotoxic metal mixtures in environmentally linked Parkinsonism *(DOD W81XWH1810106/CDMRP, NIH R01 ES026892, and Eugene and Linda Lloyd Endowed Chair).*

PS 2999 Altered Prefrontal-Hippocampal Network Activity following Chronic Early-Life Lead Exposure in Rats

T. A. Allen, N. W. Schultheiss, D. R. Brooks, J. L. McGlothan, and T. R. Guilarte. *Florida International University, Miami, FL.*

Childhood lead exposure affects millions of people and causes irreversible mental health problems that persist in adulthood. In particular, chronic early-life lead exposure (CELLE) is a major risk factor in schizophrenia. Likewise, CELLE models in rats show many of the behavioral, neurochemical, and neuropathological endpoints of schizophrenia. Importantly, CELLE animals show impaired pre-pulse inhibition (PPI) and reduced parvalbumin-positive GABAergic interneurons in the prefrontal cortex and hippocampus. However, the consequences of CELLE on prefrontal-hippocampal network states have not been examined. Here, we recorded local-field potentials in the dorsal hippocampus and the medial prefrontal cortex as rats freely explored or retrieved sporadically-delivered rewards in an open-field environment. In CELLE rats, we found altered synchronization in the delta (1-4Hz), theta (5-11Hz), and high gamma (65-120Hz) bands, which was related to behavior. These results parallel what is reported in other rodent models of schizophrenia and may correspond to irregular EEG patterns found in schizophrenic patients. We also observed sporadic episodes of strong nonconvulsive absence seizures in CELLE rats, which were eliminated with the administration of ethosuximide (ETX, 50-200 mg/kg), a first-choice drug for absence epilepsy. Together, our findings suggest that CELLE causes aberrant long-range interactions and excitatory-inhibitory imbalances within local circuits of the prefrontal-hippocampal system. Understanding the network mechanisms at play in CELLE will lay the foundation for developing diagnostic tools and therapeutic strategies in childhood lead exposure.

PS 3001 Oxidative Stress, Trace, and Toxic Metal Levels in Alzheimer's Disease in an African Population

I. O. Omotosho, M. Ngwube, and J. Abdulmalik. *University of Ibadan, Ibadan, Nigeria.*

Alzheimer's disease (AD) is an age-related neurodegenerative disease characterized by loss of memory resulting from neurodegenerative disorders, this has been attributed to oxidative stress and accumulation of Amyloid (Aβ) protein in the brain. Environmental and genetic alterations have been implicated as the pathogenesis of the disease. This work investigated levels of selected trace (Iron, Zinc and Copper) and toxic (Cadmium and Lead) metals in AD patients. In this case-control study, a total of 38 participants aged ≥60years consisting of 18 clinically diagnosed with AD and 20 apparently healthy age-matched adults were recruited from the University College Hospital Ibadan Geriatric Centre. Semi-structured questionnaires were used to obtain demographic information, clinical history, lifestyle and dietary patterns from participants. Plasma levels of iron, copper, zinc and blood levels of lead and cadmium were analyzed using Atomic Absorption Spectrophotometry (AAS). Plasma levels of malondialdehyde (MDA), total antioxidant capacity (TAC), hydrogen peroxide (H_2O_2), and total plasma peroxide (TPP) were determined spectrophotometrically, while oxidative stress index (OSI) and copper to zinc ratio (Cu:Zn) were calculated. Mean plasma level of zinc was significantly lower in the cases (86.04±11.07μg/dl) compared to controls (108.80±12.47μg/dl), while blood lead (13.85±2.96μg/dl, 8.32±2.10μg/dl) and cadmium (1.34±0.71μg/L, 0.71±0.14μg/L) levels were significantly higher in cases than in controls respectively. Although Fe and Cu levels were similar in cases and controls, Cu:Zn ratio was significantly elevated in cases compared to controls (p=0.000). Though other OS markers were not significantly different in both groups, TPP was significantly higher in cases (64.96±7.20 μmol/H_2O_2 vs. 55.41±2.38μmol/H_2O_2) while MDA correlated inversely with TAC in cases (r= -0.477, p=0.045). The low plasma Zn coupled with high blood Pb and Cd levels may precipitate the elevated TPP and Cu:Zn ratio in cases. The reduced metallothionine defense of the system as indicated by the elevated Cu:Zn ratio in cases may also exacerbate this problem. Increased oxidative stress influenced by the high toxic metal level in cases may be participatory in the progression of AD.

PS 3002 Toxicogenomics for Understanding the Evolutionary Neurotoxicology of Manganese

R. B. Hernández[1], C. Suñol[2], B. Michalke[3], and A. Golshani[4]. *[1]Universidade Federal de São Paulo, Diadema, Brazil; [2]Institut d'Investigacions Biomèdiques de Barcelona, Barcelona, Spain; [3]Helmholtz Zentrum München, Neuherberg, Germany; and [4]Carleton University, Ottawa, ON, Canada.* Sponsor: R. Hernández, EUROTOX

Manganese (Mn) is the twelfth most abundant element in the earth's crust. Mn is an essential trace mineral in nutrition that can be neurotoxic and neurodegenerative via environmental and/or nutritional acute and chronic exposure, especially during stages of development. Studies from our group, applying "omics" approaches, have revealed that environmentally relevant concentrations of Mn^{2+} (0.001-1.5 mM) disrupt metal homeostasis (K, Ca, Fe and Cu); protein metabolism, including translation, post-translation, and protein degradation as well as associated pathways such as those involved in energetics, cell signaling, cell cycle and neurotransmitter metabolism, in a suite of organisms, from yeast to human. Notably, these events during or after protein biosynthesis, have been associated with neurodegenerative disorders such as Alzheimer's disease, Amyotrophic Lateral Sclerosis, Parkinson's disease, and Huntington's disease. These findings suggest that disruption of protein biosynthesis is a key mechanism for Mn-induced neurotoxicity and neurodegeneration, but sometimes involving different genes or proteins. However, it is well known that from yeast to human, the *protein* translation is a complex, highly conserved and coordinated process mediated by the ribosome and some cases affected by metalloenzymes. Hence, for under-

standing eco-evolutionary dynamics, under the effects of manganese, the ionome-wide data and protein biosynthesis needs to be considered before drawing comparisons to humans.

3003 Genetic and Conditional Stimulation of Adult Neurogenesis Rescues Mice from Cadmium-Induced Impairments of Hippocampus-Dependent Learning and Memory

H. Wang, and Z. Xia. *University of Washington, Seattle, WA.*

Cadmium (Cd) is a heavy metal that has been recognized as one of the most toxic environmental pollutants. Because of its long half-life, Cd accumulates in human bodies and induces adverse effects in various organs. Cd is suggested to be a neurotoxicant. However, the full spectrum of its neurotoxicity is not fully understood. Our previous studies have found that Cd exposure can impair hippocampus-dependent memory, as well as adult hippocampal neurogenesis in mice. In order to establish a causal relationship between Cd-induced impairments of adult hippocampal neurogenesis and hippocampus-dependent memory, we conducted a rescue experiment to see if enhancing adult neurogenesis could rescue mice from Cd-induced decline of cognition. In this study, a group of a specific transgenic mouse (caMEK5) which allows inducible and conditional activation of adult neurogenesis upon tamoxifen treatment was exposed to 0.6 mg/L Cd through drinking water for 38 weeks. Behavior tests were conducted during the exposure period to investigate the effect of Cd on hippocampus-dependent learning and memory in mice. At 17 weeks into Cd exposure, impaired hippocampus-dependent spatial working memory was found in Cd-treated mice and then tamoxifen was administrated to increase adult hippocampal neurogenesis. At 6 weeks after tamoxifen treatment (31 weeks into Cd exposure), the spatial working memory in Cd-tamoxifen treated mice were recovered while the Cd-vehicle group still exhibited impaired spatial memory. In addition, after 38 weeks of Cd exposure, the hippocampus-dependent contextual memory was also impaired in Cd-vehicle treated mice, but not in other groups. We further examined the condition of adult hippocampal neurogenesis in caMEK5 mice after Cd and tamoxifen treatment by using immunostaining. There was a significant decrease in the total number of $BrdU^+$ cells and $BrdU^+$ $NeuN^+$ cells in the dentate gyrus of the hippocampus in the Cd-vehicle group, suggesting that Cd exposure impairs adult hippocampal neurogenesis in caMEK5 mice. However, we did not discover the similar effects of Cd in the Cd-tamoxifen group, which confirms that tamoxifen treatment recovered the impaired adult hippocampal neurogenesis. In addition, we found Cd exposure increased the brain Cd concentrations in caMEK5 mice. Overall, our study suggests that inhibition of adult hippocampal neurogenesis plays an important role in Cd-induced impairments of hippocampus-dependent learning and memory.

3004 Early-Life Lead (Pb^{2+}) Exposure Induces Transgenerational Effects on Zebrafish Brain Transcriptome

D. N. Meyer[1], E. J. Crofts[1], C. Akemann[1], K. Gurdziel[1], D. Weber[2], and T. R. Baker[1]. *[1]Wayne State University, Detroit, MI; and [2]University of Wisconsin—Milwaukee, Milwaukee, WI.*

Lead (Pb^{2+}) is a major public health hazard for urban children, with profound and well-characterized developmental and behavioral implications across the lifespan. The ability of early Pb^{2+} exposure to induce epigenetic changes is also well-established, which suggests that Pb^{2+}-induced neurobehavioral deficits may also be heritable across generations. Understanding the long-term and multigenerational repercussions of lead exposure is crucial for clarifying both the genotypic alterations behind these behavioral outcomes and the potential mechanism of heritability. To study this, zebrafish (*Danio rerio*) embryos (<2 hours post fertilization; EK strain) were exposed for 24 hours to waterborne Pb^{2+} at a concentration of 10 μM. The exposed F_0 generation was raised to adulthood and spawned to produce the F_1 generation, which was subsequently spawned to produce the F_2 generation. Previous avoidance conditioning studies determined that a 10 μM Pb^{2+} dose resulted in learning impairments persisting through the F_2 generation. RNA was extracted from control- and 10 μM Pb^{2+}-lineage F_2 brains, (n=10 for each group), sequenced, and transcript expression was quantified utilizing Quant-Seq. 648 genes were differentially expressed in the brains of F_2 lead-lineage fish versus F_2 control-lineage fish. Pathway analysis revealed altered genes in processes including nervous system development and function, neurotransmission, learning, conditioning, memory, endocrine system function, hormone regulation, and epigenetic modification, all of which are implicated in lead-induced neurobehavioral deficits and/or their inheritance. These data will inform future investigations to elucidate the mechanism of adult-onset and transgenerational health effects of developmental lead exposure.

3005 Lead Aggravates the Diabetic-Induced Neurodegeneration and Neuroinflammation and Neuro-Protecting Effect of *C. carandas*

A. Kumar, and B. Sharma. *University of Allahabad, Allahabad, India.*

Diabetes, an unresolved metabolic disorder and lead contamination are prevalent problems in the contemporary society. Previously, reported suggest that either diabetes or lead exposure resulted in neurodegeneration in male rats. The aim of this study was to evaluate whether diabetic rats exposed to lead demonstrate a higher degree of neurotoxicity, inflammation and neurodegeneration when compared with lead-exposed control rats. And neuroprotective, anti-inflammatory and antioxidant activity of *C. carandas* constituents were also evaluated. Diabetes was induced by injecting single dose of streptozotocin (40 mg/kg body weight). Control and diabetic rats were exposed to lead through oral gavage for a period of 21 days and assessed for neuro-inflammatory markers and oxidative end points. Significant reduction in brain antioxidant enzyme activity, membrane proteins and ion channels including Acetylcholinesterase, Na^+-K^+ ATPase levels and glutathione levels were observed in diabetic rats with an elevation in levels of superoxide anions, hydrogen peroxides, lipid peroxidation. Mild histopathological malformations were observed in the brain of the diabetic rats. TNF-α, IL-6 transcripts and nuclear factor-κB expression were increased in the diabetic rat brain. Similar oxidative and neurotoxicity was observed in lead-exposed control rats. Further, lead exposed diabetic rats showed additional deterioration in hippocampal and inflammation end points and noteworthy elevation in oxidative toxicity suggesting that treatment with lead exacerbates neurotoxicity in streptozotocin-induced diabetic rats. The ameliorative efficacy of aqueous extract of C. Carandas was analysed in diabetic rat exposed to lead. Study shows the significant neuroprotective and anti-inflammatory activity of extract.

3006 Impact of Manganese Exposure on Mood in Welders

K. M. Ahmed, M. Servati, H. Monsivais, and U. Dydak. *Purdue University, West Lafayette, IN.*

Manganese (Mn) is an essential trace element found in many biological tissues. Yet, chronic exposure to Mn is neurotoxic and can lead to cognitive, psychiatric and motor deficits, with mood disorders being reported as one of the earliest symptoms in humans exposed to Mn. The goal of this study was to assess whether mood changes in welders exposed to Mn were associated with Mn exposure or neuroimaging markers, such as elevated brain Mn levels and thalamic γ-aminobutyric acid (GABA) levels, assessed by magnetic resonance imaging (MRI) and spectroscopy (MRS). Forty-five male welders were recruited from a local manufacturer. Each subject underwent an MRI/MRS exam to assess brain Mn deposition, as measured by the R1 relaxation rate, and thalamic GABA levels. The Brief Symptom Inventory (BSI) was administered to assess nine domains of mood, as well as a Global Severity Index (GSI). Individual exposure to Mn was assessed using personal air sampling and a work history questionnaire. Spearman Rank Tests were performed to test for associations between raw mood scores and R1 values, thalamic GABA levels and Mn exposure in the welders. Furthermore, the standardized t-scores for the mood values were compared against normative standards. Comparing the BSI t-score of the 9 mood categories including GSI, a summary score indicating the subject's distress level, against the male adult non-patient norm disclosed that 49% of the welders were classified as "clinical cases". The subdomains of somatization (SOM), obsessive-compulsive (OC) behavior and interpersonal sensitivity (IS) were significantly associated with elevated past year Mn exposure (SOM, IS: rho >=0.3, p< 0.05) and/or toenail Mn levels (SOM, OC: rho ≥ 0.3, p<0.05). Thalamic GABA levels were significantly associated with depression scores (rho=-0.44, p=0.02), and Mn levels of the Caudate Nucleus were found to be inversely associated with 5 of the 9 mood domains, as well as the overall GSI (all rho < -0.3, p< 0.05). In agreement with previous literature we report increased changes in mood and associations with increased Mn exposure in a typical occupational welding setting in the US with Mn exposure levels around 0.1 mg/m3. The association of depression scores with thalamic GABA is in line with reports of thalamic lesions being implicated with depression. However, the findings of an inverse relation to brain Mn levels will need to be investigated further. Factors, such as alcohol consumption and shift work will need to be considered as confounders.

3007 Methylmercury Exposure *In Vivo*-Induced Differential Effects on AMPA-Current in Brainstem Hypoglossal Motorneurons from Mice Expressing Wild-Type or the Mutant Human Superoxide Dismutase 1 (hSOD1) G93A Genes

Y. Yuan, J. M. Bailey, J. B. Spitsbergen, and W. D. Atchison. *Michigan State University, East Lansing, MI.*

The exact causes of Amyotrophic lateral sclerosis (ALS), a progressive and fatal neurological disorder due to loss of upper and/or lower motoneurons (MNs), remain elusive. Gene-environment interactions are believed to be an important factor in the development of ALS. We previously showed that *in vivo* exposure of mice overexpressing the human superoxide dismutase 1 (hSOD1) gene mutation (hSOD1G93A; G93A), a mouse model for ALS, to environmental neurotoxicant methylmercury (MeHg) accelerated the onset of ALS-like phenotype. We also showed that mouse genotypes appear to affect the sensitivity of brainstem hypoglossal MNs to the MeHg-induced acute and chronic effects on neuronal excitability, synaptic transmission and AMPA receptor (AMPAR)-mediated currents *in vitro* and *in vivo*. Here we examined the time-courses of effects of MeHg on AMPAR-mediated currents in hypoglossal MNs in brainstem slices prepared from G93A, hSOD1wild-type (SOD1hWT) and WT mice following *in vivo* exposure to MeHg for defined time periods. Mice were exposed daily to 3 ppm MeHg via drinking water beginning at postnatal day 28 (PND28) and continued until PND47, 64 or 84, then acute brainstem slices were prepared and AMPAR-mediated currents were examined using whole cell patch-clamp recording technique. Brainstem slices of untreated littermates were prepared at the same time points to serve as control. AMPA-current was evoked at a holding membrane potential of -50 mV. MeHg exposure had no significant effect on AMPA-current in slices from SOD1hWT mice during any of those exposure time periods. MeHg also did not cause any significant effect on AMPA-current in G93A and WT hypoglossal MNs at PND47. However, at PND64 and 84, MeHg significantly increased the AMPA-current in hypoglossal MNs from G93A mice ($p<0.01$), whereas it significantly decreased the AMAP-current in hypoglossal MNs from WT mice ($P<0.05$). Therefore, MeHg exposure *in vivo* caused differential effects on AMPA-current in hypoglossal MNs from mice with different genetic backgrounds. MeHg appears to preferentially stimulate the AMPAR-mediated currents in G93A hypoglossal MNs in an exposure time-dependent manner, which may contribute to the AMPAR-mediated MN excitotoxicity, thereby facilitating development of ALS-like phenotype. *Supported by NIEHS/NIH grant ES024064.*

3008 BTBD9, a Restless Leg Syndrome-Associated Protein, Regulates Manganese-Induced Toxicity in *Caenorhabditis elegans*

P. Chen[1], F. Zheng[1], J. Bornhorst[2], and M. Aschner[1]. *[1]Albert Einstein College of Medicine, Bronx, NY; and [2]Universität Potsdam, Nuthetal, Germany.*

Restless Legs Syndrome (RLS) is a common neurological disorder seen in ~10% of the US population. RLS-associated sleep deprivation can seriously impact life quality, causing anxiety, depression and attention-deficit/hyperactivity disorder (ADHD) symptoms. Moreover, RLS may portend hypertension, heart disease and stroke. RLS exhibits both familial and non-familiar (idiopathic) forms, with ~60% of cases having a family history of the disease. BTBD9 is one of the genetic risk factors, associated with decreased serum iron (Fe) level. Interestingly, lymphocytes from RLS patients have an altered Fe management protein profile, which also regulates manganese (Mn) homeostasis. This raises the question as to whether the symptoms inherent to RLS patients are the result of Fe deficiency or elevated concentrations of another metal that opportunistically increases when Fe levels are low. Here we present novel data that BTBD9 functions to regulate Mn homeostasis in *Caenorhabditis elegans* (*C. elegans*). A blast search identified *hpo-9* as the BTBD9 homolog in *C. elegans*, with ~75% sequence similarity. A mutant strain tm3719 (*hpo-9*$^{-/-}$) carrying 761 bp deletion of *hpo-9* was obtained. We found that *hpo-9*$^{-/-}$ worms were more sensitive to Mn exposure. Upon Mn treatment, *hpo-9*$^{-/-}$ worms showed a significantly lower survival rate and more severe DAergic neurodegeneration compared with wild type worms. Interestingly, no difference was seen when worms were exposed to Fe. However, a low level of Fe (0.1 µM) pretreatment was able to protect Mn-induced lethality. To better characterize HPO-9 protein, a transcriptional fusion construct was created with green fluorescent protein (GFP) driven under *hpo-9* promoter. We found that GFP was present high in the head and pharynx and low in the intestine and seam cells. Using a confocal microscopy, we found that *hpo-9* was expressed in dopaminergic neurons, indicating that HPO-9 might play a role in dopamine signaling. To confirm that, we over-expressed HPO-9 in DAergic neurons of *hpo-9*$^{-/-}$ worms and found that it rescued Mn-induced DAergic neurodegeneration. Together, our results suggest a novel role for *hpo-9*/BTBD9 in regulating Mn homeostasis and possibly dopamine signaling in *C. elegans*. *Supported by NIEHS ES010563.*

3009 Modulating Effects of Resveratrol Supplementation on As_2O_3-Induced Neurotoxicity in Mice Hippocampus

K. Mehta, B. Kaur, K. K. Pandey, and P. Dhar. *AIIMS, New Delhi, India.*

The ubiquitous distribution of arsenic makes it an environmental contaminant of global concern. Reported literature, identifies oxidative stress as key factor underlying inorganic arsenic (*iAs*) induced toxicity. Hence, the need of the hour is to identify safe therapeutic approaches for amelioration of *iAs* induced toxicity. The aim of the present study was to determine the ameliorative potential of resveratrol (antioxidant) on cognitive functions, oxidative stress, morphology and apoptosis in hippocampus (CA1) of female mice following arsenic trioxide (As_2O_3) exposure. Healthy adult female mice were randomly divided as control (normal; vehicle) and experimental groups receiving As_2O_3 alone (2, 4 mg/kg bw) or along with Resveratrol (40 mg/kg bw) by oral route for 45 days. The behavioral study (OFT, EPM and MWM) was carried out from Day 33-45. Perfusion fixed hippocampal tissues were processed for Cresyl violet and TUNEL staining whereas fresh hippocampi were subjected to biochemical estimation of reduce glutathione (GSH). As_2O_3 alone exposed animals showed dose-dependent enhanced anxiety levels and impairment of cognitive functions (learning and memory deficits) when subjected to OFT, EPM and MWM testing. Hippocampal GSH levels were found to be significantly down-regulated in As_2O_3 alone treated animals, thereby suggestive of As_2O_3-induced oxidative stress in these animals. Morphometric observations of Hippocampus (CA1) of As_2O_3 exposed group showed significant reduction in thickness of Stratum Pyramidale (SP), decrease in density and area of Pyramidal neurons. TUNEL study revealed intense dark brown staining of nuclei of pyramidal cells was observed in SP (CA1) of As_2O_3 alone treated animals. Co-treatment of resveratrol with As_2O_3 was helpful in restoration of these changes to a substantial extent. Our observations support modulating effect of Resveratrol against As_2O_3-induced cognitive dysfunctions, altered morphology, apoptosis and oxidative stress in female mice hippocampus.

3010 Nrf2 Knockout Causes Differential Effects of MeHg on Keap1 and Cystine/Glutamate Antiporter mRNA Expression in Mouse Primary Spinal Cord Astrocytes

D. Wiwatratana[1,2], G. Berrios-Vazquez[1], and W. D. Atchison[1]. *[1]Michigan State University, East Lansing, MI; and [2]King Mongkut's University of Technology Thonburi, Bangkok, Thailand.*

Methylmercury (MeHg)-induced neuronal degeneration involves multiple pathways which are to some extent cell-type dependent. Dysregulation of intracellular calcium homeostasis and glutamate transmission are common targets. Redox homeostasis is also involved; it is regulated by the Nrf2-ARE pathway. Nrf2-ARE pathway activation increases the expression of antioxidant genes such as glutathione (GSH) synthetase, GSH peroxidase (Gpx), the cystine/glutamate antiporter (system Xc-) and multidrug-resistant associated protein (Mrp). Astrocytes are also a target for MeHg. Astrocytic Nrf2-ARE pathway is more active compared to neurons. Thus, neurons require the antioxidants supplied by astrocytes, particularly during oxidative stress, and dysregulation of the Nrf2-ARE pathway in astrocytes could be detrimental to neurons. Perturbation of the Nrf2-ARE pathway has been reported in MeHg-induced toxicity in cortical and cerebellar astrocytes as well as neurons, but not the spinal cord. In this study, spinal cord astrocytes (SCA) derived from wild type C57BL6J (WT) and Nrf2 knockout (Nrf2 KO) mice were compared for their susceptibility to MeHg toxicity. Examination of viability showed that the Nrf2 KO-derived SCA were more susceptible to MeHg compared to WT-derived SCA. Exposure of SCAs from these two genotypes for 1h to 5µM MeHg, a concentration that was previously reported to decrease SCA viability in WT mice, significantly reduced Nrf2 KO SCA cell viability (60% of the vehicle) when compared to WT SCA. Following vehicle treatment, several genes involving the glutathione synthesis (*Gclc*) and redox status (*Gpx1* and *GPx4*) were reduced in Nrf2 KO SCA compared to WT SCA. Conversely, expression of *Keap1*, *Abcc1* (Mrp1) and *Slc7a11* (system Xc-) mRNA were all significantly higher than in WT SCA. Increase expression of *Abcc1* and *Slc7a11* could reflect compensatory pathway(s) in the maintenance of the redox homeostasis in Nrf2 KO mice. MeHg treatment for 18h reduced the majority of these antioxidant genes in both WT and Nrf2 KO derived SCA. MeHg slightly affected the expression of *Keap1* in WT SCA, but significantly reduced it in Nrf2 KO SCA. After 18h MeHg treatment, *Slc7a11* mRNA was greatly increased in WT SCA (5-fold induction), but it appeared to be reduced in Nrf2 KO SCA. The differential

effects of MeHg on the expression of *Keap1* and *Slc7a*11 in WT and Nrf2 KO are consistent with a gene X environmental effect of MeHg on SCA. *This research was supported by NIH grant R01ES024064, and R25NS090989- ENDURE Program.*

3011 The Impact of Iron Deficiency on Lead Toxicity in the Brain

J. Cubello, A. Greminger, and M. Mayer-Proschel. *University of Rochester School of Medicine and Dentistry, Rochester, NY.*

Iron deficiency (ID) is the most prevalent micronutrient deficiency in the world. Pregnant women are particularly susceptible due to enhanced iron (Fe) requirements needed for fetal development. Lead (Pb), unlike Fe, is a nonessential divalent metal and still represents a ubiquitous environmental toxin that has been linked to many neurodevelopmental impairments. The neurodevelopmental impacts of ID and Pb exposure have been studied mainly individually with minimal research considering co-exposure. This is surprising considering that ID and Pb both impact areas of lower socioeconomic status and have been associated with similar neurodevelopmental and behavioral deficits. Preliminary data from our laboratory using a dietary model of ID combined with low-level lifelong Pb exposure revealed that offspring of ID rat dams had significantly enhanced brain Pb accumulation compared to iron normal rat dam offspring under identical Pb exposures. Despite previous reports demonstrating positive correlations between brain Pb concentration and behavioral deficits, enhanced Pb accumulation in ID offspring was neither associated with exacerbated functional impairments defined by analysis of the auditory brainstem response (ABR) nor was the behavioral phenotype statistically different compared to that of single-exposed ID or Pb animals. We did however, observe region-specific exacerbated expression of glial fibrillary acidic protein (GFAP), a marker of astrogliosis. Astrocytes may therefore serve a neuroprotective function in the presence of co-exposure contributing to subsequent offspring phenotype. In support of this, preliminary *in vitro* data demonstrated enhanced Pb accumulation in ID astrocytes compared to IN astrocytes using Inductively-Coupled Plasma Mass Spectrometry (ICP-MS). We hypothesize that astrocytic Pb sequestration under ID transiently protects surrounding neurons and oligodendrocytes from Pb-induced toxicity, but the long-term impacts of Pb loading on astrocytes could contribute to neurological consequences later in life. To test our hypothesis, we use *in vivo* and *in vitro* approaches combined with elemental analysis of Fe and Pb using ICP-MS to determine preferential Pb loading into astrocytes and its short- and long-term consequences on astrocytes themselves and survival and function of neurons and oligodendrocytes. *Supported by R01HD094563.*

3012 Regulation of Brain Manganese Homeostasis by SLC30A10

C. A. Taylor[1], S. Hutchens[1], T. Jursa[2], W. Shawlot[1], M. Aschner[3], D. R. Smith[2], and S. Mukhopadhyay[1]. *[1]University of Texas at Austin, Austin, TX; [2]University of California Santa Cruz, Santa Cruz, CA; and [3]Albert Einstein College of Medicine, Bronx, NY.*

Manganese (Mn) is an essential metal involved in various biological processes. However, overexposure to Mn is neurotoxic. In humans, loss-of-function mutations in the Mn efflux transporter, SLC30A10, result in an inherited form of Mn toxicity (Tuschl et al., 2012). Patients have increased Mn levels in the brain and liver and present with parkinsonian motor deficits. Mn preferentially builds up in the basal ganglia, specifically in the globus pallidus, and is associated with neuronal death in this region. To gain a better understanding of Mn neurotoxicity and subsequent motor deficits, our lab studies the role of SLC30A10 activity in regulating brain Mn. Our recent work revealed that activity of SLC30A10 in the liver and gastrointestinal tract regulates basal brain Mn levels by mediating Mn excretion. In contrast, activity in the brain reduces brain Mn levels during overexposure (Taylor et al., 2019). Here, we examine the role of SLC30A10 in the brain by using pan-neuronal/glial *Slc30a10* knockout mice, which lack SLC30A10 activity in neurons and glia (astrocytes and oligodendrocytes). Previous results showed Mn-treated knockouts have higher Mn levels in the basal ganglia and thalamus compared to Mn-treated controls. In the present study, we assess motor function of Mn- and vehicle-treated knockouts and controls using the open field test. Mn overexposure alone resulted in reduced locomotion in the open field. Loss of SLC30A10 function in the brain also resulted in reduced locomotion during normal conditions or following Mn overexposure. These results suggest SLC30A10 activity in the brain is critical in protecting against Mn-induced motor deficits. Ongoing work aims to determine the neuronal subtypes most important for the neuroprotective activity of SLC30A10. Results from these experiments provide critical insight into how SLC30A10 activity in the brain regulates brain Mn homeostasis and protects against Mn neurotoxicity and subsequent behavioral deficits.

3013 Lead Poisoning Impairs Thyroid Hormone-Dependent Changes in Brain Development in *Xenopus laevis* Tadpoles

L. I. Dahora, Z. Husain, C. Buenaventura, A. Robinson, H. M. Bailey, and C. K. Thompson. *Virginia Polytechnic Institute and State University, Blacksburg, VA.*

Lead (Pb) poisoning during early development is associated with behavioral deficits, including low IQ. While the specific mechanisms by which Pb affects brain development are still not fully understood, one hypothesis is that Pb may impair thyroid hormone (TH) signaling by dysregulation of TH distributor proteins (THDPs). To address this issue, we assessed the effects of Pb on TH-dependent cellular and molecular mechanisms of development, with focus on neural development, in *Xenopus laevis* tadpoles (stage 47, ~10 days post fertilization). We found that seven days treatment with Pb decreased expression of two critical THDPs. Pb decreased expression of transthyretin (TTR) in the liver in a dose-dependent manner and 1000 ppb Pb treatment decreased expression of lipocalin-like prostaglandin D_2 synthase (L-PTGDS) in the brain. To determine if Pb impairs TH-dependent mechanisms of development, we treated tadpoles with 1000 ppb Pb bath for 5 days and added one of three different concentrations of thyroxine (T_4) for the final two days of treatment. We found that Pb inhibited the ability of exogenous T_4 administration to initially increase body length compared to controls. Following fixation, we performed immunostaining for the proliferative marker phospho-histone 3 (pH3) on dissected brains and quantified the number of pH3+ cells as well as the volume of the forebrain, midbrain, and hindbrain. We found that Pb exposure impaired T_4-induced increase in neuronal proliferation and impaired T_4-induced changes in brain volume during development. Ongoing experiments will determine whether the effects of Pb on T_4-mediated changes in cell proliferation are likely due to changes in expression of TTR and L-PTGDS in the choroid plexus by using overexpression and knockdown of these genes using transfection of plasmid constructs or morpholinos, respectively. In addition, we are currently examining localization of Pb accumulation in the brain using µCT. The current results from these experiments suggest that Pb impairs TH-dependent mechanisms of brain development, and future results will address the degree to which this is mediated by impairment of THDP function.

3014 Thiol Antioxidant Barrier in Blood Is a Proper Biomarker of Individual Sensitivity for Methylmercury Neurotoxicity in Rats

M. Fujimura[1], F. Usuki[2], and T. Unoki[1]. *[1]National Institute for Minamata Disease, Minamata, Japan; and [2]Joint Research Center for Human Retrovirus Infection, Kagoshima, Japan.* Sponsor: A. Naganuma

The main target organ for methylmercury (MeHg) is the nervous system, and its irreversible neurological dysfunction remains an important issue. Recovering from this dysfunction is very difficult and requires proper biomarkers for individual susceptibility in order to predict and protect against MeHg neurotoxicity. However, a proper biomarker of MeHg neurotoxicity has not yet been established. Previous studies have demonstrated a critical role for oxidative stress in the pathogenesis of MeHg neurotoxicity. Because MeHg has high affinity for selenohydryl groups, sulfhydryl groups, and selenides, proteins with selenohydryl and sulfhydryl groups should play a critical role in mediating MeHg-induced oxidative stress. Plasma oxidative stress markers and selenoproteins were investigated in MeHg-intoxicated rats showing a specific clinical sign (hind limb crossing behavior) and neuropathological changes in cerebellum and spinal peripheral nerve after 4 weeks of MeHg exposure. The thiol antioxidant barrier (-SHp) level significantly decreased 2 weeks after MeHg exposure, which is an early stage at which no systemic oxidative stress, histopathological changes, or clinical sign were detected. In addition, each -SHp level 2 weeks after MeHg administration was significantly correlated with the subsequent neurological symptoms and neuropathological changes. On the other hand, a significant increase in blood oxidation level (d-ROM) and a decrease in selenoprotein P1, which is a selenium-containing protein in plasma, abundance were observed in 4 weeks after MeHg administrated rats. These results suggest that decreased capacity of -SHp can be a proper biomarker of ongoing MeHg neurotoxicity and the individual protective capacity against the MeHg body burden.

3015 Synergistic Toxic Effects and Mechanisms of Lead (Pb) and Disinfection By-Products (DBPs) in Drinking Water on Human Colon Epithelial Caco-2 Cell, Liver HepG2 Cell, and Nervous SH-SY5Y Cell

J. Liu[1], S. Pradhan[1], H. Lujan[1], C. M. Sayes[1], and V. K. Sharma[2]. *[1]Baylor University, Waco, TX; and [2]Texas A&M University, College Station, TX.*

Chlorine disinfection aimed at inactivating pathogens is an essential process in drinking water treatment plants. During disinfection, halogenated disinfection byproducts (DBPs) can be generated from the reactions of chlorine with natural organic matter and halide ions in the source water. Halogenated DBPs have been shown to induce chronic adverse effects on cells in culture and rodent models. A certain amount of disinfectant residue is maintained in the water distribution system to prevent the regrowth of microorganisms. Lead (Pb)-containing plumbing materials are widely present in water distribution pipelines in the US Disinfectant residues can react with the pipe materials and enable the release of lead (in the form of Pb^{2+}) into water. Lead is a heavy metal that primarily affects the peripheral and central nervous systems, kidneys, red blood cells, and calcium metabolism after ingestion. In this study, we measured the cytotoxicity of lead (Pb^{2+}) and halogenated DBPs on human cells separately as well as the synergistic cytotoxic effects of Pb^{2+} and DBPs co-exposures, and investigated the mechanisms of ATPase inhibition, ROS generation, calcium dysregulation, and SUMOylation of p53. The human cells selected included the colon epithelial Caco-2 cell, liver HepG2 cell, and nervous SH-SY5Y cell. Data was collected over a dose-response and time-response experimental design and compared to a series of controls. The results showed that the combined toxic effect of lead and each DBP on the cell cultures were both dose and time dependent. Our data suggest that lead affects the formation of DBPs during disinfection (in the water distribution pipelines) and the overall quality of drinking water.

3016 Neuroprotective Effect of N-Acetylcysteine on Mouse Motor-Neuron-Like Cells in Methylmercury-Induced Toxicity

N. M. Camacho-Fontánez[1], D. Wiwatratana[2], and W. D. Atchison[2]. *[1]Universidad Ana G. Méndez Gurabo, Gurabo, PR; and [2]Michigan State University, East Lansing, MI.*

Methylmercury (MeHg), causes neurodegeneration by mechanisms including oxidative stress and excitotoxicity. MeHg induced overproduction of reactive oxygen species (ROS) is partly due to reduction of glutathione (GSH). Both ROS and MeHg activate the nuclear factor erythroid-derived 2-like 2 (Nrf2) pathway. MeHg also induces glutamate release and causes excitotoxicity. As N-acetylcysteine (NAC) has antioxidant qualities and is a precursor for GSH synthesis, we tested its neuroprotective effects on motor neuron-like cells (NSC34) in MeHg-induced toxicity. Cells were treated for 2h with 0.01, 0.1 or 1mM NAC before exposure to 5µM MeHg. Cell viability was measured every 3h for 36h of MeHg exposure. NAC caused a concentration-dependent protective effect against MeHg-induced cell death. At 1mM, NAC protected NSC34 cells against MeHg for over 36 h. A morphological study using bright filed imaging displayed that 1mM NAC pretreatment or co-treatment with 5µM MeHg for 18h protected NSC34 cells from the loss of synaptic integrity and degeneration. To test whether the mechanism of action of NAC involved the Nrf2 pathway, expression of superoxide dismutase-1 (SOD1) and -2 (SOD2), the downstream paths underlying the Nrf2 pathway were compared to vehicle treatment and MeHg exposure. At 18h MeHg exposure alone, SOD1 and SOD2 expression were up-regulated, which might suggest the cells loss of redox homeostasis, and the Nrf2 antioxidant pathway was activated. NAC co-treatment with MeHg protected the dysregulation of SOD1 and SOD2 expression in these cells. The expression of excitatory amino acid transporter 3 (EAAT3) and subunit 2 (GluA2) of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR) were examined to determine if they contributed to dysregulation of glutamate transmission following MeHg exposure. Immunofluorescence results indicated that EAAT3 and the GluA2 subunit appeared to be diminished in MeHg exposure, whereas NSC34 cells treated with 1mM NAC maintained these protein expressions as the same level of vehicle treatments. In conclusion, NAC protected against MeHg-induced neuronal degeneration and its mechanisms of action could contribute to the maintenance of redox and glutamate homeostasis in NSC 34 cells. *This research was supported by NIH grant R01ES024064, and R25NS090989-ENDURE Program.*

3017 Deletion of Astrocytic YY1 Protects against Mn-Induced Dopaminergic Neurotoxicity in Mice

E. Pajarillo[1], J. Johnson[1], A. Rizor[1], M. Aschner[2], and E. Lee[1]. *[1]Florida A&M University, Tallahassee, FL; and [2]Albert Einstein College of Medicine, New York, NY.*

Chronic overexposure to manganese (Mn) causes a neurological condition, called manganism. Emerging evidence suggests that the transcription factor yin yang 1 (YY1) mediates Mn-induced astrocytic glutamate transporters GLAST/GLT-1 dysregulation, leading to excitotoxicity. In this study, we aimed to test if deletion of YY1 in astrocytes protects mice against Mn neurotoxicity by attenuating Mn-induced repression of GLAST/GLT-1. We injected the adeno-associated viral vector 5 (AAV5) expressing *Cre* recombinase under the control of glial fibrillary acidic protein (GFAP) promoter into the substantia nigra (SN) of YY1-floxed ($YY1^{loxP/loxP}$) mice to generate SN-astrocyte specific YY1 knockout (YY1-cKO). Three weeks after injection, Mn was treated by nostril instillation (30 mg/kg/day, 3 wks), followed by behavioral studies and immunohistochemistry, qPCR and WB analyses. Results showed that YY1 was ablated in SN astrocytes in YY1-cKO mice, displaying normal behaviors. Mn decreased locomotor activity and motor coordination in WT mice, whereas YY1-cKO mice attenuated those Mn-induced deficits. Moreover, at the molecular levels, YY1 deletion attenuated Mn-reduced tyrosine hydroxylase (TH) protein levels, a marker of dopaminergic neurons, in SN and striatum. Mn also decreased GLAST/GLT-1 mRNA and protein levels in SN, whereas deletion of astrocytic YY1 attenuated these Mn effects. These results suggest that astrocytic YY1 plays a critical role in Mn-induced dopaminergic toxicity, possibly via dysregulation of astrocytic GLAST/GLT-1, leading to excitotoxic neuronal injury. These findings indicate that astrocytic YY1 may serve as a potential target for therapeutics to treat Mn toxicity. *Supported by National Institutes of Health, National Institute of Environmental Health Sciences (NIH/NIEHS): R01 ES024756 (EL), R01 ES10563 (MA), R01 ES10563 (MA), R01 ES07331 (MA) and 1R21 ES025415 (MA).*

3018 Chronic Early-Life Lead Exposure Disrupts Behavior and µ-Opioid Receptor Levels in the Rat Brain: Implications to Mental Disorders

D. Albores-Garcia, D. R. Brooks, J. L. McGlothan, and T. R. Guilarte. *Florida International University, Miami, FL.*

Environmental factors have been associated with psychiatric disorders and recent epidemiological studies suggest an association between prenatal lead (Pb^{2+}) exposure and schizophrenia (SZ). Preclinical studies show that developmental Pb^{2+} exposure recapitulates specific neuropathological and dopaminergic system changes present in SZ. However, the mechanisms underlying the negative symptoms of SZ have not been fully elucidated. µ-opioid receptors (MOR) are key in hedonic functions and reward pathways, and have been hypothesized to play a role in the negative symptomatology of SZ, as MOR levels are decreased in SZ patients (Ashok et al, 2019) In this study, we examine the effect of chronic early life lead exposure (CELLE) on sensorimotor gating using pre-pulse inhibition of the acoustic startle (PPI) and MOR levels in the brain of rats in early adolescence (postnatal day 28, PN28), late adolescence (PN50) or adulthood (PN120). Our CELLE paradigm results in blood lead levels averaging ≤1.9 (control) or 22 ± 0.07 µg/dL (Pb^{2+}) at PN28. Chronic Pb^{2+} exposure did not affect PPI in PN28 male rats ($F_{1,35}$ = 0.54, p=0.47), however PPI deficits were present at PN50 and PN120 ($F_{1,35}$= 11.3, p=0.002, $F_{1,35}$= 9.3, p=0.004 respectively), consistent with the age trajectory of PPI deficits in SZ. We found no effect of Pb^{2+} exposure on PPI in female rats. MOR levels in relevant brain regions were measured using autoradiography. At PN28 MOR levels were increased in the striatum (p=0.07), nucleus accumbens (NAC), p=0.04; basolateral amygdala (BLA), p=0.002; and thalamic nuclei (lateral post-thalamic nuclei (LPTN), p=0.003; stria medullaris of the thalamus, p=0.01) of male Pb^{2+} rats compared to controls. PN28 Pb^{2+}females had increased levels of MOR in NAC, p=0.005; BLA p=0.04, LPTN p=0.006 and medial thalamus p=0.002. No changes in MOR levels were observed at PN50 in both sexes, and there was a decrease in MOR levels in medial thalamus (p=0.02) of Pb^{2+} exposed males at PN120 compared to controls. No changes were observed in females at PN120. These studies show that chronic early life Pb^{2+}-exposure results in PPI inhibition, an endophenotype for SZ and produces differential changes in the opioid system. Our findings along with previous studies suggest the role of environmental factors, such as Pb^{2+}, as a risk factor for mental disorders and indicate that our CELLE model may serve as an environmental animal model of SZ. *NIEHS grant #ES006189-25 to TRG.*

3019 Mechanism of Mn-Induced YY1 Activation via Aurora B Kinase and Casein Kinase II in Astrocytes

A. Rizor[1], E. Pajarillo[1], M. Aschner[2], and E. Lee[1]. *[1]Florida A&M University, Tallahassee, FL; and [2]Albert Einstein College of Medicine, Bronx, NY.*

Chronic exposure to manganese (Mn) causes a neurological disorder known as manganism. The mechanisms underlying Mn neurotoxicity are not well understood, but includes dysregulation of the astrocytic glutamate transporter excitatory amino acid transporter 2 (EAAT2), leading to excess extracellular glutamate levels and subsequent excitotoxicity. Decreases in EAAT2 expression and activity are associated with pathogenesis in several neurological disorders, including Parkinson's disease (PD) and manganism, and involve the repressive action of the transcription factor Yin Yang 1 (YY1). In the present study, we investigated the mechanisms of Mn-induced YY1 activation to determine if Mn increases YY1 expression via the cytokine TNF-α, oxidative stress and activation of NF-κB signaling. We also tested if Mn activates YY1 via phosphorylation, leading to the transcriptional repression of EAAT2. Our results demonstrate that Mn exposure induces phosphorylation of YY1 via kinases Aurora B kinase (AurkB) and Casein kinase II (CKII), leading to increases in YY1 nuclear translocation, YY1 interaction with histone deacetylases (HDACs 1 & 3), and EAAT2 repression. Mn-induced TNF-α production and oxidative stress was also associated with proinflammatory signaling upstream of NF-κB. Accordingly, treatment with IKK16, an inhibitor of IKKβ, and antioxidants attenuated Mn-induced activation of NF-κB and YY1 and restored EAAT2 expression. Taken together, these results indicate that Mn-induced oxidative stress/inflammation upregulates YY1 via NF-κB, and that Mn also induces YY1 phosphorylation, leading to EAAT2 reduction and subsequent excitotoxic neuronal injury.

3020 Role of APL-1 in Manganese- and Paraquat-Induced Toxicity in *Caenorhabditis elegans*

A. C. Martins Jr.[1], B. N. Krum[1], F. A. Antunes Soares[1], T. Ke[1], A. B. Bowman[2], and M. Aschner[1]. *[1]Albert Einstein College of Medicine, Bronx, NY; and [2]Purdue University, West Lafayette, IN.*

Alzheimer's disease affects over five million Americans and is the sixth leading cause of death. The molecular mechanisms and factors that trigger the onset and disease progression remain largely unknown. However, misfolding and aggregation of β-amyloid (Aβ) plaques in the brain characterize the disease secondary to changes in amyloid precursor protein (APP) processing. Environmental and occupational factors such as manganese (Mn) and paraquat (PQ) have been implicated in the etiology of Alzheimer's disease and the ensuing changes in APP cleavage. Here we used *Caenorhabditis elegans* (*C. elegans*) as a model to explore putative mechanisms of neurodegeneration secondary to exposure to Mn or PQ. Specifically, APL-1, the *C. elegans* orthologue of mammalian APP was studied to evaluate its role in the disease. Studies were carried out in wild-type N2 and APL-1 (yn5) strains to assess sensitivity to reactive oxygen species (ROS) generation, as well as in BY200 worms, where dopaminergic neurons are labeled with green fluorescent protein (GFP) allowing for the evaluation of neurodegeneration. The results showed that the APL-1 strain was more sensitive to Mn or PQ than wild-type worms. Moreover, we observed increased levels of ROS upon exposure to Mn (25mM) and PQ (0.5 and 1mM) in N2 worms compared with controls. Worms exposed to Mn or PQ showed increased dopaminergic neurodegeneration, consistent with the increased ROS levels. Our results suggest that both Mn and PQ cause increase in ROS levels and neurodegeneration.

3021 Essential Amino Acids Are Crucial for Manganese Potentiation of Insulin/IGF Dependent S6, but Not AKT Phosphorylation

R. C. Balachandran[1], M. R. Bryan[2], M. G. Thomas[1], M. Aschner[3], and A. B. Bowman[1]. *[1]Purdue University, West Lafayette, IN; [2]Vanderbilt University Medical Center, Nashville, TN; and [3]Albert Einstein College of Medicine, Bronx, NY.*

Manganese (Mn) is essential for life, including brain development, nerve and cognitive functioning. Several kinases of the insulin/IGF signaling cascade are Mn-dependent. Studies have shown that Mn activates kinases in the IGF pathway including AKT, mTOR which are neuroprotective in Huntington's disease. As Mn is a known insulin mimetic, the overarching goal here was to identify direct molecular targets in insulin signaling pathway that are altered at non-cytotoxic threshold exposures. Prior *in vitro* studies have established that Mn-dependent AKT signaling is synergistically augmented by IGF (1nM) and Mn at higher concentrations (200 and 500 μM) acting at insulin/IGF receptors (IR/IGFR). AKT (S473) phosphorylation consistently occurs under simplified saline buffer exposures, but the response of the ribosomal protein kinase S6 (S235/236), downstream of AKT and mTOR in the IGF signaling cascade has shown inconsistent effects. We hypothesize that essential amino acids (EAA) play a role in Mn dependent activation of S6 kinases. To test this hypothesis, we subjected an *in vitro* model, *STHdh*, murine striatal cell lines to insulin/IGF deprivation and followed by a 3 hour exposure to Mn (100 μM), and/or IGF (1 nM) and IR/IGFR inhibitor (BMS-536924 at 100 nM) in both the presence and absence of EAA. We observed that in complete media with EAA and insulin, AKT phosphorylation increased at 200 μM Mn but not at 100 μM Mn. Mn mediated increases in AKT phosphorylation were seen in both the presence and absence of EAA which was inhibited by BMS. Furthermore, in support of our hypothesis, we observed a Mn potentiated increase in S6 phosphorylation occurred exclusively in the presence of EAA, and BMS blocked this effect. We find that IGF alone does not increase the phosphorylation of S6 in absence of EAA, despite AKT activation. In addition, 100 μM Mn potentiates the effect of IGF on S6 only, not AKT, in a Mn-dependent manner through IGF signaling pathway only in the presence of EAA. This suggests a potential parallel pathway through which EAA is facilitating the Mn- dependent phosphorylation of S6. We are exploring the effects of Mn on insulin/IGF signaling using a similar exposure paradigm in other model systems. This study will help us better understand the effects of Mn on insulin signaling pathway, which is crucial in context Mn neurotoxicity.

3022 Determination of *In Vitro* Methylmercury Exposure Paradigms Relevant to *In Vivo* MeHg Levels in the Human Developing CNS

M. Neely[1], L. Prince[2], N. A. Marinelli[3], E. B. Warren[3], M. Aschner[4], and A. B. Bowman[2]. *[1]Vanderbilt University Medical Center, Nashville, TN; [2]Purdue University, West Lafayette, IN; [3]Vanderbilt University, Nashville, TN; and [4]Albert Einstein College of Medicine, Bronx, NY.*

The human developing brain shows high vulnerability to methylmercury (MeHg) and the severity of the symptoms seem to depend on exposure levels, duration and developmental stage. To assess the effect of MeHg on the developing CNS, we established hiPSC-derived neuronal cultures. We argue that physiologically relevant *in vitro* toxicant exposure paradigms are best determined by comparing toxicant levels accumulated in *in vitro* cells with levels measured *in vivo*, rather than translating *in vivo* levels into cell culture medium concentrations. Here, we set out to determine relevant MeHg exposure paradigms to study the effect of MeHg on developing human neurons. Developing human mesencephalic dopaminergic floor plate cells differentiated from hiPSC were exposed to 100 nM or 1 μM MeHg continuously for 5 days during the proliferative neural precursor cell (NPC) stage. After the end of the 5 day exposure cell samples were collected daily and MeHg content measured and normalized to protein content. 24 hours after the last exposure cellular Hg contents were 3.3 ± 0.08 ng/mg protein and 37.8 ± 2.70 ng/mg protein for the 5 day long exposures to 0.1 μM and 1 μM, respectively. Based on our calculations using published values for brain density (1.05 g/ml) and brain protein concentration (100 mg protein/g wet weight) we determined that a 5 day exposure to 1 μM MeHg results in a cellular Hg content within the range that has been reported to cause delayed psychomotor development (3 ppm), while the same exposure paradigm at 0.1 μM MeHg resulted in levels just below the reported lowest-observed-adverse-effect-level (0.5-1 ppm). We further found that dopaminergic NPCs extrude about 60% of the accumulated Hg every 24 hours for the first 48 hours with a decreasing rate thereafter. Neither of these two exposure paradigms (100 nM and 1 μM for 5 days) resulted in loss of cell viability or changes in proliferation rates. We are currently testing if Hg accumulation and extrusion differs during different neuronal differentiation stages and in different neural lineages and are determining if there are any MeHg-induced effects on functional phenotypes including neuronal electrical activity. *NIEHS R01 ES007331, ABB, MA.*

3023 Developmental MeHg Exposure Disrupts Stage-Specific Neuronal Differentiation in a Human-Induced Pluripotent Stem Cell Model

L. M. Prince[1], M. D. Neely[2], M. Henley[1], K. Smith[1], M. Thomas[1], M. Aschner[3], and A. B. Bowman[1]. *[1]Purdue University, West Lafayette, IN; [2]Vanderbilt University, Nashville, TN; and [3]Albert Einstein College of Medicine, Bronx, NY.*

Although methylmercury (MeHg) is an extensively studied developmental neurotoxicant, little is known about which neuronal lineages and stages of development are most sensitive to MeHg exposure. Exposures in both mammalian and invertebrate models have suggested that MeHg may target dopaminergic neurons. However, historic accidental poisonings of MeHg have

shown that loss of cerebral and cerebellar glutamatergic neurons is a hallmark of MeHg toxicity. Additionally, it is unknown whether this loss was due to MeHg inhibiting differentiation, migration, or to neuronal death. Therefore, we aimed to understand which neuronal lineages and stages of development are most sensitive to MeHg exposure, using the human-induced pluripotent stem cell (hiPSC) model. hiPSCs were differentiated down the cortical glutamatergic and the floor plate dopaminergic lineages, and exposed to 0, 0.1, or 1μM MeHg. Exposures occurred five days over the course of development to the neuroprogenitor (NP) stage (days 4 to 10 of differentiation) and/or five days over the course of development of early post-mitotic neurons (days 14 to 20 of differentiation). Cell lysates were collected for protein quantification and total mercury quantification. Differentiation potential was determined by examining expression of lineage-specific markers with qRT-PCR at days 11 and 21 of differentiation. In the cortical lineage, MeHg exposure did not significantly affect expression of NP markers at day 11. However, at day 21, MeHg was shown to cause an increase in expression of FOXG1 (n=3, one-way ANOVA, p=0.0384), a telencephalic NP marker, and a corresponding decrease in expression of TBR1 (n=3, one-way ANOVA, p=0.0271), an early deep layer cortical glutamatergic neuron marker. In concordance with these results, we saw a continued mercury bioaccumulation over the 14 to 20 day exposure window. In contrast, during the day 4 to 10 exposure window, mercury concentration appeared to reach saturation after the first 24 hours of exposure. This suggests differences in transport or storage of MeHg between these stages of development may play a role in the sensitivity of differentiating NPs to MeHg. Future studies will focus on the floor plate dopaminergic lineage and the mechanisms by which MeHg disrupts neuronal development in a stage- and lineage-dependent manner.

3024 Molecular Mechanisms of Cobalt-Induced Toxicity in *Caenorhabditis elegans*

F. Zheng[1,2], P. Chen[1], A. B. Bowman[3], H. Li[2], and M. Aschner[1]. *[1]Albert Einstein College of Medicine, Bronx, NY; [2]Fujian Medical University, Fuzhou, China; and [3]Purdue University, West Lafayette, IN.*

As a component of vitamin B12, cobalt is an essential metal. However, high levels of cobalt may lead to metallosis, characterized by sensorineural hearing loss, visual and cognitive impairment and peripheral neuropathy. Excessive serum cobalt can arise from a variety of sources, including diet, exposure from industrial fabrication, or from alloys used in tooth and hip joint replacements. In a long-term follow-up human trial, the mean serum cobalt concentration was 4-fold higher in the cobalt chrome metal-on-metal arthroplasties (1.5 μg/L) compared with the metal- on-polyethene cohort (0.4 μg/L, P < .001). Previously, we have shown that cobalt overexposure results in defects in rat neural cells, including lethality, hypoxia and the loss of learning, memory and spatial-exploration abilities. In the present study, we sought to unveil the molecular mechanisms of cobalt induced neurotoxicity in *Caenorhabditis elegans* (*C. elegans*). Exposure to cobalt chloride for 2 h significantly decreased the survival rates in the nematodes (IC50= 20.69 mM). As a common consequence of cobalt exposure, oxidative stress was detected using 2′,7′-dichlorodihydrofluorescein diacetate / 2′,7′-dichlorofluorescein (H2DCFDA) assay and a reporter strain VP596 (reporter gene construct). In VP596 animals, GFP (green fluorescent protein) is driven by the promoter of glutathione S-transferase 4 (*gst-4*) gene which is activated upon oxidative stress. As an upstream regulator of *gst-4*, and a homologue of the nuclear factor erythroid 2-related factor 2 (Nrf2) in mammals, *skn-1* levels were found to be significantly upregulated by cobalt induced oxidative stress. Furthermore, we identified mitochondrial oxidative stress by MitoTracker assay and altered mitochondrial morphology by confocal microscopy following cobalt exposure. mRNA levels of mitochondrial dynamic related genes such as *drp-1*, *fzo-1* and *miro-1* have also changed accordingly. In addition, qRT-PCR results indicated that genes regulating apoptosis (*egl-1*, *ced-3*, *ced-4*, *ced-9*) and autophagy (*bec-1*, *lgg-1*) were altered in cobalt induced toxicity. In conclusion, our results demonstrate that cobalt exposure can induce oxidative stress and mitochondrial dysfunction, in turn, leading to lethality, activation of autophagy and induction of apoptosis in *C. elegans*. *The study was supported by NIEHS (R01ES07331, R01ES10563), NSFC (81903352) and Provincial Natural Science Foundation of Fujian Province (2019J05081).*

3025 Chronic Exposure to Methylmercury Induces Puncta Formation in CEP Dopaminergic Neurons in *Caenorhabditis elegans*

T. Ke[1], A. Tsatsakis[2], A. Santamaría[3], F. Soare[4], A. A. Tinkov[5], A. Skalny[5], A. Docea[6], A. B. Bowman[7], and M. Aschner[1]. *[1]Albert Einstein College of Medicine, Bronx, NY; [2]University of Crete, Heraklion, Greece; [3]Instituto Nacional de Neurología y Neurocirugía, Mexico City, Mexico; [4]Universidade Federal de Santa Maria, Santa Maria, Brazil; [5]P.G. Demidov Yaroslavl State University, Yaroslavl, Russian Federation; [6]University of Medicine and Pharmacy, Craiova, Romania; and [7]Purdue University, West Lafayette, IN.*

The neurotoxin methylmercury (MeHg) produces dopaminergic neuron damage in various models. Previous studies have demonstrated the utility of *Caenorhabditis elegans* (*C. elegans*) as an alternative and complementary experimental model in dissecting out mechanism of MeHg-induced dopaminergic neurodegeneration. However, sensitive morphological biomarkers of dopaminergic neurodegeneration that precede frank MeHg neurotoxicity and neuronal cell death are lacking. By establishing a chronic exposure *C. elegans* model using OH7193 strain, we have discovered a propensity of MeHg exposures (5 μM, 10 days) to induce bright puncta of *dat-1*::mCherry aggregates(>70%) specifically in the dendrites of CEP dopaminergic neurons in a dose- and time-dependent manner. In contrast, the puncta formation was not induced in other neurons including: 2 ADEs, 2 PDEs, cholinergic neurons (2 AIYs) or glutamatergic neurons (2 PVDs). Features of the puncta, along with shrinking dendrites are distinct from those inherent to normal mCherry fluorescent protein aggregates, and instead resemble the dendritic varicosities in substantia nigra (SNc) neurons of patients with Parkinson's disease (PD). Moreover, the expression levels of *gst-4* and tubulins (*tba-1* and *tba-2*) genes were not significantly modified under this chronic exposure paradigm, though *gst-4* showed significant changes in a one day exposure paradigm. We hypothesize that the puncta formation occurs from a diverse set of mCherry-linked cellular macromolecules altered by MeHg, which could exhibit a localized, high intensity of mCherry signal. We are continuing to investigate the components of the puncta using this model.

3026 Manganese-Induced ROS and AChE Variants Alteration Leads to SN56 Basal Forebrain Cholinergic Neuronal Loss after Acute and Long-Term Treatment

P. V. Moyano Cires, J. Garcia, J. Sanjuan, M. J. Anadon, M. Lobo, J. Garcia, M. T. Frejo, E. Sola, A. Pelayo, and J. Del Pino. *Universidad Complutense de Madrid, Madrid, Spain.*

Manganese (Mn) induces cognitive disorders and basal forebrain (BF) cholinergic neuronal loss, involved on learning and memory regulation, which could be the cause of such cognitive disorders. However, the mechanisms through which it induces these effects are unknown. Mn induces oxidative stress generation, and alters AChE gene expression in other brain regions, effect involved with BF cholinergic neuronal loss. Otherwise, cholinergic system, mainly in BF, is involved on learning and memory regulation, and an alteration of cholinergic transmission in BF, as Mn produces in other brain regions, could induce these effects. Thus, we hypothesized that Mn could induce BF cholinergic neuronal loss through oxidative stress generation, cholinergic transmission and AChE variants alteration. This study shows that Mn impaired cholinergic transmission in SN56 cholinergic neurons from BF through alteration of AChE and ChAT activity and CHT expression. Moreover, Mn induces, after acute and long-term exposure, cell death on SN56 cholinergic neurons and this effect is independent of cholinergic transmission alteration, but was mediated partially by oxidative stress generation and AChE variants alteration. Our results provide new understanding of the mechanisms contributing to the harmful effects of Mn on cholinergic neurons and their possible involvement in cognitive disorders induced by Mn.

3027 Sex-Specific Effects of Developmental Dieldrin Exposure on Susceptibility to α-Synuclein Preformed Fibrils in Mice

J. Kochmanski[1], A. O. Gezer[1], S. E. VanOeveren[1], A. Cole-Strauss[1], C. J. Kemp[1], J. R. Patterson[1], K. M. Miller[1], D. E. Herman[2], A. McIntire[2], J. W. Lipton[1], S. Fleming[2], K. C. Luk[3], C. E. Sortwell[1], and A. I. Bernstein[1]. *[1]Michigan State University, Grand Rapids, MI; [2]Northeast Ohio Medical University, Rootstown, OH; and [3]University of Pennsylvania, Philadelphia, PA.*

Parkinson's disease (PD) is characterized by progressive degeneration of dopaminergic neurons in the nigrostriatal pathway and the formation of α-synuclein-containing Lewy bodies. While an abundance of research has investigated specific PD-linked genetic loci, the majority of PD cases (~90%) are sporadic (i.e. not caused by monogenically inherited *mutations*) and are likely due to a complex interaction between genes and environmental factors. Building on this concept, epidemiological and mechanistic studies have shown an association between exposure to persistent organic pollutants, including pesticides and industrial toxicants, and an increased risk of PD. One potential mediator of the relationship between environmental exposures and PD is the epigenome, which is sensitive to the environment, established during cellular differentiation, and regulates gene expression throughout the lifespan. Our research aims to determine whether developmental exposures, in particular to the organochlorine pesticide dieldrin, alters PD risk by establishing a poised epigenetic state early in life that mediates susceptibility to parkinsonian neurotoxicity in adulthood. To test this hypothesis, we combined a developmental dieldrin exposure paradigm with the α-synuclein (α-syn) pre-formed fibril (PFF) model in mice. In a previous study, we found that dieldrin exposure establishes a sex-specific poised epigenetic state early in life, including at genes that may mediate susceptibility to neurotoxicity into adulthood. Here, we showed sex-specific effects of developmental dieldrin exposure on expression of genes involved in neuroinflammation. We also observed a male-specific exacerbation of PFF-induced deficits in dopamine packaging and motor behavior by dieldrin exposure in the challenging beam test six months after PFF injections. In contrast, female mice did not show a dieldrin-induced exacerbation of PFF-induced toxicity, and they did not show any PFF-induced motor deficits on the challenging beam test despite similar PFF-induced neuropathological and neurochemical changes. The dieldrin-induced, male-specific increase in neuronal vulnerability is consistent with previous results in the MPTP model, and reflects the increased prevalence of PD in males. Taken together, our results suggest that the exposure+PFF two-hit model is a novel paradigm that can be used to explore the mechanisms by which PD-related exposures alter neuronal vulnerability to synucleinopathy in Parkinson's disease.

3028 Neurological Effects of *In Vivo* Chlorpyrifos Exposures in Rats

A. D. Hulgan[1,2], M. K. Miklasevich[1,2], N. M. Gargas[1,2], T. Ethridge[1,3], S. M. McInturf[1], K. L. Mumy[1], and J. G. Rohan[1]. *[1]Naval Medical Research Unit Dayton, Wright-Patterson AFB, OH; [2]Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD; and [3]Oak Ridge Institute for Science and Education, Oak Ridge, TN.*

Military personnel are at risk for exposures to various chemicals such as pesticides, which are common contaminants found in the environment, food, and water. Adverse neurological effects of pesticide exposures have been documented in Gulf War veterans. The objective of this project is to characterize the neurological effects of *in vivo* chlorpyrifos (CPF) exposures on neurological function, using not only behavioral testing but also electrophysiology to directly assess neuronal function. A secondary objective of this project is to explore whether administration of transcranial direct current stimulation (tDCS) can alleviate the detected neurological effects. Rats were exposed to a single dose of CPF via oral gavage and endpoints were determined approximately 3 hours post exposure to assess acute effects and >50 days post exposure to assess delayed effects. Dose levels were 0 (control), 10 (low), 30 (mid), or 60 (high) mg/kg body weight. We found statistically significant reduction in motor activity of animals 3 hours following a one-time gavage of 60 mg/kg CPF (high). There was an increased startle response in animals exposed to the high dose of CPF. Electrophysiology data revealed statistically significant reduction in paired pulse facilitation (PPF), a measure of short term synaptic plasticity, in hippocampal neurons. These effects were transient and no longer observed 50 days post exposure. No additional delayed effects were found. We also determined that tDCS administration in high dosed CPF group did not significantly alter the reduced motor activity observed at 3 hours post exposure. We also assessed the effects of repeated CPF exposures. Here, animals were exposed to 0 (control), 5 mg/kg (mid) or 10 mg/kg (high) CPF for 5 days/week over a 2-week period. Data analyses are underway and our results thus far revealed statistically significant reduction in motor activity at 1 day following the last day of exposure in animals that were repeatedly exposed to CPF. In conclusion, we found that exposure to CPF induced a significant but transient reduction in motor activity as well as decreased PPF in the hippocampus. Furthermore, tDCS was unable to reverse the reduced motor activity of animals that were singly exposed to CPF.

3029 Human Allele-Specific Methylated Regions Have Increased Resilience to Rotenone Exposure in α-Synuclein Knockdown Neurons

D. M. Freeman, M. Watfa, and Z. Wang. *Johns Hopkins University, Baltimore, MD.*

Allele specific DNA methylation (ASM) describes genomic loci that maintain CpG methylation at only one inherited allele rather than having coordinated methylation across both alleles. The most prominent of these regions are ASMs that control the expression of imprinted genes and are commonly associated with genetic disorders such as Beckwith-Wiedemann and Prader-Willi syndromes. Imprinted genes are significantly enriched in the brain and their regulation influences cognitive function and behavior throughout aging. They are dependent on DNA methyltransferase I (DNMT1) and are hypothesized to be critical for mechanistic insights into environmental disease. We have identified DNMT1 dependent regions in the human genome which include both germline ASMs and non-traditional ASMs. We explored the vulnerability of these regions to environmental factors using a rotenone induced neuronal cell model. We observed significant up-regulated expression (>1.5 fold change) and hypomethylation at two genes, *HCN2* and *NEFM*, with implications in neurodegeneration. Intriguingly, α-Synuclein had an unexpected role in connecting ASMs to exposure sensitivity. α-Syn is a protein expressed in neurons to support synaptic transmission but misfolded α-Syn can promote the formation of Lewy bodies, a pathological hallmark in neurodegeneration. We have shown increased resilience of SH-5YSY α-Syn knockdown (KD) cells to mitochondrial damage induced by rotenone. We analyzed the transcriptome of rotenone treated wild-type and α-Syn KD SH-5YSY with RNA sequencing. Rotenone altered the expression of 526 genes in wild-type and 128 genes in α-Syn KD cells (1.5 fold change; FDR<0.05). In rotenone treated α-Syn KD, the cellular defense response was significantly enriched ($p<10^{-3}$) and three DNMT1 dependent imprinted genes were significantly up-regulated compared to wild-type. We are currently investigating changes in DNA methylation at these imprinted regions as well as in other predicted ASMs to determine if targeting α-Syn promotes cellular resilience to rotenone by maintaining DNA methylation patterns. This work will provide additional mechanistic insights into gene environment interactions in neurodegeneration and provide support to the hypothesis of developmental origins of adult disease.

3030 The Chronic Exposure to Herbicide Atrazine Increases the Expression of Genes Associated to GABA and Glutamate Systems in Albine Male Rats

D. Reyes-Bravo, P. Villalobos-Aguilera, J. Almonte-Zepeda, M. Giordano, and V. M. Rodriguez. *Instituto de Neurobiología, Queretaro, Mexico.*

The herbicide atrazine (ATR; 2-chloro-4-ethylamino-6-isopropylamino-s-triazine) is widely used to destroy grasses and broadleaf weeds in crops like corn, sorghum and some fruits. Several studies in rodents have shown that acute, repeated or chronic exposure to ATR is associated with alterations in the nigrostriatal dopaminergic pathway, while its effects on GABAergic and glutamatergic (Glu) pathways have been barely studied. For the evaluation of the ATR effects on GABAergic and glutamatergic systems, Sprague-Dawley male rats were exposed daily to 1 or 10 mg ATR/kg of BW for 12 months. At the end of the ATR treatment, the levels of mRNA of several genes involved in the production, vesiculation, reuptake, and receptors of GABA and Glu in striatum (str), nucleus accumbens (NAcc), prefrontal cortex (PFC), ventral midbrain (vMID) and hippocampus (HIPP) were evaluated by absolute qPCR. Increases in the expression of the glutaminases *gls* and *gls2* in STR, NAcc, HIPP and PFC of rats exposed to 1 and/or 10 mg ATR were found. For the GABAergic genes, increased expression of *gad67* and *vgat* in STR and/or vMID in rats exposed to 1 and/or 10 mg ATR were detected. The expression of genes involved in the glutamatergic system, like *vglut-2* and *grin1* in HIPP of rats exposed to 1 and/or 10 mg ATR we also increased, as was *gria1* in STR and PFC in the group exposed to 1 mg ATR. In the same fashion, the expression of *glast* and *mglur1* increased in STR of rats exposed to 1 and 10 mg ATR groups. These findings show that the GABAergic and Glu systems are targets of ATR exposure. *Funding: UNAM-DGAPA-PAPIIT IN203916, IN208119, and CONACYT 251510.*

3031 Acute Neurotoxicologic Evaluation of Sabadilla Alkaloids

M. R. Bauter[1], T. Osmitz[2], and W. Droege[2]. *[1]Eurofins Product Safety Labs, Dayton, NY; and [2]Science Strategies LLC, Charlottesville, VA.*

Sabadilla, *Schoenocaulon officinale* Grey (Liliaceae), has long been used in folk medicine as a botanical species with insecticidal potency and low mammalian toxicity. Among the alkaloid fraction of the seeds (3-6%) which makes up the insecticidal activity, two lipophilic alkaloids, veratridine and cevadine, have the highest reported insecticidal potency. Sabadilla alkaloids, like pyrethrins, exert neurotoxic activity in insects by inhibiting the closing of Na+ channels and disrupting cell membrane depolarization. The potential of SABA-10 (formulation consisting of 10% Sabadilla alkaloids) to produce adverse effects was investigated using an acute oral neurotoxicity study in rats. Test substance-related observations in female rats included abnormal gait, ataxia, hypoactivity, hyperactivity, immobile, irregular respiration, hunched posture, and tremors. Additionally, significant increases observed in female foot splay and motor activity on Day 1 were indicative of transient neurobehavioral impairment. Functional observations that were considered relevant indications of short term adverse detailed clinical/functional signs in female rats included inactivity, ataxic/impaired gait, incapacitation, impaired locomotion, tremors, unusual behaviors (i.e. head shaking, opening and closing of mouth), and slow surface righting. The NOAEL for acute neurotoxicity of SABA-10 was determined to be 50 mg/kg/day for female and 400 mg/kg/day (the highest dose tested) for male rats. All adverse clinical and functional observations on the day of dosing resolved within 24 hours or by the next interval, with no histopathological evidence of permanent central or peripheral nervous system findings.

3032 Identifying the Genetic Determinants of Physiological Response to Combinatorial Environmental Exposures

M. Kobayashi, M. Ghadiali, J. Nguyen, C. McClure, and P. Allard. *University of California Los Angeles, Los Angeles, CA.*

C. elegans behavior is conditioned by the cumulative interaction of many factors, such as natural environmental stimuli and manufactured toxicants (Anderson et al., 2004). Specifically, we are interested in how deleterious environmental exposures, alone or in combination, can modulate behaviors mediated by serotonin, an important neurotransmitter conserved across nearly all animal phyla. We focus on two exposures that are known to affect serotonin-dependent behaviors: (1) high temperature as a model for warmer climate and (2) the common pesticide chlorpyrifos. We aim to use genetic methods to identify genetic loci that convey resistance of the serotonergic system when under environmental stress by either temperature, chlorpyrifos, or both. We hypothesize that specific gene networks control the function and resilience of the nervous system, and that combinatorial exposures may uncover new nodes of stress response and resilience. For this, we will use of a resource available in the common genetic model system *C. elegans* where several, genetically-distinct wild isolates are available using a natural diversity resource, (Cook et al., 2016). This will address a key gap, as behavior has been assessed only in the wild type isolated from Bristol, England. By using a model for serotonin-mediated behaviors developed by our lab and an added heat stimulus model, the behavioral profile of each wild isolate will be investigated across temperature ranges and chlorpyrifos concentrations to assess which wild type isolates are able to convey enhanced thermotolerance through survivability. Preliminary data from the seven strains which are from diverse regions, including the Bristol, England strain as a control were compared at several temperatures, focusing on the critical temperature of 33°C for percent of worms surviving (40 worms per replicate, 1 trial each). Fold change for strain with the origin of Israel, between control was 13.84% and for strain with the origin of Peru was 4.33%, indicating enhanced survivability. When survival and behavior have been measured, we will use Quantitative Trait Loci (QTL) analyses to identify the loci responsible for increased or decreased sensitivity to these exposures alone or in combination. We therefore hypothesize that this synergistic exposure will adversely impact the serotonergic system and conveyed thermotolerance, evident in altered serotonin-mediated behaviors. Genetic analysis of specific gene networks will undercover how animals from different environmental conditions and that are exposed to varied environmental stimuli can differ in terms of behavior, and what key genetic differences can contribute to this.

3033 *CHD8* Expression Influences Pesticide-Induced Neurotoxicity in a Mouse Model of Autism

J. A. Jiménez, A. H. Tuttle, and M. J. Zylka. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

The considerable plasticity of the developing brain renders it exceptionally vulnerable to genetic and environmental perturbations. Autism Spectrum Disorder (ASD) is a common neurodevelopmental disorder with a strong but complex genetic component associated with key molecular pathways early in development. Yet, genetic risk factors seem insufficient to explain an increase in ASD prevalence over the past 15 years, raising the possibility that nonheritable risk factors are also at play. Exposure to exogenous agents during a critical developmental period has been suggested to contribute to ASD etiology. However, given the evidence on ASD heritability, environmental factors that play a role in ASD development likely influence mechanisms also involving some element of genetic susceptibility. Thus, there is an urgent need to identify mechanisms by which nonheritable factors may interact with susceptibility genes. In this study we investigate how haploinsufficiency in one of the most high confidence ASD risk genes, Chromatin Helicase DNA Binding Protein 8 (*CHD8*), influences pesticide-induced neurotoxicity. *In vitro* assessment of neuronal activity, as measured by expression of immediate early genes, c-fos and Npas4, suggests that *CHD8* influences neuronal excitability upon exposure to deltamethrin, an insecticide that functions by inhibiting sodium channel function. RNA-sequencing of cortical tissue at postnatal day 5 following *in vivo* developmental exposure describes an impairment in pathways involved in the maintenance of excitatory-inhibitory balance in *CHD8* mutant mice that is further enhanced by deltamethrin exposure. Developmental exposure to deltamethrin was also associated with autism-like phenotypes at 6 months of age, suggesting that inappropriate neuronal excitability during development can result in behavioral abnormalities later in life. Altogether, these data suggest that homeostatic mechanisms expressed to maintain appropriate levels of neuronal activity despite ongoing challenges to the network are altered in *CHD8* mutant mice influencing the development of autism-like behaviors. Our results generate new knowledge on the possible mechanisms underlying one of the most common autism-associate*d mutations* and contributes to the identification of environmental risk factors for ASD.

3034 Mitochondrial Stress Modulates Elongator Protein 3 (ELP3) Function and Subcellular Localization in Cell Culture and Animal Models of Parkinson's Disease

A. Abdalla, A. Charli, E. Malovic, H. Jin, V. Anantharam, A. Kanthasamy, and A. Kanthasamy. *Iowa State University, Ames, IA.*

Parkinson's disease (PD) has increasingly been linked with mitochondrial dysfunction. Exposure to mitochondria-targeting neurotoxicants, e.g., those neurotoxic pesticides that act as mitochondrial complex I inhibitors, has been linked to the pathogenesis of environmentally linked PD, but the molecular mechanisms underlying the enhanced vulnerability of dopaminergic neurons to mitochondrial toxicants are not fully understood. The histone acetyltransferase ELP3 (Elongator Protein 3) is the catalytic subunit of the RNA polymerase II elongator complex and plays an essential role in transcript elongation and maturation of projection neurons. Dysregulation of ELP3 has been implicated in a number of human disorders, but its potential role in the pathogenesis of PD remains elusive. In this study, we observed that the mitochondria-targeting pesticides rotenone and tebufenpyrad can disrupt ELP3's function in dopaminergic neurons in cell culture and rodent models of PD. Particularly, treatment with mitochondria-targeting pesticides upregulated ELP3 at both the mRNA and protein levels. In vehicle-treated dopaminergic neurons, ELP3 was present in the nucleus, mitochondria and cytosol. However, in neurons exposed to mitochondria-targeting pesticides, ELP3 levels were significantly decreased in both the nucleus and mitochondria but increased in the cytosol. These results suggest that mitochondria-targeting pesticides induce translocation of nuclear and mitochondrial ELP3 to the cytoplasm. Overall, our results suggest that ELP3 is a novel cellular target in models of PD that undergoes characteristic changes in expression levels and subcellular localization in dopaminergic neurons in response to neurotoxic, mitochondria-targeting stressors. *NIH grants ES026892 and ES027245 and Eugene and Linda Lloyd Endowed Chair.*

3035 The Repeated Injection of the Insecticide Thiacloprid Alters Striatal Dopamine Levels in the Albino Male Rat

A. K. Mora-Gutierrez, J. T. Almonte-Zepeda, M. S. Mendoza-Trejo, M. Giordano, and V. M. Rodriguez. *Instituto de Neurobiología, Querétaro, Mexico.*

Neonicotinoid insecticides are used in agriculture and for the treatment of ectoparasites in domestic pets. These pesticides have been associated with neurotoxic effects in the dopaminergic systems since they can increase the striatal DA release and increase the tyrosine hydroxylase immunoreactivity in substantia nigra pars compacta, in addition to causing hyperactivity in rats. The neonicotinoid insecticide thiacloprid (THI) is used for the treatment of potato, oilseed monkfish, pome fruit, vegetables, and ornamental crops and its use worldwide has gradually increased since 2005. In order to evaluate the effects of the repeated exposure to THI, male rats received an IP injection with 40 mg THI/kg of BW three times a week for two weeks while control group received sterile bi-distilled water injections. Fifteen minutes before and 2 hours after injection, locomotor activity was recorded. Forty-eight hours after the last THI injection striatum (STR), nucleus accumbens (NAcc) and ventral midbrain (vMID) were collected for DA and metabolites analysis. We found alterations in locomotor activity after THI administration. The striatal levels of dopamine were decreased without alterations in its metabolites. These data point to the nigrostriatal system as a target of the neonicotinoid THI. More studies are necessary in order to unveil the specific effects of THI in the nigrostriatal dopaminergic system. *Funding: UNAM-DGAPA-PAPIIT IN208119 and CONACYT 251510.*

3036 Salubrinal Protects against Deltamethrin-Induced Disruption of Hippocampal Neurogenesis in Mice

M. M. Hossain, and A. Belkadi. *Florida International University, Miami, FL.*

Environmental factors, including pesticide exposure, are thought to be significant contributors to the neurodegeneration and cognitive deficits. Emerging evidence indicates that adult neurogenesis in the hippocampus is important for learning and memory. Approximately 1400 newborn neurons are added to adult human hippocampus every day and provide about 2% annual turnover during aging, suggesting that adult neurogenesis contributes significantly to human hippocampal function (Spalding et al., 2013). In our previous study, repeated exposure to deltamethrin (3 mg/kg) caused ER-stress, reduction of hippocampal neurogenesis, and deficits in learning and memory in adult mice. Here, we sought to determine the potential relationship between ER stress and hippocampal neurogenesis following exposure to deltamethrin. Immunohistochemistry of various markers along with bromodeoxyuridine (BrdU) were used to examine neurogenesis. We found that single oral exposure to deltamethrin (3 mg/kg) resulted in reduction of progenitor cell proliferation as BrdU- and Ki67-positive cells were significantly decreased in the dentate gyrus (DG) of the hippocampus. Furthermore, deltamethrin-treated mice exhibited significant reduction in the expression of doublecortin (DCX)-positive cells, suggesting potential impairment of hippocampal neurogenesis. These were accompanied by ER stress as the protein levels of CHOP and GRP78 were significantly increased in the hippocampus following exposure to deltamethrin. To determine whether ER stress is associated with inhibition of neurogenesis, a group of mice were treated with two intraperitoneal (i.p.) injections of 1 mg/kg salubrinal (eIF2α inhibitor) 24 h and 30 min before the administration of deltamethrin. The data revealed that salubrinal prevented ER stress and attenuated deltamethrin-induced reduction of BrdU-, Ki67-, and DCX-positive cells in the DG of hippocampus. Collectively, these results demonstrate that exposure to deltamethrin leads to ER stress mediated inhibition of adult hippocampal neurogenesis, which may subsequently contribute to deficits in learning and memory in mice. *Supported in part by R01ES027481.*

3037 Disease-Toxicant Screen Reveals a Neuroprotective Interaction between Mutations in Alpha-Synuclein Implicated in Multiple System Atrophy (MSA) and Acute Exposure to Endosulfan

E. L. Strand, B. A. Larkin, R. Ziar, and G. F. Kwakye. *Oberlin College and Conservatory, Oberlin, OH.*

Pesticides and other environmental factors are known to modulate the pathogenesis of multiple system atrophy (MSA), a sporadic disease with alpha synuclein (α-Syn) implicated in its etiology. Aggregation of α-Syn within glial cytoplasmic inclusions (GCIs) in oligodendrocytes is a hallmark of MSA. However, the identity of environmental risk factors and how they interact with α-Syn and GCIs remain ill-defined. Recognizing the similarities between MSA pathophysiology and the neurotoxicology of various pesticides, we hypothesized that they may exhibit disease-toxicant interactions revealing cellular pathways underlying neurodegeneration. Here we utilize pesticides and OLN-93 rat oligodendroglial cell model of MSA to perform a gene-environment interaction screen. We report that oligodendroglial cells expressing mutant forms of α-Syn associated with familial cases of MSA, A53E-α-Syn and G51D-α-Syn, exhibit reduced sensitivity to endosulfan toxicity when compared to wild-type (WT-α-Syn) following 24 h exposure. This neuroprotective gene-environment interaction with endosulfan pesticide is highly specific, as it does not occur with dieldrin, mancozeb, chlorpyrifos, and MPP+. Analysis of the oxidative stress signaling pathway showed decreased production of reactive oxygen species and lipid peroxidation with endosulfan exposure in the mutant cells compared to WT-α-Syn. Indirect examination of cellular bioenergetics revealed that G51D-α-Syn cells show neuroprotection against endosulfan-induced reduction of mitochondrial membrane potential compared to WT-α-Syn. Additionally, the activity of caspase-3 and caspase-9 are significantly altered in A53E-α-Syn mutant cells with endosulfan exposure. Thus, this disease-toxicant interaction screen has revealed that expression of mutant α-Syn, A53E-α-Syn and G51D-α-Syn, results in reduced sensitivity to endosulfan neurotoxicity through distinct cellular pathways.

3038 Protection against Parathion-Induced Neurotoxicity by a Menadione/Vitamin C Combination Drug

J. D. Laskin[1], Y. Jan[1], M. L. Neal[2], V. Mishin[1], C. Kim[2], M. M. Hossain[2], and J. R. Richardson[2]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; and [2]Florida International University, Miami, FL.*

Accidental or intentional exposures to parathion, an organophosphorus (OP) pesticide, can cause severe poisoning in humans. Parathion toxicity is dependent on its metabolism by the cytochrome P450 system to paraoxon (diethyl 4-nitrophenyl phosphate), a highly poisonous nerve agent and potent inhibitor of acetylcholinesterase (AChE). Exposure to paraoxon can result in tremors, convulsions, dyspnea, respiratory arrest and unconsciousness. Previously, we reported that menadione, which functions by reducing cytochrome P450-mediated metabolic activation of parathion to paraoxon, significantly reduced lethality and overall toxicity of parathion in a rat model. Earlier studies have suggested that vitamin C may stabilize menadione; a mix of menadione/vitamin C is also undergoing clinical trials for cancer. In the present studies, we examined the effects of vitamin C on the ability of menadione to mitigate parathion toxicity. We found that vitamin C did not alter menadione-mediated cytochrome P450 inhibition using recombinant CYP1A2 and CYP3A4. It also did not interfere with the ability of menadione to suppress paraoxon formation and inhibition of AChE. Thus, a menadione/vitamin C mix significantly reduced parathion metabolism by liver microsomes in a concentration-dependent manner. This mix increased the IC_{50} values of AChE inhibition after parathion activation by rat liver microsomes from 0.8 to 2.7 μM and human liver microsomes from 1.9 to 81.6 μM, when compared to parathion. Administration of menadione/vitamin C to rats significantly increased parathion levels in serum, reduced parathion neurotoxicity and prolonged animal survival, similar to those found in menadione-treated rats. Taken together, these data indicate that vitamin C does not alter the protective effects of menadione against parathion intoxication and a menadione/vitamin C mix might be an effective therapeutic candidate to mitigate parathion-induced neurotoxicity. *Support: NIH grants AR055073, NS108956, and ES005022.*

3039 Evaluation of Serotonin-Modifying Toxicants Using a Standardized Tracking and Behavioral Model in *C. elegans*

C. McClure, and P. Allard. *University of California Los Angeles, Los Angeles, CA.*

CPF is a commonly used organophosphate pesticide in the US despite evidence that it can cause life-long, persistent changes in the serotonergic system of mammals. Serotonin is responsible for modulating behavior and plays an important role in behavioral plasticity, memory, and learning. Here, we use the model system *C. elegans* as it shows a high degree of conservation of the serotonergic system with mammals including serotonin receptor, transporter, and synthesis and shows alterations in behavior in response to serotonin deficiency. We will evaluate this pesticide, CPF, using a self-designed and standardized behavioral model for serotonin-mediated behaviors, and monitor its effects on behaviors and alterations to the serotonergic system. We will also evaluate how this exposure can influence gene expression and epigenetic mechanisms transgenerationally. We hypothesize that CPF will alter se-

rotonin-controlled behaviors and the serotonergic system, and that this will be seen transgenerationally and is influenced by changes in gene expression and epigenetic mechanisms. We have characterized the serotonin-controlled behaviors of enhanced slowing responses (ESR) via food deprivation, and basal slowing responses (BSR) under normal conditions for both wild type worms and mutant strains deficient in serotonin, dopamine, or both. Wild type worms display a significantly slower locomotion rate in their ($P < 0.0001$) when compared with their BSR by measuring either center point speed (fold change= 1.9) or absolute peristaltic speed (fold change 1.5). Other new insights into the behavior of mutants such as *mod-5* (deficient in serotonin) and *cat-2* (deficient in dopamine) reveal that *mod-5* wavelength shows no difference when compared to wild type for the BSR, while *cat-2* shows significantly (ESR = 1.27 fold change, BSR= 2.6 fold change) higher wavelength in both ESR and BSR($P < 0.0001$). This in-depth individual behavioral analysis and subsequent dose response study using our behavioral model we have developed is the first of its kind and will address a significant gap of knowledge into the transgenerational effects of serotonin modifying agents on behavior.

3040 Ultrastructural and Biochemical Alterations in Maneb-Treated Rat Hippocampal Astrocytes

M. Akhtar, and L. D. Trombetta. *St. John's University, Jamaica, NY.*

Maneb is a broad-spectrum manganese containing dithiocarbamate fungicide commonly used to control plant diseases on food and feed crops. There is increasing evidence that agricultural chemicals and other environmental contaminants, including metals such as manganese, are implicated in neurodegenerative diseases. In addition, there are several lines of evidence suggesting that Maneb exposure may play a role in the development of Parkinson's disease. Astrocytes play a critical role in normal brain physiology. This study evaluated Maneb-induced biochemical and ultrastructural changes in rat hippocampal astrocytes. Rat hippocampal astrocytes were exposed to 13.5 μM (LC_{50}) of Maneb for 24 hours. Biochemically, Maneb significantly increased lipid peroxidation, glutathione oxidation, SOD activity, and HO-1 and SP-70 levels as well as altered the regulation of stress-responsive and antioxidant gene expression in rat hippocampal astrocytes. Furthermore, Maneb treated cells had significantly elevated intracellular manganese and copper levels. These biochemical changes triggered apoptotic cell death via the intrinsic pathway as measured by cytochrome c release and activation of caspase-9 and -3/-7. Apoptosis was further confirmed by cellular externalization of phosphatidylserine and TUNEL assay. Evaluation of Maneb-induced ultrastructural changes revealed distorted and swollen mitochondria characterized by dilated and disrupted cristae and matrix dilution when compared to controls. Myelin whorl formation and non-membrane bound lipid droplets were also observed. In addition, the rough endoplasmic reticulum appeared deranged and swollen. Nuclei often appeared abnormal with a distorted shape and condensed chromatin. This study provides direct biochemical and ultrastructural evidence of Maneb-mediated mitochondrial toxicity in mammalian astrocytes.

3041 Mechanisms of Chlorpyrifos-Driven Programmed Cell Death in Neurons

F. L. Anderson, K. M. von Herrmann, A. L. Young, and M. C. Havrda. *Dartmouth College, Lebanon, NH.*

Age-related neurodegenerative diseases, including Alzheimer's disease and Parkinson's disease, are characterized by progressive neuronal loss observable in multiple brain regions. A small percentage of these cases can be attributed to genetic mutations however, the majority arise from unknown causes. Exposure to environmental toxicants, such as pesticides and heavy metals, is strongly associated with an increased risk of developing age-related neurodegenerative diseases. These epidemiologic data emphasis the need to characterize the molecular mechanisms underlying increased risk associated with widely used toxicants. Such foundational studies are anticipated to improve our understanding of the initiation and progression of neurologic disorders and inform the development of new treatments. Chlorpyrifos (CPF) is a widely used, commercially available, blood-brain-barrier permeant organophosphate pesticide. Exposure to CPF is associated with increased risk of developing multiple age-related neurodegenerative diseases, but the mechanisms of toxicity underlying CPF exposure in neurons are not completely understood. We conducted unbiased transcriptomic and ontologic analyses of CPF-exposed primary neuron cultures seeking pathways characterizing CPF-induced neurotoxicity. These studies identified the pro-apoptotic mediator *Bbc3/Puma* (Bcl-2 binding component-3/*p53* upregulated modulator of *a*poptosis) and other transcripts related to the greater *p53* pathway, as significantly elevated as the result of CPF exposure compared to vehicle-treated controls. We next cultivated primary cortical neurons isolated from WT and *Bbc3*$^{-/-}$ mice and discovered the IC_{50} of CPF to be significantly higher in neurons lacking *Bbc3* compared with WT controls. Real-time PCR analysis confirmed up-regulation of *Bbc3*, *p53*, and the *p53*-apoptotic pathway related gene *Pmaip1* (encoding the NOXA protein) resulting from CPF exposure in WT neuronal cultures, that was not observed in CPF-treated *Bbc3*$^{-/-}$ cultures. Further characterization of CPF-exposed WT and *Bbc3*$^{-/-}$ cultures identified cleavage of caspase 3 and PARP in WT cultures exposed to CPF, but not in identically treated *Bbc3*$^{-/-}$ cultures. Data suggest that *Bbc3* is a key node in a programmed cell death pathway initiated in neurons resulting from CPF exposure. Studies provide experimental evidence to support epidemiologic findings related to CPF and a platform for further analysis of cellular mechanisms related to disease-associated pesticides on the brain.

3042 A Cell Viability Study on the Effects of Glyphosate, Mancozeb, and Their Combination on Mouse Neuroblastoma Cells

H. A. Ebid, and L. D. Trombetta. *St. John's University, Queens, NY.*

The extensive application of pesticides results in increased human exposure to complex mixtures of these compounds. The toxicological effects of pesticides have long been studied. Most of the studies however are concerned with single pesticide exposures and there is a lack of information regarding the toxicity of pesticide mixtures. In this study we are examining the combination of two of the most widely used pesticides, Glyphosate and Mancozeb. Glyphosate is a systemic non-selective herbicide. Since its introduction in the 1970s, Glyphosate has been considered safe to mammals. Recent evidence however links Glyphosate to multiple adverse human health effects. Mancozeb is a broad-spectrum fungicide. Mancozeb has been associated with neurotoxicity, developmental toxicity, immunotoxicity and carcinogenicity. In this study we investigated the toxicity of Glyphosate and Mancozeb alone and in combination on the viability of mouse neuroblastoma (Neuro- 2A) cells. Cell viability was assessed using Trypan Blue Exclusion Assay. Neuro-2A cells were treated for 24 hours with Glyphosate alone (100μM, 500μM, 1000μM, 5000μM and 10,000μM) or Mancozeb alone (2μM, 4μM, 6μM, 8μM and 10μM). Glyphosate and Mancozeb treatments resulted in a significant reduction in cell viability at all concentrations when compared to control except Glyphosate 100μM and Mancozeb 2μM. Cells were also treated with combination of Glyphosate (100μM) and Mancozeb (6μM). Three forms of combination were used including Mancozeb (30 minutes) followed by Glyphosate (24 hours), Glyphosate (30 minutes) followed by Mancozeb (24 hours) or Glyphosate plus Mancozeb (24 hours). Glyphosate and Mancozeb combination treatments resulted in a statistically significant reduction in cell viability when compared to Glyphosate alone and Mancozeb alone treatments except for Glyphosate plus Mancozeb (24 hours) combination treatment, which was only statistically significant from Glyphosate alone treatments. From these results we concluded that Glyphosate and Mancozeb combinations, Mancozeb (30 minutes) followed by Glyphosate (24 hours) as well as Glyphosate (30 minutes) followed by Mancozeb (24 hours) are more toxic than Glyphosate alone and Mancozeb alone on the viability of Neuro-2A cells.

3043 Inhibition of Neurite Outgrowth upon Exposure to Chlorpyrifos

C. Powell, and M. Pomeroy-Black. *LaGrange College, LaGrange, GA.*

Chlorpyrifos is an organophosphate insecticide that has been shown to have toxic effects on the human nervous system. Research suggests that chronic, low dose exposure to chlorpyrifos contributes to Parkinson's disease and interferes with neurodevelopment. It was hypothesized that if dopaminergic neurons in culture were exposed to 2 μM, 10 μM, and 20 μM chlorpyrifos for 24 hours, then neurite outgrowth would decrease with increasing concentration. Cells were exposed to three concentrations of chlorpyrifos (2 μM, 10 μM, or 20 μM) and a control (0.02% ethanol). After 24 hours, the cells were fixed and microscopic images of neurites were captured. The results indicate that there was a concentration-dependent decrease in neurite outgrowth between the control and 2uM chlorpyrifos in comparison to both 10 μM and 20 μM chlorpyrifos. Finally, there was a significant decrease in neurite outgrowth between 10 μM and 20 μM chlorpyrifos. To investigate the role of specific proteins contributing to this effect, Western blot analysis on cell lysates was conducted. Analysis of the blots indicated no significant difference in α-tubulin concentration or PKC concentration. The data indicate that increased concentrations of chlorpyrifos result in significantly decreased neurite outgrowth but that neither α-tubulin nor PKC are significantly suppressed during this event. Decreased neurite outgrowth likely contributes to decreased neurotransmission of dopaminergic neurons, thereby contributing to the Parkinson's disease and delayed neurodevelopment.

3044 Mylein Degeneration Is Accompanied by Differential mRNA Expression of Basic Myelin Protein in the Central Nervous System of Hens Treated with Diisopropyl Phosphorofluoridate (DFP)

T. V. Damodaran[1], M. K. Attia[1], and M. B. Abou-Donia[2]. [1]*North Carolina Central University, Durham, NC; and* [2]*Duke University, Durham, NC.*

Diisopropyl phosphorofluoridate (DFP) produces organophosphorus-ester induced delayed neurotoxicity (OPIDN) in the hen, human and other sensitive species. We studied the effect of single dose of DFP (1.7 mg/kg/s.c.) on the level of myelin degeneration by advanced histological quantitative techniques and mRNA expression of Myelin Basic Protein (MBP) which is one of the components of myelin sheath by northern blotting. The hens were sacrificed at different time points i.e. 1, 2, 5, 10, and 20 days. Total RNA was extracted from the following brain regions: cerebrum, cerebellum, brainstem, and spinal cord. Northern blots prepared using standard protocols were hybridized with MBP as well as with beta-actin and 28S RNA cDNA (controls) probes. The results indicate a differential/spatial/temporal regulation of MBP levels in the highly susceptible tissues like brainstem and spinal cord while the resistant tissue cerebrum tissue showed generally increased or control levels in various time points. Histologically, the greatest amount of myelin disintegration was noted in the ventral tract caudally and in the dorso-ventral tract rostrally. Major degeneration of the myelin sheath was noted at 10 days post treatment and beyond. Two phases of myelin disintegration namely a) contraction myelin sheath and b) sheath disintegration were noted during earlier and later time points respectively. The distribution of the damage in the CNS followed the lumbosacral region of spinal cord leading to the anterior (ventral tract). The spino-cerebellar tract as well as posterior columns in the upper thoracic and cervical regions also showed myelin degeneration. Hence our results indicate differential expression of MPB accompanied by degeneration of myelin sheath is either one of the reasons for the development of OPIDN or the result of progressive changes taking place during OPIDN.

3045 Effects of Cyfluthrin on Gene Expression Profiling of Oxidative Stress Pathways in SH-SY5Y Cells

A. Anadón, I. Ares, J. Rodríguez, B. Lopez-Torres, M. Martínez, M. Martínez-Larrañaga, and M. Martínez. *Universidad Complutense de Madrid, Madrid, Spain.*

Exposure of humans to chemicals that negatively affects CNS is of concern. The worldwide application of pyrethroid insecticides necessitates an appraisal of their potential hazards to man and animals. Oxidative stress has been postulated to be one of the key contributors to dopaminergic neurodegeneration. The human dopaminergic neuroblastoma cell line, SH-SY5Y, is a commonly used cell line in studies related to neurotoxicity, oxidative stress, and neurodegenerative diseases. In this study, we show that the treatment of SH-SY5Y cells with the pyrethroid insecticide cyfluthrin in a dose dependent manner (1-25 μM) after 24 h incubation period, led to a robust cellular ROS formation and an increase of MDA and NO levels. Gene expressions linked to apoptosis, proinflammation and oxidative stress also were evaluated. Quantitative Real-Time PCR assays for Bax, Bcl-2, Casp-3, BNIP3, AKT1, p53, APAF1, NFκB1, TNFα, and Nrf2 mRNA were performed to analyze mRNA gene expressions. Moreover, this study analyzed, by Real-Time PCR array, the expression of 84 key genes related to oxidative stress (antioxidants, ROS metabolism and pathway activity signature genes) after cyfluthrin exposure. It was observed in the RNA samples from cyfluthrin treated SH-SY5Y cells a greater or lower fold change than 3 in comparison with the control in the expression of the 13 genes included in PCR array. Our results showed that the major over-expressed genes by cyfluthrin were CYBB, DUOX1, DUOX2, AOX1, BNIP3, HSPA1A and NOS2. The major over-expression was detected for CYBB gene (7.35-fold); melatonin (1 μM) provided a significant decrease on mRNA expression level of CYBB (7.35-fold to 2.53-fold). According to our experimental data, the possibility to use measurement of CYBB expression as an oxidative biomarker of the pyrethroid intoxication is a key to be clarified. *Work supported by Project Ref. RTA2015-00010-C03-03 from Ministerio de Economía, Industria y Competitividad, Spain.*

3046 Interethnic Human Differences in the Biotransformation of Chlorpyrifos and Resulting Acetylcholinesterase Inhibition

S. Zhao[1], L. Kamelia[1], R. Boonpawa[2], S. Wesseling[1], B. Spenkelink[1], and I. M. Rietjens[1]. [1]*Wageningen University and Research, Wageningen, Netherlands; and* [2]*Kasetsart University, Sakon Nakhon, Thailand.*

Chlorpyrifos (CPF) is a well-known insecticide used all over the world. The acute toxicity upon exposure to CPF is due to inhibition of acetylcholinesterase (AChE). The aim of the present study was to assess the interethnic differences in the biotransformation of CPF and resulting red blood cell (RBC) AChE inhibition in both the Chinese and the Caucasian population by using ethnic-specific physiologically based kinetic (PBK) models for CPF and reverse dosimetry. In this way, an *in vitro* concentration response curve for RBC AChE inhibition was converted to an *in vivo* dose response curve for both populations. The extrapolated RBC AChE inhibition dose response curve revealed that the Caucasians were predicted to be 4- to 7-fold more sensitive to CPF-induced *in vivo* RBC AChE inhibition than the Chinese. This interethnic difference was mainly due to the fact that the Caucasians appear to be more efficient in the bioactivation of CPF to chlorpyrifos-oxon (CPO) but less efficient in detoxification of CPO to 3,5,6-trichloro-2-pyridinol (TCPy). Altogether, the developed ethnic-specific PBK models for CPF can predict the human interethnic differences in sensitivity towards CPF exposure, with the Caucasians being more sensitive than the Chinese showing similar endogenous levels of CPO and AChE inhibition at lower dose levels.

3047 Spatiotemporal Phosphoprotein Signaling in a Mouse Model Using Corticosterone and Relevant Organophosphates

J. A. Penatzer[1], N. Prince[1], K. A. Kelly[2], L. T. Michalovicz[2], J. P. O'Callaghan[2], and J. W. Boyd[1]. [1]*West Virginia University, Morgantown, WV; and* [2]*NIOSH, Morgantown, WV.*

Each year, 3 million people are exposed to organophosphates, contributing to approximately 300,000 deaths; many do not report appreciable acute effects immediately following exposure, but report symptoms of adverse neurological effects years later, as is the case for the 250,000 veterans from the 1991 Persian Gulf War who suffer from Gulf War Illness (GWI). Previous GWI research has focused on models that dose with acetylcholinesterase (AChE) inhibitors (chemical warfare agents and pesticides) and exogenous corticosterone (CORT), to simulate high stress, in efforts to mimic chronic neuroinflammation associated with GWI symptomology. An investigation into early phosphoprotein responses in the cortex and striatum were performed to better understand the similarities of the early cellular changes involved in these etiologies. Using a mouse model, adult male C57BL/6J mice were exposed to CORT in the drinking water for 7 days followed by a single injection of diisopropyl fluorophosphate (DFP; 4.0 mg/kg, i.p.) or chlorpyrifos oxon (CPO; 8.0 mg/kg, i.p.) on day 8 and euthanized 30 min, 2 h, and 24 h post-injection via focused microwave irradiation. To evaluate brain-region-specific effects, 20+ post-translationally modified protein targets were measured using a multiplex ELISA (e.g., ERK1/2, IkB-a, JNK, MEK1) for both dosing regimens. Several phosphoprotein responses (ZAP70 and JNK) were found to be significantly increased ($p<0.05$) for CORT+CPO exposure, but not for CORT+DFP in both brain regions. Conversely, CREB and ERK were significantly phosphorylated for DFP exposures relative to CPO. This suggests the neuroinflammatory response in this mouse model may be driven by off-target mechanisms of AChE exposure. Further investigation of other relevant exposures and their phosphoprotein signaling effects must be performed to better understand potential biomolecular drivers of GWI-like symptomology.

3048 RNA-seq Evaluation of DDT Exposure in the Hippocampus of Humanized APOE Mice

A. Eid[1], I. Mhatre[1], R. P. Hart[2], and J. R. Richardson[1]. [1]*Florida International University, Miami, FL; and* [2]*Rutgers, The State University of New Jersey, Piscataway, NJ.*

The Apolipoprotein 4 (APOE) gene variant is the strongest genetic risk factor for late-onset Alzheimer's disease (LOAD). However, it is not entirely predictive of LOAD, and emerging evidence points to environmental factors in the etiology of disease. We have previously reported that individuals with increased levels of the primary metabolite of the pesticide dichlorodiphenyltrichloroethane (DDT) and harboring an APOE4 allele performed worse on a task of cognitive function. In the present study, we utilized male and female targeted replacement humanized APOE3 (E3) and APOE4 (E4) mice to identify the effects of DDT exposure on gene expression changes in the

hippocampus. Three-month-old E3 and E4 mice were exposed to 3 mg/kg DDT by oral gavage every 3 days for 5 months. Animals were euthanized at 8 months and RNA-sequencing was performed on hippocampal samples using the NovaSeq 6000. Data were analyzed using DESeq2 in R. Contrasts were made within each genotype across sex, between the genotypes, and across exposure groups. Each contrast underwent a Wald test, and a likelihood-ratio test for significance and only significant transcripts were used for g:profiler analysis. Between males and females, within each genotype, there were 13 (E3) and 36 (E4) differentially regulated biological process pathways. Between each genotype, within each sex, there was 1 (males) and 49 (females) differentially regulated biological process pathways. There were no significantly altered biological processes in any of the DDT exposed animals compared to their respective control within each sex and genotype. However, when analysis was restricted to DDT-treated E4 and E3 males, there were a total of 51 downregulated biological process pathways in the E4 males compared to the E3 males. These pathways included cell-cell signaling ($P_{adj}=1.1\times10^{-3}$), chemical synaptic transmission ($P_{adj}=7.3\times10^{-3}$), regulation of cation channel activity ($P_{adj}=1.5\times10^{-2}$) and regulation of the action potential ($P_{adj}=1.8\times10^{-2}$). These data suggest a gene x environment interaction with exposure to DDT and the APOE4 genotype, that occurs exclusively in males and affects pathways consistent to the known effects of DDT on the neuron. *Supported in part by NIH R01ES026057.*

3049 Epigenetic Histone Acetylation and BDNF Dysregulation in a Rat Model for Gulf War Illness

A. Ribeiro, M. Kronfol, F. Jahr, E. Hawkins, R. Blair, J. McClay, and L. S. Deshpande. *Virginia Commonwealth University, Richmond, VA.*

Around 35% of the returning soldiers from the First Gulf War exhibit chronic multi-symptom illness also known as the Gulf War Illness (GWI), chief among which are the neurological morbidities of depression, mood disorders, and cognitive impairment. While the causes for GWI are known, the persistence of GWI is still not fully understood. Epigenetic mechanisms respond to external stimuli such as the environment and experiences, and the effects of such exposures can become embedded in the genome to produce long-lasting changes in cellular regulation. Epigenetic processes include chemical modifications including DNA methylation and histone acetylation and deacetylation. DNA methylation changes have been reported in GWI, however, the role of histone modifications in GWI is ill understood despite its importance as a major epigenetic mechanism for neurological disorders. Male Sprague-Dawley rats (3-m, n= 30) were exposed to DFP (0.5 mg/kg s.c., 5-d) or ice-cold PBS and, 6-m later assessed for mood and memory function using a battery of rat behavioral assays. Rats were then sacrificed and brains harvested for protein studies and epigenetic analyses. Histone acetylation and deacetylation is catalyzed by two enzymes: histone acetyltransferase (HAT) and histone deacetylase (HDAC) activity. Antibody-specific western blotting studies revealed a significant upregulation in HDAC1 protein in GWI rats compared to age-matched control rats indicative of possible increase in HDAC activity in GWI. The brain derived neurotrophic factor (*Bdnf*) gene has been implicated in many neurological disorders that share symptomatology with GWI neurological symptoms. We conducted a locus-specific study of this epigenetic modification using chromatin immunoprecipitation (ChIP) and observed decreases in H3K9ac at the *Bdnf* promoter adjacent to exon 4. Such a decreased histone acetylation would indicate lower levels of *Bdnf* gene transcription. Indeed, a significant decrease in Bdnf protein was subsequently noted in GWI rat hippocampus compared to age-matched control rats (n= 8 rats/condition, t-test, $p<0.05$). Increased HDAC activity and aberrant BDNF expression could underlie pathological synaptic plasticity in GWI rat model that expresses itself as GWI neurological symptoms. Our studies further indicate that HDAC inhibitors could prove to be effective therapies for GWI behavioral symptoms. These studies are currently underway in our laboratory.

3050 Development and Validation of a Simple High-Resolution Liquid Chromatography-Orbitrap Mass Spectrometry Method for the Determination of Six Strobilurin Fungicides in Mouse Brain Tissue

P. E. Dunlap[1], Z. Zhou[1,2], D. M. Crizer[1], G. M. Childers[1], C. A. McPherson[1], G. Harry[1], and M. J. DeVito[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; and [2]Southern Medical University, Guangzhou, China.*

Strobilurin fungicides are a class of broad-spectrum fungicides widely used to control diseases, boost yields, and improve quality/production of crops in modern agriculture. Although they are bio-degraded in about 21 days, the inappropriate and widespread use, and high residue rates of these chemicals, may cause high exposure and potential toxicity to humans. These fungicides are of neuro, reproductive, developmental, and immune toxicity concern. To better explore the potential toxicity of these substances, a fast and simple analytical approach is essential. In this study, a high-resolution liquid chromatography orbitrap mass spectrometry method was developed and validated to determinate six strobilurin fungicides, azoxystrobin, kresoxim-methyl, picoxystrobin, trifloxystrobin, dimoxystrobin, and fluoxastrobin in mouse brain tissue. About 20 mg of brain tissue was accurately weighed into a lysing matrix tube (MP Biomedicals, lysing matrix D) and then homogenized after adding water and acetonitrile in a volume ratio of 20/80. Samples were then centrifuged and the supernatant was removed for analysis. The samples were separated on a Thermo Hypersil Gold aQ (100 × 2.1mm, 1.9µm) column using an isocratic method with mobile phase consisting of water and acetonitrile (63/27), containing 0.1% formic acid. The flow rate was 0.3 mL/min with 4 min of total run time. Target compounds were detected on a Q-Exactive Orbitrap mass spectrometry in targeted-SIM/dd-MS^2 mode. The method was validated in terms of limit of detection (LOD), limit of quantitation (LOQ), linearity, precision, accuracy and matrix effects. The LODs and LOQs were about 0.02 ng/mL and 0.1 ng/mL based on 3 and 10 times of signal-to-noise, respectively. The linearity is excellent with a $R^2 > 0.98$ over the concentration range of 1.0 - 100 ng/mL. The recoveries and matrix effects were 91.4 -115.5% and 82.6-108.0%, respectively. The method is precise with an RSD < 15%. The method was applied to analysis of six strobilurin fungicides in mouse brain tissue after dosing and showed good performance. This approach is very simple, fast and sensitive, and will be very helpful for further toxicological studies of strobilurin fungicides.

3051 Mitochondrial Dysfunction Induces Epigenetic Dysregulation by H3K27 Hyperacetylation to Perturb Active Enhancers in Parkinson's Disease Models

M. Huang[1], D. Lou[2], A. Charli[1], D. Kong[2], H. Jin[1], V. Anantharam[1], A. Kanthasamy[1], Z. Wang[2], and A. G. Kanthasamy[1]. *[1]Iowa State University, Ames, IA; and [2]Johns Hopkins University, Baltimore, MD.*

Genetic mutations explain only 10-15% of cases of Parkinson's disease (PD), while an overriding environmental component has been implicated in the etiopathogenesis of PD. But regardless of where the underlying triggers for the onset of familial and sporadic PD fall on the gene-environment axis, mitochondrial dysfunction emerges as a common mediator of dopaminergic neuronal degeneration. Herein, we employ a multidisciplinary approach to convincingly demonstrate that neurotoxicant exposure- and genetic mutation-driven mitochondrial dysfunction share a common mechanism of epigenetic dysregulation. Under both scenarios, lysine 27 acetylation of likely variant H3.2 (H3.2K27ac) increased in dopaminergic neuronal models of PD, thereby opening that region to active enhancer activity via H3K27 hyperacetylation. These vulnerable epigenomic loci represent potential transcription factor motifs for PD pathogenesis. We further confirmed the mitochondrial dysfunction induced H3K27ac during neurodegeneration in *ex vivo* models of PD. Our results reveal an exciting axis of 'exposure/mutation-mitochondrial dysfunction-metabolism-H3K27ac-transcriptome' for PD pathogenesis. Collectively, the novel mechanistic insights presented here interlinks mitochondrial dysfunction to epigenetic transcriptional regulation in dopaminergic degeneration as well as offer potential new epigenetic intervention strategies for PD. *Support: R01ES027245, R01ES026892, R01NS100090 and R01NS088206, Eugene and Linda Lloyd Endowment and Armbrust Endowment.*

3052 Bisphenol A Neurotoxicity in Human Neuroblastoma Cells: Role of Alpha-Synuclein Aggregation and Mitochondrial Dysfunction

B. Bediako, T. Hamad, A. Ishaque, and A. Elnabawi. *University of Maryland Eastern Shore, Princess Anne, MD.*

Bisphenol A (BPA) is considered a major public health concern. Exposure to even a low dose of BPA has been linked to diverse negative pathological, cellular, and molecular effects. Synucleinopathies are a group of human neurodegenerative diseases characterized by the accumulation of α-synuclein in various regions of the central and peripheral nervous system. α-Synuclein is involved in the pathogenesis of misfolding-related neurodegenerative diseases, in particular Parkinson's disease. A misfolding event leads to the formation of oligomers, which are believed to result in cell toxicity and eventually lead to the death of neuronal cells. Neurodegeneration has increasingly been associated with mitochondrial dysfunction and inhibition of the electron transport chain. Neurons require high levels of energy in order to operate. The production of ATP in neuronal cells may be reduced due to mitochondrial dysfunction. Direct association of α-synuclein with mitochondria has been repeatedly and constantly observed in model cells and in different brain re-

gions of the transgenic mouse model. This study was aimed at examining the cellular and molecular mechanisms that might underlie BPA-induced neurodegeneration. Human neuroblastoma SH-SY5Y cells were exposed to various concentrations of BPA in the presence and absence of α-synuclein. Cell viability, mitochondrial dysfunction, and α-synuclein intracellular aggregation were evaluated. Exposure to BPA for 3h resulted in a significant decrease of mitochondrial membrane potential similar to CCCP, the mitochondrial uncoupler positive control. The cellular level of ATP was significantly reduced after exposure to BPA for 24h. Incubation of α-synuclein with increasing BPA concentrations *in vitro* resulted in a progressive acceleration of α-synuclein-BPA complex formation in a concentration-dependent manner. Treatment of SH-SY5Y cells for 48h with α-synuclein showed significant neurotoxic effect with cell death. Furthermore, BPA-treated cells showed increased level of α-synuclein aggregation indicating that the ability of BPA to promote aggregation may contribute to neurodegeneration. These results suggest that impairment of mitochondrial function and enhancement of α-synuclein aggregation represent potential mechanisms underlying BPA neurotoxicity. *Supported by Title III.*

3053 Power Spectrum Analysis of EEG in a Translational Nonhuman Primate Model after Chronic Exposure to Low Levels of the Common Marine Neurotoxin Domoic Acid

R. L. Petroff[1], M. Murias[2], B. Crouthamel[1], N. McKain[1], K. S. Grant[1], S. Shum[1], J. Jing[1], N. Isoherranen[1], and T. M. Burbacher[1]. *[1]University of Washington, Seattle, WA; and [2]Northwestern University, Chicago, IL.*

Domoic acid (DA), the focus of this research, is a marine algal neurotoxin and epileptogen produced by species in the genus *Pseudo-nitzschia* and found in finfish and shellfish across the globe. The current regulatory limit for DA is set to protect humans from acute toxic effects, but there is a growing body of evidence suggesting that regular consumption of DA contaminated seafood at or below the regulatory limit may lead to subtle health effects in young children and older adults. In previous research from our laboratory, a translational nonhuman primate model was used to assess the reproductive and neurodevelopmental effects of chronic DA exposure near the regulatory limit. Healthy adult female *Macaca fascicularis*, orally administered DA at levels near the current regulatory limit (0.075 and 0.15 mg/kg/day) for at least 9 months, showed signs of unanticipated neurotoxicity; intention tremors while performing a reaching task. This neurobehavioral effect was significantly related to the DA dose, but the biological underpinnings of the behavior were largely unknown. The present research is the first to investigate how *in vivo* neurological function is related to chronic DA exposure and DA-intention tremors, using sedated, quantitative electroencephalography (qEEG). In the EEG recordings, we captured the never before documented electrooculographic (EOG) artifacts in this macaque species. Analysis of dose-response relationships suggests that neuroelectrical function of the 0.15 mg/kg group is significantly decreased in the delta range (1-4 Hz, $p < 0.05$), as well as significantly increased in the theta range (5-8 Hz, $p < 0.05$). Tremors, however, were not associated with any measures of the power spectrum, suggesting that the observed neurotoxicity may not be early signs of epileptic activity that results from acute DA exposures. This research is the first to utilize *in vivo* EEGs in a translational, noninvasive toxicological primate study, showcasing how EEG can be successfully implemented on the small nonhuman primate model. Results from the study reveal new insight into our understanding of DA toxicities after exposure to levels found in the real-world and will be an important component of DA research needed to best protect public health across the globe.

3054 Chemical Screen of Human iPSC-Derived Neurons for Mitochondrial Dysfunction

P. P. Kakad[1], S. P. Sherman[1], Y. Chushak[2], H. A. Pangburn[2], J. M. Gearhart[2], and A. G. Bang[1]. *[1]Sanford Burnham Prebys Medical Discovery Institute, La Jolla, CA; and [2]Henry M. Jackson Foundation for the Advancement of Military Medicine, Dayton, OH.*

Neurons have high metabolic rates that increase their vulnerablity to toxic mitochondrial insult, resulting in cell dysfunction and death due to reactive oxygen species (ROS) generation and insufficient levels of energy. Here, we report a high throughput, first line evaluation based on hiPSC-derived neurons to identify chemicals that cause mitochondrial dysfunction. To test this approach, a library of 73 suspected or known neurotoxic chemicals was assembled, representing diverse chemical classes. Chemicals were selected from ToxCast/Tox21 to allow comparisons with public data bases, and to support quantitative structure activity relationship (QSAR) modeling. We utilized iCell neurons (Fuji Film Cellular Dynamics, Inc.), an hiPSC-derived population of primarily GABAergic neurons. High-content image-based screening was performed in dose response, on 384 well-plates using a live cell, acute exposure, multiplexed assay for mitochondrial membrane potential (MMP) and generation of ROS. In parallel, we also screened for effects on neurite growth in a fixed cell assay. For mitochondrial and neurite assays, nuclear parameters, count, intensity, area, and shape, were monitored as measures of cytotoxicity. Of the 73 chemicals tested, we identified 34 hits in the mitochondrial assay, 3 of which were also identified as hits in the neurite assay. Hits depolarized MMP and/or increased ROS at concentrations lower than those that decreased cell viability based on nuclear measures. Our hit set contains both chemicals that were previously reported to be mitochondrial disrupters, as well as those that are novel. Companion QSAR mitochondrial toxicity models built on a ~7000 compound Tox21 mitochondrial toxicity library was applied to these results and had a high predictability for compounds screened in this human neuron assay system. Future development of this scalable source of human neurons, in terms of neuronal sub-type, and complexity of phenotypic read-outs, will provide a powerful approach to determine neurotoxicity of large collections of chemicals, especially when combined with *in silico* QSAR analyses.

3055 Altered BCRP Transport Activity at the Blood-Brain Barrier following 2,4,6-Tribromophenol Exposure

R. E. Cannon, A. W. Trexler, G. A. Knudsen, and L. S. Birnbaum. *NIEHS/NTP, Research Triangle Park, NC.*

The brominated chemical, 2,4,6-Tribromophenol (TBP, CAS No. 118-79-6), is used in the production of flame-retardant epoxy resins and wood preservatives. TBP is a byproduct released into the environment by food processing and water treatment facilities. TBP is found in shellfish and predatory fish and in humans TBP has been detected in blood and breast milk. Mechanistically, TBP interferes with estrogen and thyroid hormone signaling pathways, which are known regulators of ATP binding cassette (ABC) transporters of the blood-brain barrier (BBB). The BBB resides in the brain microvasculature is a highly regulated two-component system containing tight-junction proteins and ABC efflux transporters. Using a steady-state confocal microscopy-based assay, this study examined the effects of TBP (0.1 nM-100 nM) on the transport activity and expression of Breast Cancer Resistance Protein (BCRP), and Multidrug Resistance Associated Protein 2 (MRP2) at the BBB. BCRP and MRP2 transport activities were measured in rat brain capillaries after *ex vivo* and *in vivo* TBP exposures. Freshly isolated rat brain capillaries treated *ex vivo* with TBP (0.1-100 nM) for 4 h produced no significant changes in MRP2 transport activity in either sex. However, exposing capillaries *ex vivo* to similar TBP concentrations significantly decreased BCRP transport activity in both males and females. Time course studies revealed that the TBP mediated decreases in BCRP transport activity in both males and females occurred two hours after TBP (100nM) exposure. *In vivo* TBP dosing by oral gavage at 30 pmol/kg, 300pmol/kg, and 3nmol/kg significantly decreased BCRP transport activity in both sexes relative to vehicle controls. Immunochemistry and western blots analysis of brain capillaries revealed no changes in BCRP protein levels in TBP treated compared to untreated controls. This work shows that relatively low concentrations of TBP (0.1-100 nM) alters ABC transporter activity at the BBB which can disrupt brain homeostasis, hinder drug delivery, and increase the likelihood of CNS exposure to harmful xenobiotic toxicants. *This research was supported by the Intramural Research Program of NIH/NCI [Project ZIA BC 011476] and does not necessarily represent US EPA policy.*

3056 Repeated Exposure of 3,4-Dichloro-1-Butene Leads to Decreased Grip Strength and Alters Peripheral Nerve Function and Somatosensory Evoked Potentials in Adult Male Long-Evans Rats

G. Jung, K. McDaniel, and D. Herr. *US EPA, Research Triangle Park, NC.*

3,4-Dichloro-1-butene (DCB) is used in manufacturing rubber and cosmetics. An analysis using Hard-Soft Acid-Base (HSAB) concepts predicted that DCB will react with cellular proteins and potentially cause neurotoxicity after repeated exposure. Adult male Long-Evans rats were treated with DCB via oral gavage (corn oil vehicle) using concentrations of 0, 100, 175, or 225 mg/kg/day for 8 weeks. Behavioral observations (open field activity, foot splay, grip strength) were conducted weekly. Peripheral nerve function was evaluated *in vivo* with nerve excitability testing, consisting of compound muscle action potential (CMAP) or nerve action potential recordings by stimulating the tail (motor and mixed) nerves and sciatic (motor) nerve. Compound nerve action potentials (CNAP) and nerve conduction velocity (NCV; tail nerves) were assessed *in vivo*, along with somatosensory function by recording evoked potentials (SEPs) over the cortex and cerebellum. Animals treated with DCB had a dose-related suppression in weight-gain compared to controls throughout the study. Behavioral tests indicated a reduction in forelimb and hindlimb

grip strength in the high-dose group. At all doses, nerve excitability data showed an effect on tail mixed nerve action potentials, suggesting alterations to nerve fibers that were consistent with neuronal depolarization (altered Na^+ conduction) and possible K^+ channel activity. In the high-dose group, CNAP recordings showed an increase in amplitude and NCV, possibly due to a loss of small nerve fibers. A reduction in latency was seen in the SEP cerebellum recordings, suggesting faster conduction and/or less inhibitory input. These changes further support the possibility that small afferent nerve fibers were altered. DCB treatment was associated with the development of an additional peak (N1-P1) at the front of the somatosensory cortical response, changes which could be related to effects at the cortical level or possibly a splitting of the afferent volley. Overall, this data indicates that treatment with DCB over this dose range and duration influences peripheral nerve and somatosensory function. Future studies should include histopathology to assess nerve fiber degeneration. *This is an abstract of a proposed presentation and does not necessarily reflect US EPA policy*.

PS 3057 Exploring the Effects of Developmental Exposure to Flame Retardant Mixture and Components on Adult Wistar Rat Behavior

S. K. Witchey, L. Al Samara, and H. B. Patisaul. *North Carolina State University, Raleigh, NC.*

FireMaster 550 (FM550) is one of the most commonly used fire retardants (FR) on foam-based furniture and baby products. This commercial mixture includes 2 brominated compounds, 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (EH-TBB) mixed with bis (2-ethylhexyl) tetrabromophthalate (BEH-TEBP), and two organophosphates, triphenyl phosphate (TPhP) and assorted isopropyl triphenylphosphate (ITP) isomers, in the ratio: 36% EH-TBB, 14% BEH-TEBP, 18% TPhP and 32% ITPs by weight. As an additive FR, components of FM550 are readily leaching from consumer goods with detectable levels found globally in indoor dust, indoor/outdoor air, aquatic biota and food leading to widespread human exposure. Due to the structural similarities with known neurotoxicants and endocrine-disrupting chemicals (EDCs), including polybrominated diphenyl ethers (PBDE) and organophosphate pesticides, this is of great concern. Previously our lab demonstrated sex specific behavioral outcomes following developmental exposure to FM550 with males displaying increased anxiety and females being hyperactive. We are now exploring the relative contributions of the FM550 components on vulnerable brain and placental endpoints. The present, ongoing, studies focus on adult behaviors. Female Wistar rats were exposed to either vehicle, 1000µg brominated mixture (EH-TBB and BEH-TEBP), 1000µg ITP mixture or 2000µg FM550 mixture once daily from gestation day 0 to postnatal day 21. To monitor growth, all female and male offspring weights are collected regularly. Beginning on PND 65, at least one male and one female per litter are being evaluated using an array of behavior tests to assess repetitive impulsive behaviors, activity levels, social behaviors, anxiety-like behavior and short and long-term memory. Preliminary analysis suggests increased running wheel activity in males and females exposed to FM550 or the ITP mixture. These outcomes are helping to elucidate which FM 550 components contribute to sex-specific effects of exposure.

PS 3058 Addressing the Impact of Polychlorinated Biphenyl Environmental Mixtures on Ryanodine Receptor Activity

A. C. Campbell, and E. B. Holland. *California State University Long Beach, Long Beach, CA.*

Polychlorinated biphenyls (PCBs) are halogenated aromatic hydrocarbons with 209 congeners. They were commonly used in commercial and industrial products until their ban in 1979 due to the rising concerns over their adverse effect on humans and the environment. Despite the ban, PCB congeners are still found in the air, in environmental water, on sediment, and in organismal and human samples. Some PCB congeners can alter the activity of ryanodine receptors (RyR), a Ca^{2+} channel important for neuronal and muscle cell Ca^{2+} homeostasis. Most studies focus on the effect of individual PCBs on RyR activity, but PCBs are found in mixtures in the environment. The aim of this study is to address the additivity of environmental mixtures of PCBs on RyR activity using radio-ligand binding assays. Currently, the binding assay was validated in a crude protein preparation and has confirmed that the highly active PCB 95 causes a 700% increase in activity at the ryanodine receptor. The development of a sucrose gradient is underway to further purify the crude protein in order to isolate the target ryanodine receptor. Based on previous research, the developed hypothesize predicts that PCBs will act additively towards RyRs, providing more insight into the influence of environmental mixtures on RyR based cellular pathways and organismal physiology. *Acknowledgements: This research was supported by the National Institute of General Medical Sciences of the National Institutes of Health under Award Numbers; UL1GM118979; TL4GM118980; RL5GM118978.*

PS 3059 Whole Genome Transcriptome Analysis in a Genetic Model of Gulf War Illness

B. C. Jones[1], L. Lu[1], F. Xu[1], D. Ashbrook[1], D. B. Miller[2], J. P. O'Callaghan[2], M. K. Mulligan[1], and R. W. Williams[1]. *[1]University of Tennessee Health Science Center, Memphis, TN; and [2]NIOSH, Morgantown, WV.*

Gulf War illness (GWI) affected up to 30% of the nearly one million personnel sent to the Persian Gulf in 1991. The probable cause was exposure to organophosphorus compounds coupled with high circulating glucocorticoids as would be expected in a combat theater. Previously, we developed a mouse model consisting of 7 days of exposure to corticosterone in the drinking water followed by injection with diisopropylflurophosphate (DFP, surrogate for sarin) and assessment of pro-inflammatory cytokines in frontal cortex and hippocampus 6h after DFP treatment. In order to assess genetic-based individual differences in susceptibility to developing GWI, we applied the model to male and female C57BL/6J and DBA/2J mice. Consequently we observed wide-genetic differences in pro-inflammatory gene expression by qPCR in the prefrontal cortex. We then subjected the prefrontal cortex to genome-wide transcriptome response by RNA-seq, comparing the combined corticosterone-DFP treatment. Gene ontology analysis showed altered immune function and apoptosis as the top systems affected. We also verified a previous nomination of Spondin 1 and ILb1 as candidate genes underlying individual differences in susceptibility. *This research was supported in part by CDMRP grant W81XWH-17-1-047.*

PS 3060 Assessing the Differential Sensitivities of a Microelectrode Array Assay and a Neurite Outgrowth Assay for Detecting CNS Liabilities Using a Set of Neurotoxic and Seizurogenic Compounds

C. J. Strock, S. Qin, S. Jagtap, Y. Feng, and J. Bradley. *Cyprotex US LLC, Watertown, MA.*

Domoic acid is a neurotoxin first associated with the poisoning of 107 individuals and three subsequent deaths on Prince Edward Island in 1987 after these individuals consumed mussels containing this toxin. Due to its neurologic adverse effects, including memory loss, the illness was called amnesic shellfish poisoning. The toxin has since been attributed to the diatom, *Nitzschia pungens* f. *multiseries*, which was ingested by the mussels during normal filter feeding. In our lab, we use domoic acid as a tool compound when testing neurons on a microelectrode array (MEA) platform (Axion Biosystem's Maestro). Domoic acid completely eliminates all spontaneous spike activity when treating neurons at concentrations > 1 µM. When tested in a neurite outgrowth assay, using a high content imager (ArrayScan VTi), domoic acid does not affect cell health or neurite outgrowth when tested up to 10 µM for 72 hours. We tested various neurotoxins and seizurogenic compounds on the MEA platform and in the neurite outgrowth assay to the compare results and assay sensitivities. The antipsychotic haloperidol demonstrated seizurogenic liabilities at 3.16 µM on the MEA but had an IC50 of > 30 µM in an HCS assay. $GABA_A$ antagonist, picrotoxin, has a seizurogenic MEA profile as low as 0.2 µM but does effect cell health and neurite outgrowth at concentrations up to 10 µM. Chlorpromazine, on the other hand, has a seizurogenic profile and effects cell health and neurite outgrowth at similar concentrations (3 µM). With the results from domoic acid, haloperidol, picrotoxin, chlorpromazine and 6 additional controls compounds, we have determined that the MEA platform is more sensitive to detecting electrophysiological CNS liabilities than the neurite outgrowth assay. Alternatively, compounds which affect neurons by non-electrophysiological cytotoxic effects can be detected more sensitively than the acute MEA assay. Therefore, an effective overall strategy would be to test compounds for safety in both assays.

3061 Neurotoxicity of Diethylene Glycol in a Rat Model

C. Jamison, J. Fitzgerald, M. McKinney, H. Mitchell, B. Latimer, R. Dayton, and K. McMartin. *Louisiana State University Health Sciences Center Shreveport, Shreveport, LA.*

Diethylene glycol (DEG) can be found in consumer products, but can also be an adulterant in medicines by acting as counterfeit glycerin. DEG poisonings have been characterized predominately by acute kidney injury (AKI), but have also been known to affect the nervous system via delayed neurological sequelae such as decreased reflexes, face and limb weakness, or quadreparesis, as observed in a patients 2-7 days after DEG ingestion. Characterizing these poorly understood neurological symptoms of DEG poisonings in an animal model can clarify the overall toxicity and make mechanistic connections between the kidney injury and neuropathy. Male Wistar-Han rats were administered by oral gavage a water control or doses of 4 - 6 g/kg DEG every 12 or 24 h and monitored in metabolic housing for up to 7 days. Urine was collected every 12 h and endpoint blood and cerebrospinal fluid (CSF) were collected for renal plasma biomarkers and total protein estimation, respectively. Motor function tests were conducted before and after treatment. Kidney, brain, and spinal cord tissue were harvested after euthanasia for later pathology analysis. Of the 29 rats that were treated with DEG, 8 developed AKI with confirmation by renal plasma biomarkers. AKI primarily occurred after doses that were administered every 12 h. There was a marked increase in renal DGA accumulation in rats that developed AKI, compared to rats without AKI, confirming the role of DGA in the nephrotoxicity. The level of DEG in all treated animals stayed in the same range (15-25 mg/mL), with no obvious differences between rats with and without AKI. The total protein content of CSF in rats with AKI was significantly higher than controls and rats without AKI, indicating the first evidence of nervous system damage from DEG treatment in an animal model. Significant decreases in grip strength as well as in locomotor and rearing activity were observed in rats with AKI compared to controls and to rats without AKI. Initial pilot studies did not show dramatic changes in myelination (Luxol fast blue) in animals with elevated CSF protein, compared to controls or to unaffected but treated animals. The observation of increased CSF protein and motor function deficits, only in rats with AKI, indicate the development of neurotoxicity in this subacute animal model and strongly suggest that kidney injury needs to occur before neurological symptoms are observed. *Funding Source: American Chemistry Council and NIH (R15 ES029704).*

3062 Environmental Polychlorinated Biphenyls Mixtures Inhibit the Dopamine Transporter

J. A. Griffin, and E. Holland. *California State University Long Beach, Long Beach, CA.*

Dopamine is a monoamine transmitter that contributes to the motor and reward system in in the body. When neurons experience a change in dopamine availability it can cause symptoms of addiction, attention deficit hyperactivity disorder (ADHD), and Parkinson's disease. Polychlorinated biphenyls (PCBs) congeners are man-made environmental pollutants that disrupt the dopamine transporter (DAT) that is responsible for dopamine uptake from the synaptic cleft. When DAT is altered it may lead to altered cognitive proficiency. To date 46 non-dioxin like (NDL) PCB congeners have been found to alter DAT activity and include those highly chlorinated in the ortho position. NDL PCBs are present in the environment as mixtures; however, currently how these mixtures contribute to altered activity is currently unknown. The focus of this study is to examine the activity of PCBs in binary and complex mixtures towards DAT. I will use radioligand binding assay in female rat synaptosomes, with [3H] WIN- 35, 428 in the presence or absence of single PCBs or the mixture there of. Preliminary data confirms the inhibitory activity of NDL PCB congener PCB 95. The binding assay inhibitory concentrations (IC50) from this work and that of others will then be used to develop and apply a neurotoxic equivalency scheme (NEQ) to published PCB mixtures concentration to predict DAT activity. Preliminary applications of a DAT NEQ based on the highly potent PCB 110, found that the serum of children serum in East Chicago had a NEQ of 10.73 nanograms per gram. This NEQ represents a measurement of neurotoxicity relative to PCB 110. The ability of NDL PCBs to induce DAT inhibition and alter dopamine concentrations can aid in addressing its harmful persistent neural activity during neurodevelopment and its effect on initiating neurological disorders especially Parkinson's disease. *Supported by the National Institute of General Medical Sciences of the National Institutes of Health under Award Number R25GM071638.*

3063 A Chemically Defined Hydrogel Substrate Promotes Accelerated Maturation and Neurite Extension of Cortical Glutamatergic and Motor Neurons for High-Throughput Screening

C. Lebakken[1], T. Sampsell[1], G. Kaushik[1], W. Richards[1], K. Xu[2], Z. Du[2], M. Hendrickson[2], and S. Visuri[1]. *[1]Stem Pharm, Madison, WI; and [2]BrainXell, Madison, WI.*

Human neural cells manufactured from patient-derived induced pluripotent stem cells (iPSCs) hold great promise for modeling neurodevelopmental disorders, discovering precision therapies, and screening for potential risks from environmental toxins. However, many neurological phenotypes arise in mature neurons, and human iPSC-derived neurons can require extensive time in culture (1-3 months) to reach full maturity. These lengthy cultures slow the discovery process and are costly due to labor and reagent requirements. We hypothesized that optimizing culture substrate properties through the use of tunable synthetic matrices would improve maturation. Currently, neurons are cultured on a variety of substrates including charged polymers (poly-lysines or poly-ornithines) or animal-derived matrices. Using JMP™ software, we employed Design of Experiment (DOE) methodology utilizing Box-Behnken response surface modeling to screen for synthetic polyethylene glycol-based (PEG) hydrogel formulations that promoted viability, cell adhesion, desired morphology, and accelerated maturation of cortical glutamatergic neurons. In the experimental design, we varied PEG concentrations, crosslinkers and cell adhesion peptide composition and concentrations. To facilitate the quantitative DOE analysis, we utilized neurons derived from a human iPSC reporter line with a fusion protein comprising nanoluciferase (Nluc, Promega) and synaptophysin (SYP), a synaptic vesicle glycoprotein that is expressed in virtually all mature neurons and acts as a marker for quantification of synapses. We identified hydrogel formulations that 1) support cortical glutamatergic neuron adhesion as scored morphologically and assessed quantitatively via cellular ATP (Cell Titer Glo 2.0, Promega) and 2) accelerate maturation, as demonstrated through a time-course of synaptophysin expression. Finally, these hydrogel formulations supported over two-fold increases in neurite length over a poly-D-lysine substrate. When incorporated into neuronal high-throughput screening efforts, the identified hydrogel substrates will improve overall outcomes and decrease the culture time required to reach the necessary maturation state.

3064 Chronic Glucocorticoid Exposure Primes the Neuroinflammatory Response to Nerve Agent Sarin

K. A. Kelly, L. Michalovicz, and J. P. O'Callaghan. *NIOSH, Morgantown, WV.*

Chronic exposure to the glucocorticoid corticosterone (CORT), at levels associated with high physiological stress, can exacerbate CNS proinflammatory responses to neurotoxic insults in animal models. Persistent sickness behavior, a prominent component of Gulf War Illness (GWI), is associated with neuroinflammation. Veterans of the 1991 GW were exposed to the stresses of war, being prophylactically treated with the reversible acetylcholinesterase (AChE) inhibitor pyridostigmine (PB), organophosphate pesticides chlorpyrifos (CPO) and dichlorvos (DDVP) and potentially the nerve agent sarin. We have previously shown CORT exacerbation of the neuroinflammatory response to CPO, DDVP, and the sarin surrogate diisopropyl fluorophosphate (DFP). Here, we confirm that sarin exposure also causes a neuroinflammatory response that is exacerbated by chronic CORT pretreatment. CORT (200 ug/mL in 0.6% EtOH) was given in the drinking water for 1 week prior to sarin administration at an LD20 dose (0.1 mg/kg, s.c.) on day 8. Animals were euthanized at 6 hours and brains were dissected and then frozen for RNA and protein analysis. RNAseq analysis of cortex revealed 1535 genes that were significantly up-regulated in the CORT+sarin group. Of these, 211 were significantly greater than sarin alone. These 211 genes were interrogated with DAVID to find GO terms which included cytokine production, MAP kinase phosphatase activity, and cytokine binding. Kegg pathways include: cytokine-cytokine receptor interaction, Jak-STAT signaling pathway, MAPK signaling pathway, and hematopoietic cell lineage. The neuroinflammatory response was further confirmed with elevated pSTAT3 protein by ELISA and elevated neuroinflammatory cytokines and chemokines mRNA (TNFα, IL6, CCL2, IL1β, LIF, and OSM) by qPCR. Together these findings confirm those we have previously shown with sarin surrogate, DFP and provide additional support for the hypothesis that GWI is a chronic, stressor-primed, neuroinflammatory condition potentially instigated by the combined exposures to stressors and irreversible AChE inhibitors.

3065 Microscopic Analysis of the Intracellular Distribution of the Aryl Hydrocarbon Receptor at the Single Neuron Level *In Vivo*

E. Kimura[1,2,3], M. Kohda[2], F. Maekawa[1], and C. Tohyama[2,4]. *[1]National Institute for Environmental Studies, Tsukuba, Japan; [2]University of Tokyo, Tokyo, Japan; [3]Japan Society for the Promotion of Science, Tokyo, Japan; and [4]University of Tsukuba, Tsukuba, Japan.*

The aryl hydrocarbon receptor (AhR), a ligand-activated transcription factor, is present in the cell cytoplasm and plays an essential role in the induction of various dioxin toxicities, including neurotoxicity. Once activated by a ligand such as dioxin, the AhR-dioxin complex translocates from the cytoplasm into the nucleus, and induces its downstream signaling cascade. This signaling event suggests that the intracellular dynamics of AhR is involved in dioxin toxicities. However, the dioxin-induced nuclear translocation of AhR *in vivo* remains to be unclear. Thus, this study aimed to identify AhR-expressing neurons in the mouse brain by immunofluorescent staining, and examine dioxin-activated AhR distribution in neurons. Mice were administered 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) at a dose of 20 µg/kg b.w. or vehicle (control group). To identify AhR-rich-brain regions, we utilized the Allen Brain Atlas, an *in situ* hybridization database for numerous transcripts in the mouse brain. A distinct *AhR* transcript signal was observed in the locus coeruleus (LC) of the developing and adult mouse brains. The LC consists of noradrenergic (NA) neurons expressing tyrosine hydroxylase (TH); therefore, we examined AhR expression in NA neurons (LC-NA neurons) in the brains of 5-, 7-, and 14-day-old mice, using anti-AhR and TH antibodies. Microscopic analysis revealed that almost all of the TH-positive cells in the LC were positive for AhR, and that the immunostaining intensity of AhR in the nucleus of LC-NA neurons remained unaltered during development. AhR was not detected in LC-NA neurons of *AhR*-null mice (a kind gift from Prof. Y. Fujii-Kuriyama, then at University of Tsukuba) by immunostaining, confirming the specificity of the anti-AhR antibody. Furthermore, we analyzed the distribution of AhR in LC-NA neurons of TCDD-exposed adult mice (12-weeks old), and revealed a significant increase in nuclear AhR in LC-NA neurons in the TCDD group compared to that in the control group. In conclusion, this study is the first to demonstrate the ligand-induced nuclear translocation of AhR at the single cell level *in vivo*. Our findings provide a new approach to reveal molecular mechanisms of neurotoxicity induced by AhR agonists.

3066 Effects of N-Acetylcysteine on Mouse Primary Spinal Cord Astrocyte During MeHg-Induced Toxicity

G. B. Vazquez, D. Wiwatratana, and W. D. Atchison. *Michigan State University, East Lansing, MI.*

A low concentration of methylmercury (MeHg) has been reported to be toxic to motor neurons (MNs) derived from mouse spinal cord, human iPSC and brainstem slices of humanized transgenic SOD1 G93A mice. Mechanisms of MeHg toxicity on MNs include dysregulation of intracellular calcium homeostasis, glutamate transmission, and redox homeostasis. Astrocytes (AST) play important roles in the maintenance of glutamate and redox homeostasis in neurons. The antioxidant N-acetyl cysteine amide (NACA) provided protection against MeHg-induced SCA degeneration to primary cultures of spinal cord astrocytes (SCA). In this study, we examined perturbation by MeHg of the Nrf2 pathway in SCA by determining the expression of antioxidant genes underlying Nrf2, and the role of NAC in the protection of SCA against MeHg toxicity. NAC caused a concentration-dependent protection indicated by the reduction of cell viability. SCA were pretreated with 0.1mM, 1.0mM, or 10mM NAC 2h before exposure to 5µM MeHg or cotreated continually with these concentrations of NAC with MeHg. At 0.1 mM, NAC lost its efficacy at protection against MeHg-induced SCA degeneration at 30h of exposure, while 1mM and 10mM NAC maintained their protection across 150h of 5µM MeHg exposure. The 1mM NAC was sufficient to protect SCA; the level of protection at this concentration did not differ from that at 10mM NAC or vehicle treatment level. At 18h of MeHg exposure, MeHg induced the reduction of Keap1, Gclc, Gpx1, Gpx4, and Txnrd1 mRNAs but not Nrf2 mRNA expression. Application of 1mM NAC before, or cotreatment with MeHg, prevented reductions of the antioxidant mRNAs which were maintained at the same levels of the vehicle and NAC treatment alone. The mechanism by which NAC causes protection against MeHg could be partly to it activating Nrf2 since NAC treatment alone induced the increase of Nrf2 mRNA expression. *This research was supported by NIH grant R01ES024064, and R25NS090989- ENDURE Program.*

3067 Potential Toxicity Induced by Exercise Mimetics AICAR and GW501516 on Voluntary Exercise Capacity of Ischemic Mice

A. Al Shoyaib, F. F. Alamri, and V. T. Karamyan. *Texas Tech University Health Sciences Center, Amarillo, TX.*

Despite stroke being the leading cause of permanent disability in the world, no FDA approved pharmacological treatment is available for promoting functional recovery from stroke related disabilities. Exercise mimetics are an emerging class of pharmacological agents deemed to possess the effects of physical exercise on the body. It is believed, such agents may be used to replace physical exercise in patients with impaired motor function. In this study, we hypothesized that the combination therapy of AICAR and GW501516, two most studies exercise mimetics, could promote motor function recovery after ischemic stroke. However, potential toxicity of this combination therapy on exercise capacity of mice was observed when AICAR+GW was given along with voluntary running exercise after ischemic stroke in mice. For this study, we used photothrombotic stroke model to induce ischemic stroke in CD1 male mice. For pharmacological treatment, AICAR (5mg/kg, IP) and GW501516 (500 mg/kg, SC) were given every other day starting from 24 hours post-stroke and continued until 9 days post-stroke. The mice started voluntary exercise with running wheel from 7 days post-stroke and continued until 20 days post-stroke. We measured the amount of exercise per mouse per session with the help of a digital counter attached to each running device. Additionally, to assess motor recovery gridwalk test was performed on 3 days pre-stroke and 1, 7, 14, 21days post-stroke. Our results indicate, the drug treated mice group was running consistently less compared to the vehicle treated group. In fact, at the later stage of the experiment, the vehicle treated group was running on average around 10,000 meters per day however, the drug treated group was running half of that amount, around 5,000 meters per day. These running discrepancy indicated a potential drug induced toxicity in the drug treated group. Additionally, our active running duration data indicate, the AICAR+GW501516 treated group was actively running almost half of time of vehicle treated group with an average value of around 2 hours and 4 hours for drug and vehicle treated group, respectively. In summary, we observed a reduced voluntary exercise capacity in terms of running distance and active running duration after AICAR+GW501516 treatment in ischemic mice. However, the mechanism of this potential toxicity has not been elucidated and further study is needed to elucidate the molecular mechanism of this observed toxicity.

3068 Applicability of hiPSC-Derived Neuronal Co-cultures and Rat Primary Cortical Cultures for *In Vitro* Seizure Liability Assessment Using Micro-Electrode Array (MEA) Recordings

A. M. Tukker, A. de Groot, and R. H. Westerink. *Universiteit Utrecht, Utrecht, Netherlands.*

Seizures are life threatening events in which neurons are hyper-excitable and fire in a hyper-synchronised manner. Drugs targeting the central nervous system pose a high risk for seizures. The potential of compounds to cause seizures is not investigated until late in the drug developmental process, meaning that once it is discovered, a lot of time and money has been invested. On top of that, current rodent based models are not always able to predict human seizurogenic compounds. There is thus a clear need for an *in vitro* screening model for seizure liability assessment, preferably using human cells to circumvent inter-species differences and to limit the number of test animals needed. We hypothesized that such human models outperform rodent models. The present study therefore aims to assess the suitability of hiPSC-derived neurons for seizure liability assessment in comparison to rat cortical cultures. We cultured an hiPSC-derived neuronal co-culture model and exposed it to eight known (non-)seizurogenic compounds (PTZ, amoxapine, enoxacin, amoxicillin, linopirdine, pilocarpine, CPZ and phenytoin). Using micro-electrode array (MEA) recordings we assessed the effect of these compounds on neuronal network activity. Data obtained from the hiPSC model was compared with data simultaneously obtained from rat primary cortical neurons. All compounds, except PTZ and enoxacin, increased either the spike, burst or network burst rate following acute exposure of hiPSC-derived neuronal cultures. Seizures were not detected in rat primary cortical neurons following exposure to amoxicillin and pilocarpine. When seizures were detected in both models, LOECS were comparable in the case of amoxapine and CPZ (LOEC 1 µM). For linopirdine, hiPSC-neurons were ten times more sensitive (LOEC 3 µM), whereas for phenytoin rat primary cortical neurons were more sensitive (LOEC 30 µM versus 100 µM voor hiPSC-neurons). We created chemical fingerprints that show that spike parameters are more sensitive for excitability in rat primary cortical neurons, whilst in hiPSC-derived co-cultures (network) burst parameters are more affected. Our data indicate that hiPSC-derived neuronal co-cultures are able to detect seizures in a manner comparable to rat pri-

mary cortical neurons. *This work was funded by NC3Rs (project number 50308-372160), ZonMW (project number 114027001) and the Faculty of Veterinary Medicine (Utrecht University, The Netherlands).*

3069 Important Laboratory Monitoring Parameters to Prevent Valproic Acid-Induced Toxicity in Long-Term Care Facilities

P. T. Huynh, W. A. Beathard, and A. T. Blaszczyk. *Texas Tech University Health Sciences Center - Jerry H. Hodge School of Pharmacy, Dallas, TX.*
Sponsor: M. Huynh

Long-term care (LTC) facilities have experienced an increase in the utilization of valproic acid (VPA) for residents suffering behavioral and psychological symptoms of dementia (BPSD). This indication is a promising strategy for antipsychotic deflection. However, there is concern that VPA is lacking the appropriate monitoring and also may be inappropriately titrated to antiepileptic blood levels, rather than therapeutic response for this indication, leading to side effects and neurotoxicity. VPA is usually well-tolerated, but previous studies have reported serious valproic acid-induced toxicity, including hepatotoxicity, thrombocytopenia, and hyperammonemic neurotoxicity, etc. Moreover, consistent monitoring parameters at low doses for indications other than epilepsy are often not obtained. Therefore, the purposes of this study are to characterize the use of VPA in LTC facilities and demonstrate the importance of VPA monitoring parameters in prevention of toxicity. The study population consisted of 1412 elderly residents residing in 13 LTC facilities across the state of Texas. Dispensing records, VPA blood levels, ammonia levels, and platelets for all residents during the 3-month study period was filtered and analyzed. As the result, the total daily doses of VPA ranged from 125 mg to 3000 mg with the majority (56%) received 125-500 mg, followed by 29% and 15% receiving 501-1000 mg and >1001mg, respectively. Seventy-eight percent of the residents received VPA for indications other than epilepsy, with 14.6% of those residents were within antiepileptic blood levels. Regarding VPA-induced toxicity, 13.8% of residents had thrombocytopenia with the vast majority (91.3%) of these residents receiving <1250 mg VPA daily. Hyperammonemia also appears to be associated with appropriate VPA dose of 125-1500 mg daily and sub-antiepileptic VPA blood levels (< 50 mg/L). The data support that hyperammonemia and thrombocytopenia are not dose related nor proportional to the blood VPA level. The results of this study emphasize the importance of appropriate monitoring ammonia levels and platelet counts regardless of VPA total daily dose, especially when used for BPSD.

3070 Effects of Age on the Susceptibility to Neurobehavioral Toxicity following Acute Domoic Acid Exposure in a Mouse Model

A. M. Hendrix[1], K. A. Lefebvre[2], and D. J. Marcinek[3]. *[1]University of Washington, Seattle, WA; [2]National Oceanic and Atmospheric Administration, Seattle, WA; and [3]University of Washington School of Medicine, Seattle, WA.*

The harmful algal bloom (HAB) toxin domoic acid (DA) contaminates marine food webs in the western United States, and acts as a potent glutamate receptor agonist following ingestion. With the duration, severity, and toxicity of HAB events expected to increase in coming years, spatial and temporal windows of concern for DA exposure are widening. It is critical that we characterize risk for members of the human communities that depend on safe seafood resources. The elderly are disproportionately represented among those that have suffered from acute DA toxicosis, and new research suggests that they are at risk for chronic DA exposures. Reduced resilience in response to physiological stress is a hallmark of aging. This reduced resilience is associated with higher systemic levels of oxidative stress and inflammation, both of which are also associated with DA toxicity. Therefore it is important to identify possible increased susceptibility of the elderly to the toxic effects of DA exposure. To this end, we are conducting a dose-response study assessing convulsive and subconvulsive responses to acute administration of DA (1-2.5 mg/kg) in young (7-9 mo) and aged (24-28 mo) mice. By assessing both subconvulsive and convulsive responses we will assess sensitivity to DA across a range of exposures. Tissue concentrations of DA at the time of observed behaviors will be measured in an effort to identify possible differences in renal clearance or tissue uptake of DA. Additional markers of oxidative stress, endoplasmic reticulum stress, neuronal apoptosis, and ultrastructural damage will be assessed to identify biochemical and histological correlates of the interaction between age and DA toxicity in the mammalian brain. A comparison of dose-response curves will allow for discussion of the extent to which age may play a role in DA susceptibility.

3071 Spontaneous Incidence of Infrequent Neurological Clinical Signs across Species: A Retrospective Analysis

C. Ballesteros, A. Parenteau, C. Li, R. Tavcar, R. Kubaszky, and S. Authier. *Charles River, Laval, QC, Canada.*

The identification of possible adverse effects is crucial in the development and safety assessment of drugs in toxicology and safety pharmacology studies. Control groups allow for the discrimination of findings (for example, changes in symptoms, signs, or other morbidity) caused by the test-item treatment from outcomes caused by other factors which could be unrelated to drug treatment. Potential spontaneous clinical observations in healthy animals can confound the interpretation of test-item related effects. Characterizing these infrequent species-specific spontaneous findings can help in the interpretation of true treatment related clinical observations. The purpose of this retrospective analysis was to determine the prevalence of incidental clinical observations which could be interpreted as neurologically related in control animals. Clinical observations documented in control animals from 141 GLP-compliant toxicology studies which were conducted between 2015 and 2019 were compiled. These studies consisted of a total of 5022 control animals (both males and females) with dosing phases ranging from 1 day to 39 weeks and recovery phases ranging from no recovery to 26 weeks. All control animals across these studies were dosed with an appropriate vehicle consistent with the formulation buffer. Species evaluated consisted of Beagle dogs, Sprague-Dawley, Wistar and Athymic Nude rats, New Zealand White rabbits, Göttingen minipigs, Cynomolgus and Rhesus monkeys, and CD-1 mice. Among the clinical signs compiled which could be interpreted as neurologically-related, signs such as salivation, tremors, uncoordinated, myoclonic jerks, muscle twitches, altered muscle tone, muscle atrophy, full muscle contraction, circling, clonic convulsions, tonic convulsions, hunched back, piloerection and hypersensitivity were observed. The prevalence of these incidental observations across the different control species was analyzed which could support interpretation of treatment-related data that is confounded by neurological incidental findings.

3072 The Impact of Environmental Organochlorines on Disruption of Dopamine Homeostasis

B. Cagle, H. J. Lehmler, and J. A. Doorn. *University of Iowa, Iowa City, IA.*

Disruption of dopamine homeostasis is a potential mechanistic link between an insult, such as exposure to pesticides, and injury/disease. Organochlorines present in the environment may alter dopamine metabolism and homeostasis. Dopamine is metabolized to 3,4-dihydroxyphenylacetaldehyde (DOPAL) by monoamine oxygenase. Previous work found DOPAL to be toxic, produce ROS, and be highly reactive towards proteins. Our goal is to determine the extent to which dieldrin, and polychlorinated biphenyls (PCBs) alter dopamine homeostasis, and if such disruption accounts for adverse outcomes. Specifically, PCB-52 and its human metabolite, 4-OH PCB-52, since PCB-52 has been found to be a major contributor towards PCBs in indoor and outdoor air. While these compounds are currently banned, they persist in the environment and pose a risk to human health. PCBs are associated with neurodevelopmental disorders, such as ADHD, while dieldrin has been linked to neurodegenerative disorders, including Parkinson's disease. Our hypothesis is that organochlorine environmental agents alter dopaminergic homeostasis yielding toxic outcomes. We have studied the toxicity of these compounds to PC12 and N27 cells, dopaminergic rat cell lines. Results show that 4-OH PCB 52 is toxic to dopaminergic PC12 and N27 cells at concentrations less than that of PCB-52 (less than 25μM) at 24hrs. The ability of PCB-52, and 4-OH PCB-52 to produce reactive oxygen species has been determined using fluorescent probes for ROS. Both PCB-52 and 4-OH PCB-52 increase mitochondrial and whole cell ROS in dopaminergic cell lines. However, this seems more prominent in mitochondria, and we expect similar results with dieldrin. Furthermore, we have used an aminophenylboronic acid agarose resin to select for DOPAL-modified proteins. Preliminary results show that treatment of N27 cells with DOPAL increases the amount of catechol-modified proteins present. We aim to identify proteins that are targets of DOPAL and/or indirect targets of organochlorines. To support such findings, we will determine how organochlorines alter dopamine metabolism in dopaminergic cells. This research will help determine the impact of organochlorines on the dopaminergic system, and provide insight into potential therapeutics to combat neurodegenerative and neurodevelopmental conditions.

3073 New Method for Detection of Seizure Potential Using Rat Electroencephalogram

K. Kinoshita[1], Y. Ishibashi[2], N. Matsuda[2], A. Okamura[1], T. Shirakawa[1], and I. Suzuki[2]. *[1]Astellas Pharma Inc., Ibaraki, Japan; and [2]Tohoku Institute of Technology, Miyagi, Japan.* Sponsor: T. Shirakawa, Japanese Society of Toxicology

Seizure is an important issue during drug development. Therefore, detection of seizure potential risk is one of the most important subjects in non-clinical studies. Recently, electroencephalogram (EEG) can play a critical role in safety assessment of drugs. While EEG is widely used to the seizure assessment, the changes of EEG before seizure event are not well understood. Therefore, in this study, we aimed to develop a novel analysis method to detect seizure potential risk using rat EEG even before occurring of seizure. Adult male Sprague-Dawley rats implanted with electrodes in prefrontal cortex and hippocampus were used, and EEGs were measured for about 3 hours after treatment of 10 seizure-inducible compounds (4-aminopyridine, pentylenetetrazol, pilocarpine, picrotoxin, strychnine, isoniazid, aminophylline, bupropion, tramadol and venlafaxine) and 3 negative control compounds (acetaminophen, aspirin and amoxicillin). Animals were divided into the high and low dose groups, which showed seizure symptoms and only preceding symptoms of seizure, respectively. Then, the EEG data was classified into 6 bands [theta (5-8 Hz), alpha (8-14 Hz), beta (15-25 Hz), gamma (30-50 Hz), high gamma (70-150 Hz) and a higher band (150-200 Hz)], and 7 parameters were calculated from each band of EEG in rats, which included spike rate, burst rate, inter burst interval, burst duration, spike in a burst, peak amplitude and inter peak interval. As a result, rats showed the seizure or only preceding symptoms (twitch, straub tails, tremors etc.) after treatments, and the abnormalities of waveform was noted in high gamma band in the EEG during seizure in the high dose groups. Analyzing of the high gamma band in EEG, spike rate and burst rate increased and inter burst interval shortened during seizure but not the negative control groups. Moreover, changes in same parameters were also detected in animals which had not shown seizure, suggesting that these parameters might be related to seizure. In conclusion, we revealed the novel analysis method that can be detected seizure potential risk even at the low dose groups that doesn't cause seizure, and EEG might be useful tool to detect a preceding biomarker for seizure in non-clinical studies.

3074 Acute Cadmium Treatment Induces Deficits in Metal Homeostasis and Autophagy via Impairing Metal Transporter Systems and Energy Homeostasis in Huntington's Disease Striatal Cells

G. F. Kwakye[1], W. Chen[1], M. Mcilvin[2], M. Saito[2], and M. Thomas[1]. *[1]Oberlin College and Conservatory, Oberlin, OH; and [2]Woods Hole Oceanographic Institution, Woods Hole, MA.*

Huntington's disease (HD) is functionally linked to environmental factors including metal dyshomeostasis and cigarette use. Interestingly, one of the most abundant heavy metals in cigarettes is cadmium (Cd), which also accumulates in the corpus striatum within the basal ganglia and causes neurotoxicity upon overexposure. We have previously reported that mutant HD protein coupled with acute Cd exposure activates protein kinase C delta dependent oxidative stress signaling mechanisms to cause neurotoxicity and cell loss in a mouse striatal cell line model of HD. To investigate the basis for the synergistic interaction between mutant HD and Cd, we hypothesized that mutant HD would alter metal transport, mitochondrial bioenergetics and protein degradation mechanisms with Cd exposure. Inductively coupled plasma mass spectrometry (ICP-MS) analysis revealed that the mutant HD genotype is associated with increased accumulation of Cd upon Cd exposure for 48h. Further, we did not observe a significant change in the levels of iron, manganese, zinc, cobalt, copper, and nickel in wild-type and mutant HD striatal cells following Cd exposure. Examination of metal transporter system implicated in Cd transport showed a decrease in the expression of divalent metal transporter 1 (DMT1) protein in mutant HD striatal cells with Cd exposure. Additionally, pretreatment with zinc, manganese, and iron as well as exogenous antioxidants rescued the Cd-induced neurotoxicity in the mutant HD striatal cells. We observed a significant decrease in energy homeostasis and increased proteasomal activity in mutant HD striatal cells as early as 6 hours with Cd exposure. Finally, acute Cd exposure did not affect the expression of huntingtin protein but significantly regulated the expression of autophagy related proteins LC3-II, ATG5, and Beclin-1. Together, these findings suggest that mutant HD exhibit greater neurotoxic properties when in tandem with Cd exposure to cause neurotoxicity via impairing metal transport and energy homeostasis as well as regulating autophagy and proteasomal degradation signaling mechanisms.

3075 Aflatoxin-Induced Lipotoxic and Non-lipotoxic Dyslipidemia in Lymphocytes and Brain of Female Albino Rats

O. Ademuyiwa[1], T. I. Awoniyi[1], T. R. Afenisumen[1], O. P. Ojo[1], R. N. Ugbaja[1], F. Oluwafemi[1], S. O. Rotimi[2], O. Rotimi[2], and D. O. Babayemi[1]. *[1]Federal University of Agriculture, Abeokuta, Nigeria; and [2]Covenant University, Ota, Nigeria.*

Aflatoxins are a group of naturally occurring mycotoxins produced by *Aspergillus flavus* and *Aspergillus parasiticus*, which typically affect grains and nuts. Aflatoxin B1 intake has been associated with immunotoxic and neurotoxic end-points in man and animals though the mechanism(s) involved is not well established. Studies have shown that dyslipidemia is an early pathological event in various diseases. This study therefore investigated the effects of aflatoxin B1 on lipid metabolism of rats. Thirty six (36) female albino rats were exposed to aflatoxin B1 (20 ppb and 40 ppb) for 2, 4 and 6 weeks. Control rats (n=18) received normal feed for the same period. At the end of aflatoxin B1 administration, lipid profiles were determined in the lymphocytes and brain of the animals. Lipotoxic and non lipotoxic dyslipidemia were observed as a result of aflatoxicosis. In the lymphocyte, aflatoxin B1 induced a dose-dependent hypercholesterolemia (42 and 31%) at 4 and 6 weeks respectively, whereas the 20 ppb dose induced hypocholesterolemia at 2 weeks. Lymphocyte triacylglycerol and phospholipid were decreased at 2 weeks, but increased at 4 and 6 weeks respectively. While brain cholesterol decreased throughout, brain triacylglycerol increased at 2 weeks, but decreased at 4 and 6 weeks with 40ppb dose of aflatoxin B1. Phospholipidosis was the hallmark of aflatoxin B1 exposure in the brain at 4 and 6 weeks. A 35% inhibition in brain HMG CoA reductase activity was observed at 4 weeks whereas the inhibition amounted to 15% by 6 weeks of aflatoxin B1 exposure. The findings of this study indicate that the immunological and neurological effects induced by aflatoxicosis may be mediated in part by the lipotoxic and non-lipotoxic dyslipidemia.

3076 Inhibition of Synaptic Plasticity and Brain/Blood Levels of 1-Bromopropane in Rats during Inhalation

Y. Fueta[1], M. Hinoue[1], M. Kanemitsu[2,1], H. Ohkubo[1], M. Fukunaga[1], E. Yasumatsu[1], T. Ishidao[1], S. Aou[2], and H. Hori[1]. *[1]University of Occupational and Environmental Health, Japan, Kitakyushu, Japan; and [2]Graduate School of Life Science and Systems Engineering, Kitakyushu, Japan.*

1-Bromopropane (1-BP) is an organic solvent used in degreasing agents and spray adhesives. Several studies have reported that 1-BP exerts toxic effects on the central nervous system, manifesting symptoms such as memory problems, in occupationally exposed populations. The adverse effects on memory are due to changes in synaptic efficacy in the brain. However, the adverse effects on synaptic plasticity and 1-BP levels in the brain that change synaptic plasticity have not been reported. We previously reported that a 2-compartment model is efficient for analyzing 1-BP concentration in the brain and blood by inhalation (2017 SOT). Therefore, the blood concentration of 1-BP that causes adverse effects on synaptic plasticity can be estimated in rats. Here, we aimed to determine the 1-BP blood level that inhibited long-term potentiation (LTP), which is induced in hippocampal slices from rats. LTP was induced by high-frequency stimulations in the hippocampal CA1 and dentate gyrus of hippocampal slices prepared from naive rats. The slices were directly perfused with 1-BP solution (0.007-6.6 mM in the slice chamber) for 5 min immediately before stimulation. The other rats were exposed to 1-BP at concentrations of 50, 200, 700, and 1500 ppm for 120 min. Blood samples were collected over time via cardiac catheterization, and brains were obtained by decapitation at 15, 30, 60, and 120 min of inhalation. The 1-BP concentration was determined using head-space gas chromatography. Subsequently, the 2-compartment model was applied to the data analysis. Our results showed that the 1-BP level that inhibits LTP in the CA1 was equal to or higher than 0.06 mM, although an inhibitory tendency was observed at the lowest concentration of 0.007 mM. The level of 1-BP in the brain exceeded the inhibition level within 15 min at 200 ppm. The ratio of blood-to-brain and brain-to-blood transfer rate constants, calculated from the 2-compartment model, was less than 1 at 50 ppm and increased as the inhalation concentration increased. Our study demonstrated that 1-BP inhibits synaptic plasticity, suggesting that the blood level of 1-BP is a useful index of adverse effects on synaptic plasticity.

3077 Endogenous and Environmental Stimuli Affect Sab-Mediated Cellular Vulnerability to Neurotoxic Exposures

A. E. Suarez, and J. W. Chambers. *Florida International University, Miami, FL.*

Perturbations in mitochondria-cell signaling drive organelle dysfunction aging and neurodegenerative diseases. Scaffold proteins dictate the outcomes of signaling events by directing the localization, organization, and abundance of signaling proteins. Our previous work demonstrates that the increasing concentrations of the outer mitochondrial membrane (OMM) scaffold Sab renders cells vulnerable to toxic insults in a c-Jun N-terminal kinase (JNK)-dependent manner, and inhibiting Sab-mediated signal protects against chemical exposures. Because, Sab levels are elevated in vulnerable brain regions, such as the hippocampus and substantia nigra, identifying stimuli that affect Sab levels could represent mechanisms of neurodegenerative pathogenesis or uncover neuroprotective strategies. Therefore, we developed an in-cell western (ICW) for Sab to evaluate if cellular and environmental stimuli alter Sab concentrations through endogenous mechanisms. The ICW performed in HEK-293 cells (Z′ = 0.71) and validated using Sab-specific shRNAs and overexpression. A small-scale screen revealed that sub-chronic exposures to mitochondrial toxins (rotenone and antimycin) and tumor necrosis factor α (TNF-α) increased Sab levels, while antioxidants (quercetin and N-acetylcysteine) reduced Sab concentrations. Signaling pathways also affected Sab concentrations. Specifically, protein kinase A (PKA) inhibitors increased Sab levels on mitochondria, and PKA activators caused a decrease in Sab abundance in a kinase-and organelle-dependent manner. Agonists of estrogen signaling were also found to decrease Sab levels, while antagonists were found to increase Sab concentrations. Finally, we discerned that benzo[a]pyrene, a byproduct of incomplete combustion, increased Sab concentrations on mitochondria, an effect that was partly diminished in JNK inhibitor (5μM SR-3306). To determine if these chemical-induced changes in Sab concentrations had a physiological impact on cells, we pretreated HEK-293 cells with either antimycin A or estradiol. Antimycin A pretreatment increased apoptotic priming and rendered cells vulnerable to chemical insults, which was reversed by silencing Sab. Alternatively, estradiol treatment increased anti-apoptotic protein levels on mitochondria and enhanced cellular resiliency to chemical exposures. These effects were mitigated by overexpression of Sab. Our findings demonstrate that Sab concentrations are influenced by the intracellular and extracellular environments, and these endogenous and exogenous cues may provide insight into the vulnerability of discrete neuronal populations.

3078 Study on Biomarkers Exposed to 1-Bromopropane

Y. Zhang, J. Xiao, Z. Li, X. Chen, J. Song, W. Cai, H. Fu, and B. Li. *National Institute for Occupational Health and Poison Control, Chinese Center for Disease Control and Prevention, Beijing, China.*

1-Bromopropane (1-BP) has been used in many industries with significant adverse effects on nervous system. Animal tests and occupational survey were performed to explore the exposure and effect biomarkers of neurotoxicity induced by 1-BP. Methods: 1. *In vivo* study: Male Wistar rats were exposed to 0, 500 and 1000 ppm 1-BP (18/group), 6 h/day for 21 consecutive days. Six rats of each group were euthanized on the 7th, 14th and 21th days. The brain tissues, urine and serum were collected. Histopathological examination was applied. 2. Epidemiological survey: The exposure and control groups were studied with 71 workers in each group. Serum and urine were collected after work. Concentrations of 1-BP in the work sites and individuals were tested. 3. Changing of NSE, S-100β and COX-2 in the cerebral cortex of rats and the serum of exposed workers were measured respectively, changes of 1-BP and its metabolite AcPrCys in the urine were detected. 1. *In vivo* study: Purkinje cell atrophy, lumbar gray matter vacuolar degeneration, tibiofibular nerve fibers swelling and thickening were tested at 1000ppm on the 21thday. cNSE and cS-100β at 1000ppm, sNSE at 500ppm were increased significantly at all checkpoints. sS-100β at 1000ppm on the 21th days was increased significantly. Compared with the control, cCOX-2 at 500 and 1000ppm was increased greatly as well as at 500ppm on the 14th and 21th days compared with the 1000ppm group. sCOX was increased greatly on the 14th days at 500ppm, and on the 7th and 14th days at 1000ppm. A correlation between the changes of COX-2 in the cerebral cortex and serum was found, and 1-BP and AcPrCys were detected in the urine, there was a correlation between the changes of sNSE and sCOX-2 and AcPrCys in the urine at 500ppm. 2. Epidemiological survey: The concentration of 1-BP in the use enterprises was generally higher than that of the production enterprises. 1-BP was detected in some urine samples and AcPrCys was detected in all urine samples of exposed workers. Correlation of AcPrCys and exposure concentration was detected. 1. Subacute nerve injury was induced by 1-BP in rats under the conditions of this test. Concentrations correlation of COX-2 between cerebral cortex and serum was found. 2. The prototypes and the metabolites (AcPrCys) of 1-BP were detected in urine in exposure groups, and a good correlation between AcPrCys and exposure concentration was found. Results indicated that AcPrCys was more sensitive than the prototype as the 1-BP exposure biomarker.

3079 Impact of N-Methyl-D-Aspartate Receptor and Complement System on Neuronal Death Induced by High Glucose

A. B. Engin[1], E. D. Engin[2], O. Gulbahar[1], A. Aral[1], and A. Engin[1]. *[1]Gazi University, Ankara, Turkey; and [2]Ankara University, Ankara, Turkey.*

In hyperglycemia glucotoxicity-induced insulin resistance is one of the important causes of oxidative stress leading to neuronal death and dementia in diabetic patients. SH-SY5Y human neuroblastoma cell line can constitute an *in vitro* model to analyze complement biosynthesis by human neurons. In this study, following the high glucose exposure, the effect of neuronal nitric oxide (NOx), oxidative stress coefficient, glutamate, methylglyoxal (MGO), glucose transporter3 (GLUT3), complement1 (C1q), C3a and complement regulatory protein (CD59) levels on cell viability were evaluated at first 48-hour period in SH-SY5Y cells. Kynurenic acid (KynA), a unique N-methyl-D-aspartate receptor (NMDAR) antagonist, was used to determine whether excitatory glutamatergic neurotransmission via NMDAR leads to neuronal death in the presence of high glucose and insulin. Excessive oxidative stress, and glutamate toxicity in neurons caused by high glucose and insulin exposure, was reduced with the addition of KynA. The increase in MGO was thought to be due to the increase in GLUT3 activity and the decrease in glutamate toxicity was due to the blockade of NMDAR. Both CD59 and C3a showed parallel alterations with C1q in all experimental conditions, where the presence of glucose was mandatory. The constant variable between C1q and CD59 or C3a was calculated as 0.8. Insulin resistance decreased C1q and CD59 levels, while KynA improved insulin resistance and significantly increased C1q and CD59 levels. This study revealed that high glucose-related neuronal death due to oxidative stress and insulin resistance could be significantly improved by NMDAR antagonist, KynA. However, C1q, CD59 or C3a did not contribute the membrane attack complex formation and subsequent neuronal death in SH-SY5Y neurons, which were exposed to high glucose and insulin. *This study was supported by The Scientific and Technological Research Council of Turkey, 214S112.*

3080 Optimizing Neurotoxic Hazard Characterization of New Psychoactive Substances (NPS): Assessing Prolonged Exposure and Reversibility of Effects on Neuronal Activity Using Microelectrode Array Recordings

A. Zwartsen[1], L. Hondebrink[2], and R. H. Westerink[3]. *[1]IInstitute for Risk Assessment Sciences and Dutch Poisons Information Center, Utrecht, Netherlands; [2]Dutch Poisons Information Center, Utrecht, Netherlands; and [3]Institute for Risk Assessment Sciences, Utrecht, Netherlands.*

New psychoactive substances (NPS) use is linked to numerous emergency department visits and deaths. However, hazard characterization of NPS is limited and often based on case studies and acute measurements on single targets, like the monoamine transporters. As this poorly relates to the human *in vivo* situation, we hypothesized that integrated measurements of neuronal activity that consider the human exposure duration and the reversibility of effects could increase the translatability and improve NPS hazard characterization. To that aim, we used rat cortical cultures grown on multi well microelectrode arrays (mwMEAs) to assess changes in neuronal activity after acute (30 min) and prolonged (5 h) exposure to 11 illicit drugs and NPS (MDMA, PMMA, methamphetamine, methylone, MDPV, α-PVP, 2C-B, 25B-NBOMe, BZP, TFMPP and cocaine). In addition, the reversibility of effects was tested following a 19 h washout period. All drugs concentration-dependently decreased neuronal activity during acute and prolonged exposure. The increase in exposure duration did not exacerbate neurotoxicity for the drugs tested. Following washout, drug- and concentration-dependent recovery was seen for all tested drugs. Following exposure to the highest concentrations of MDPV, 2C-B, 25B-NBOMe and TFMPP no recovery was seen, while exposure to methamphetamine, cocaine and BZP was fully reversible. All other drugs showed partial recovery at the highest concentration measured. Following washout, low concentrations of methylone and 2C-B caused an increase in neuronal activity compared to control. When comparing effect concentrations following washout to human concentrations, 3 out of 11 drugs were identified as long-acting substances. These long-acting substances could not be identified based on drug class, chemical structure or potency during acute exposure measurements. Hazard characterization of emerging NPS should

thus also include prolonged exposure and recovery measurements, in addition to acute exposure measurements for potency screening, to mimic human exposure as best as possible.

3081 Diglycolic Acid, the Toxic Metabolite of Diethylene Glycol, Induces Apoptosis with Secondary Necrosis in SH-SY5Y Neuronal Cells *In Vitro*

K. J. Reed, and G. M. Landry. *Massachusetts College of Pharmacy and Health Sciences, Boston, MA.*

Diethylene glycol (DEG) is an industrial solvent found in a variety of consumer products. When accidentally or intentionally ingested, toxicity manifests as severe nephrotoxicity, hepatotoxicity, and late-stage neurotoxicity. DEG metabolite-induced nephrotoxicity and hepatotoxicity have been well characterized; however, the metabolite responsible for the neurotoxicity has yet to be elucidated. SH-SY5Y cells were treated with increasing concentrations of DEG metabolites: diglycolic acid (DGA) or 2-hydroxyethoxyacetic acid (2-HEAA) for 24h or 48h. Cell death characterization was determined by flow cytometric analysis, lactate dehydrogenase (LDH) release, ethidium homodimer (EtHD) uptake, caspase-3 activation, and oligonucleosome formation. Supraphysiological 2-HEAA exposure (200 mmol/L) was the only concentration shown to induce significant necrosis. However, following DGA (6.25, 25, 50, and 100 mmol/L) exposure at both time points, SH-SY5Y cells showed significant concentration-dependent LDH release (r^2 = 0.929 at 24 h, 0.720 at 48 h) and EtHD uptake (r^2 = 0.826 at 24 h, 0.644 at 48 h) compared to controls, indicating necrosis. DGA-treated SH-SY5Y cells also showed significant dose-dependent oligonucleosome formation (r^2 = 0.841 at 24 h, 0.921 at 48 h) and caspase-3 activation (r^2 0.848 at 24h, 0.859 at 48h), but only at the 50 mmol/L concentration. Interestingly, cells exposed to DGA for 5 days showed significant EtHD uptake at concentrations as low as 15 mmol/L, indicating exposure time as an important factor in neuronal cells exposed to low, physiologically relevant DGA concentrations. Taken together, these results indicate that acute DGA treatment, not 2-HEAA, causes apoptosis followed by secondary necrosis *in vitro* at multiple time points.

3082 Correlation of Electrophysiological Parameters with Behavioral Performance in an Animal Model Using Aluminum Exposures

J. G. Rohan[1], T. Ethridge[1,2], M. K. Miklasevich[1,3], N. M. Gargas[1,3], S. M. McInturf[1], and K. L. Mumy[1]. *[1]Naval Medical Research Unit Dayton, Wright-Patterson AFB, OH; [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [3]Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD.*

We have incorporated electrophysiology as part of our neurotoxicity assessment repertoire. Specifically, we have used microelectrode arrays to effectively screen the effects of various environmental hazards and stressors on neuronal function, especially on hippocampal neurons. Electrophysiology provides quantitative assessments of synaptic transmission efficiency, synaptic plasticity, and spontaneous activity as measured by input-output (IO) relationship, short or long term potentiation (LTP), and spontaneous non-evoked activity, respectively. However, the physiological significance of changes in these electrophysiological (EP) parameters remains unclear. The overall objective of our study is to establish a correlation analysis between EP recordings and behavioral performance. We are using aluminum chloride ($AlCl_3$) exposures because they are known to induce memory loss and other cognitive deficits. Rats were exposed to $AlCl_3$ via intraperitoneal injection (IP) over 7 days at a concentration of 0 (control), 50 (mid), or 100 (high) mg/kg body weight. A separate set of rats were exposed via gavage daily for 6 weeks at the same doses. Transient decrease in motor activity was observed in the IP group, whereas impaired cognition was observed in the gavage group. In the IP group, we saw a reduction in the average IO response, enhancement in the average paired pulse facilitation (PPF), and a reduction in LTP of the mid and high dosed animals. In the gavage group, we saw an enhancement in the average IO response, enhancement in the average PPF, and reduction in LTP of the mid and high dosed animals. Small but statistically significant reduction in glutamate and acetylcholinesterase levels in the brain were observed in the IP group. Increases in plasma levels of cytokines were observed for both IP and gavage groups. Preliminary regression analysis yielded some statistically significant correlations among EP, biochemical and behavioral measurements, and thus support the hypothesis that EP recordings in conjunction with biochemical measurements can be indicative of behavioral outcome.

3083 Effects of Acute and Chronic Developmental Exposure to Bisphenol A (BPA) on Development and Function of Neuronal Networks Measured Using Microelectrode Array (MEA) Recordings in Rat Primary Cortical Cultures *In Vitro*

R. H. Westerink, A. M. Peerdeman, E. H. Huiberts, and R. G. van Kleef. *Universiteit Utrecht, Utrecht, Netherlands.*

Human epidemiological and animal *in vivo* data indicate an association between pre- and postnatal exposure to endocrine disruptive compounds (EDCs) and impaired neurodevelopment. Considering that only a fraction of the large number of EDCs has been studied for adverse neurodevelopment effects, efficient *in vitro* models are required to timely investigate the neurotoxic potential of EDCs. To date, however, developmental neurotoxicity of EDCs has hardly been studied *in vitro*. This study therefore aimed to assess EDC-induced (developmental) neurotoxicity using bisphenol A (BPA) as a reference EDC. To that aim, we used primary rat cortical cultures grown on microelectrode arrays (MEA) as *in vitro* model to investigate the effects of acute and developmental exposure on neuronal network function and formation. Cortical cultures were acutely exposed for 30 min to BPA (0.001-100 μM) on Day *in vitro* (DIV) 10 to assess effects on network formation. Additionally, cultures were developmentally exposed to BPA from DIV 4-21 to assess effects on network formation. Our data demonstrate that acute exposure of rat cortical cultures to BPA induced a concentration-dependent inhibition of neuronal activity from 1 μM onwards, with complete cessation of activity at 100 μM. Similarly, developmental exposure to the high concentration of BPA strongly inhibited development of neuronal activity up to DIV15. Surprisingly, after DIV15 neuronal activity recovered to control levels. These data demonstrate that acute BPA exposure inhibits neuronal activity, in line with its reported inhibitory effect on voltage-gated calcium channels. The recovery of neuronal activity after prolonged developmental BPA exposure suggests the involvement of adaptive mechanisms that may attenuate BPA-induced developmental neurotoxicity. *This project was funded by the EU-H2020 program (grant agreement No 825759).*

3084 Short- and Long-Term Behavioral Effects following Embryonic Exposure to Environmental Pollutants in Zebrafish

O. Jaka, A. Martínez, A. Muriana, and A. Alzualde. *Biobide, San Sebastian, Spain.*

Exposure to environmental pollutants during development is associated with adverse health effects throughout life. The developing brain is especially sensitive to such alterations and even very low levels of exposure to chemicals can cause persistent disorders in the cognitive function and in behavior. The zebrafish model is considered advantageous due to its low cost, small size, rapid development, and homology with mammals. The locomotor activity of zebrafish larvae can be assessed to evaluate the short-term effects of potential neurotoxic agents. In adults, more complex behaviors can be assessed and a longer exposure can be achieved which offers the possibility to evaluate the persistence or retard in the behavior caused by potential pollutants. In this study, the short and long-term behavioral effects of four environmental pollutants were assessed in zebrafish larvae and adults following embryonic exposure. 3-5 hours post fertilization (hpf) embryos were incubated in the media with three flame retardants: Triphenyl phosphate (TPP), Isopropylated phenyl phosphate (IPP) and 2,2′,4,4′-Tetrabromodiphenyl ether (BDE-47). The pesticide Chlorpyrifos (CPF) was used as positive control. Embryos were allowed to grow until 5 dpf for short-term effect or until adulthood for long-term effect. The lowest effective level (LEL) from the Locomotor Activity assay performed at 5 dpf was used as the highest concentration evaluated in the adult behavioral assessment. Three tests were performed to assess behavior in adults: the Open Field Test to evaluate general locomotor activity and two further tests to study anxiety-like / fear-related behavior: the Novel Tank Diving Test (NTT) to assess geotaxis (initial diving response) and the Light-Dark Preference Test (L/D) to assess scototaxis (preference for the dark area). The results showed that an anxiolytic-like behavior was induced by CPF and IPP, while BDE-47 provoked an anxiogenic-like effect. TPP treated fish showed opposite behaviors at different concentrations. Interestingly, long-term behavioral effects were induced at concentrations where no effect was detected in larvae stage. Therefore, zebrafish can be used as a sensitive and cost-effective model to evaluate the short and long-term neurobehavioral effects of potential environmental pollutants.

3085 Deletion of NRF2 Enhances Susceptibility to Neurotoxic Effects of Acrylamide in Mice

F. A. Ekuban[1], C. Zong[1], M. Takikawa[1], K. Morikawa[1], T. Sakurai[1], S. Ichihara[2], K. Itoh[3], M. Yamamoto[4], S. Ohsako[5], and G. Ichihara[1]. *[1]Tokyo University of Science, Noda, Japan; [2]Jichi Medical University, Shimotsuke, Japan; [3]Hirosaki University, Hirosaki, Japan; [4]Tohoku University, Sendai, Japan; and [5]University of Tokyo, Tokyo, Japan.*

Acrylamide (ACR) is an electrophile which has been used extensively in industry and is also formed unintentionally in food substances cooked or processed at high temperatures, such as potato chips or coffee through Maillard reaction. Acrylamide has been recognized as a potent neurotoxin which is known to cause neuropathy or encephalopathy in humans and experimental animals. As a measure of protection against neurotoxicity, the transcription factor nuclear factor erythroid 2-related factor 2 (NRF2) has been identified to be a master regulator of the cellular defense system which activates antioxidant and cytoprotective genes. However, knowledge about the exact mechanistic roles of NRF2 in ACR-induced neurotoxicity remains poorly understood. This study therefore sought to investigate and clarify the roles of NRF2 in attenuating ACR-induced neurotoxicity. Thirty-six male Nrf2-knockout (Nrf2-KO) mice from the C57BL/6JJcl background, aged 10-weeks together with their age and sex-matched wild-type (WT) counterparts were each divided into three groups of twelve and daily exposed to ACR at 0, 67 or 200 ppm in drinking water for 28 days. Following exposure of mice to ACR, Landing Foot spread test, an assessment of motor function and a major endpoint marker of neurotoxicity as well as immunohistochemistry for noradrenaline transporter (NAT) antibody in the dorsal and ventral medial prefrontal cortex were performed. NRF2-KO mice showed exacerbated impairment of motor functions evidenced by the increased hindlimb splay relative to WT mice at the same exposure levels. Immunohistochemistry results showed severe degeneration of noradrenergic axons characterized by a dose-dependent decrease in the density of noradrenergic immunoreactive axons in NRF2-KO mice relative to WT mice. Moreover, body weight, whole brain weight and cerebellum weight were significantly reduced in NRF2-KO mice compared to the WT mice. The results suggest increased susceptibility to ACR-induced neurotoxicity in mice lacking the NRF2 gene. In conclusion, NRF2 is able to attenuate the effects of ACR-induced neurotoxicity in mice and thus remains a crucial target for the preventive modulation of neurotoxicity.

3086 The Effect of Polybrominated Diphenyl Ethers on Daf-18 Gene Expression in and NaCl Chemotaxis in *Caenorhabditis elegans*

N. Carter, A. Height, K. Morrison, and C. A. Dodd. *Fort Valley State University, Fort Valley, GA.*

Autism Spectrum Disorder (ASD), affects 1 in 68 children in the United States, with no known cause. A combination of genetic and environmental factors may influence the increase incidence of the disease. A gene altered in some ASD patients is PTEN (Phosphatase and Tensin), a tumor suppressor responsible for cell cycle regulation that when dysregulated results in the overgrowth of neurons in ASD. One possible environmental factor linked to ASD is early exposure to polybrominated diphenyl ethers (PBDES). PBDE flame retardants used in foams, plastics, and some clothing, have been correlated with increased behavioral and cognitive deficits in children. The current study aims to elucidate a possible potentiation between PBDE exposure, PTEN expression, and development of ASD. The homologue for PTEN in *Caenorhabditis elegans* is DAF-18. Both the expression of Daf-18 and the effects of PBDEs on chemosensation, a behavior linked to Daf-18 expression were examined following exposure to BDE-47 in *C. elegans*. Real Time PCR was used to measure Daf-18 gene expression following chronic treatment of N2-wildtype worms with 20 µM BDE-47. For behavioral analysis, three test groups, N2 wildtype (control), N2 wildtype (PBDE treated) and the DAF-18 mutants (CB-1375 strain, positive control) were used in a NaCl chemotaxis assay. For both studies gravid adults were synchronized and allowed to hatch to the L1 stage before treatment. After treatment worms were fed and permitted to develop to the L4 stage. L4 stage worms were collected for RNA isolation and behavioral analysis. Multiple primers for Daf-18 were tested each showing upregulation of Daf-18 expression in the treated group compared to control. The chemotaxis was index calculated to determine the association of NaCl with food. At 60 min the chemotaxis index was negative for the PBDE treated worms indicating PBDEs may disrupt chemosensation. Results of the experiment showed that PBDEs can disrupt Daf-18 expression and alter behavior linked to this gene suggesting a possible potentiation of PTEN in ASD development.

3087 Assessing Possible Mechanisms of Neurotoxicity for Food Dyes Using ToxCast

N. T. Pham, M. Miller, and M. Marty. *California EPA, Sacramento, CA.*

There is evidence that some chemicals used as food colorings may be harmful to children's health. In particular, emerging child health concerns pertain to the potential impacts on neurobehavioral and possibly other neurological endpoints. Data about health effects of food additives on infants and children are limited; however, in general, infants and children are more vulnerable to chemical exposures. This work focuses on using *in vitro* high-throughput screening (HTS) approaches to assess potential chemical effects of the food dyes across multiple cellular pathways. The study uses the HTS data from the US EPA's ToxCast™ database in an attempt to better understand the potential hazards of the nine food dyes that are currently "batch-certified" for use in the US. We evaluated the bioactivity of these dyes in two ways. One was to identify ToxCast assays targeting genes associated with neurologic activity. Genes include those for acetylcholinesterase, and receptors for glutamate, opiates, dopamine, and serotonin. The food dyes would then be screened for their activity in this ToxCast assay subset. Another approach consisted of profiling the bioactivity of pesticides known to be associated with developmental neurotoxicity and assessing whether there was an overlap between the bioactivity of these chemicals with those of the food dyes. Using information from these approaches, the nine food dyes are ranked by their bioactivity using the Toxicological Prioritization Index (ToxPi). ToxPi ranking was based on a sum of chemical-assay AC50 and inactive values. From our initial results, the ToxCast data support certain literature findings such as the interaction of Red 40 with cholinergic and dopaminergic receptors, as well as the interactions of Yellow 5 and 6 with serotonin receptors. Overall, yellow and red food dyes appeared to have the majority of assay activity. ToxCast results did not support reported Red 40 interactions with glutamate receptors, or reported Blue 1 and 2 interactions with cholinergic receptors. There was no activity for food dyes in assays targeting acetylcholinesterase, or GABA or glutamate receptors. Such findings highlight the ongoing challenges in the application of current *in vitro* data to reliably identify neurotoxic chemicals. Nonetheless, this initial assessment demonstrates the use of HTS to explore modes of action in connection to downstream toxicological endpoints in the absence of other data.

3088 Sub-chronic Exposure to Aircraft Engine Oils Decreases Acetylcholinesterase and Butyrylcholinesterase Activities in Brain Tissues, Blood, and Plasma for Sprague Dawley Rats

I. Sibomana, P. T. Hellman, L. Rosado, and D. R. Mattie. *Air Force Research Laboratory, Wright-Patterson AFB, OH.*

Organophosphates are known to inhibit cholinesterase enzymes in animals and humans. However, little is known about the toxicity that may be associated with a sub-chronic exposure to organophosphate-based aircraft engine oils. This study was conducted to determine if grade 3 (G3) and 4 (G4) aircraft engine oils in their new states (G3-N and G4-N) and their used versions (G3-U and G4-U) have the potential to impact cholinesterase enzyme activities via dermal application. Male and female (n=50/gender) Sprague Dawley Rats (8-9 weeks old) were dermally exposed to water (control), new and used versions of G3 and G4 oils (10 males and 10 females/treatment) for a 21 day period to determine the oil's sub-chronic impact on cholinesterase enzymes in brain tissues, blood and plasma. Fifty recovery rats (n=25/gender; 5 rats/treatment) also received similar treatments and were kept for 14 days post-exposure to screen for reversibility, persistence, or delayed alteration in activities of these enzymes. A volume of 300 µL of oil was applied in the pad of the Hill Top Chamber System©. The chamber was attached to a fur-free test site located on the back of the rat for 6 h/day, 5 consecutive days/week for 21 days (15 total exposures). In brain tissues, both versions of G3 and G4 oils significantly ($p<0.05$) decreased (32% to 41%) the AChE activity for females. Only G3-N significantly lowered (33%) the AChE activity for males. G4-N did not cause a significant decrease in AChE. All these effects resolved by end of the recovery period. In whole blood samples, G3-U significantly decreased AChE by 29% for females at the end of exposure period and this effect persisted during the recovery period (32% decrease). Blood AChE activity for males was not affected. Butyrylcholinesterase (BChE) in plasma for males exposed to G4-N decreased by 29%, but resolved during the recovery period. In summary, AChE activities in rats were more altered than those for BChE and females were more sensitive to oil exposure than males. This study highlights potential health risks to which aircraft maintenance workers may be exposed if precautions are not taken to minimize exposure to these oils. *(In compliance with DODI 3216.01.)*

3089 Propofol Self-Administration Under a Progressive-Ratio Schedule in Rats and Rhesus Monkeys

A. Fujiwara[1], M. Iino[1], M. Sasaki[1], T. Ootsuka[1], M. Shimosawa[1], N. Murota[1], T. Anzai[2], and S. Sato[1]. *[1]Ina Research Inc., Ina, Japan; and [2]Showa University School of Medicine, Tokyo, Japan.*

A progressive-ratio schedule is a procedure used to assess the strength of reinforcing effects in self-administration studies. In non-clinical research, propofol functions as a positive reinforcer in self-administration studies under fixed-ratio schedules in rats and rhesus monkeys. While clinical misuse and abuse of propofol has been reported worldwide, and some of these instances have resulted in death, non-clinical results using propofol under the progressive-ratio schedule have not yet been reported. Therefore, in this study, we compared the strength of reinforcing effects among cocaine, ketamine and propofol under a progressive-ratio schedule in rats and rhesus monkeys. In rats (n=4), the mean breaking point of cocaine at 1 mg/kg/infusion was 88.3 and was comparable with that of ketamine at 3 mg/kg/infusion. On the other hand, the mean breaking point of propofol at 3 mg/kg/infusion was just 8.3% that of cocaine. In rhesus monkeys (n=2), the mean breaking point of cocaine at 0.1 mg/kg/infusion was 975 and the mean breaking point of ketamine and propofol were 7.5 and 29.7% of cocaine, respectively. As described above, the strength of reinforcing effects were "cocaine = ketamine > propofol" in rats and "cocaine > propofol > ketamine" in rhesus monkeys. Therefore, when choosing animal species, it is important to note that differences among species may exist when comparing in the strength of reinforcing effects.

3090 Development of a High-Content Human Co-culture Model to Predict Chemotherapy Induced-Peripheral Neuropathy

L. McCoy[1], E. Trueblood[2], B. Schimpf[2], and A. Sharma[1]. *[1]AxoSim, New Orleans, LA; and [2]Seattle Genetics Inc., Seattle, WA.* Sponsor: M. Moore

Antibody-drug conjugates (ADCs) are intended for targeted delivery of highly potent payloads to cancer cells. Tubulin-disrupting drugs are frequently used as ADC payloads and have been associated with a side effect of peripheral neuropathy (PN). Current nonclinical models of PN are practically challenging with uncertain translatability. Optimization of high-content (HC) systems offers the possibility of sensitive, cost-effective, and translatable tools for predicting potential PN in the clinic. ADCs may cause PN by a variety of mechanisms, including a bystander effect (BE) where cell permeable payloads may be released in a non-targeted way into adjacent tissue. Developing models that incorporate the BE requires the presence of support cells in the test system. We have characterized a novel, human cell-based, co-culture system comprised of induced pluripotent stem cells-derived sensory neurons (hSNs) and primary human Schwann cells (hSCs). A comparison of range of densities and ratios revealed 4:1 (hSNs:hSCs) as optimum for imaging and evaluation of neurite length and total cell number. We further characterized this system by evaluating dose responses for two known clinical neurotoxicants, paclitaxel and oxaliplatin. Analysis showed that the co-cultures were less sensitive than monocultures across all parameters tested, suggesting that support cells improve the viability of hSNs. Next, we exposed co-cultures and hSN monocultures to non-targeted ADCs conjugated with either monomethyl auristatin E (high BE) or monomethyl auristatin F (low BE). Differentiation between the neurite length in these systems, and an apparent increase in toxicity of MMAE non-targeted ADC in the presence of hSCs, points to BE as being a potential mechanism of action. These experiments demonstrated that a high-content, human cell-based, co-culture system could be an effective tool for assessing the PN potential of new therapeutics.

3090a Regulation of Synaptic Plasticity-Related Gene by Nicotine on Human Neuroblastoma SH-SY5Y Cells

L. Fan[1,2,3], H. Chen[1], A. Wang[2], Y. Liu[2], H. Hou[1], Q. Hu[1], and F. Yaning[4]. *[1]China National Tobacco Quality Supervision and Test Center, Zhengzhou, China; [2]Chinese Academy of Sciences, Hefei, China; [3]University of Science and Technology of China, Hefei, China; and [4]China National Tobacco Quality Supervision & Test Center, Zhengzhou, China.*

The nicotine addiction process shares many commonalities with the synaptic plasticity mechanisms normally involved in learning and memory. In this study, the changes of 84 synaptic plasticity-related genes in transcription level were investigated by treating SH-SY5Y cells with 2 different nicotine concentrations (6μM and 60μM) for 2 exposure time durations (12 hours or 24 hours). For 12 hours exposure, only 2 genes (CNR1, GRM5) were up-regulated after exposure to 6μM nicotine (the fold regulation is 2.28, 2.01), while 6 genes(CNR1, GRIA2, GRIN2A, GRM1, GRM8, NOS1) were up-regulated (the fold regulation is 2.55, 2.27, 2.81, 2.06, 3.35, 2.06) when the concentration of nicotine was 60μM. On the contrast, 6 genes (ARC, EGR1, EGR3, EGR4, GRM1, TNF) were down-regulated (the fold regulation is –2.23,–2.35,–2.35,–2.66,–2.17,–2.46) and only 1 gene(GRIN2B) is up-regulated (the fold regulation is 2.69) when the cells were exposed to 6μM nicotine for 24 hours, while 6 genes (GRIN1, GRIN2A, GRIN2B, GRM8, NGFR, NPTX2) were up-regulated (the fold regulation is 2.25, 2.66, 3.89, 7.73, 2.33, 2.43) and 1 gene (ARC) was down-regulated (the fold regulation is –2.22) after exposure to 60μM nicotine for 24h. These significant changed genes are associated with the formation of synaptic connections and the transmission of neural signals, suggesting nicotine plays an important role in the remodeling of synaptic structure and function in human neurons.

3091 Baseline Cardiac Phenotypes Vary across a Diverse Population: Implications for Cardiotoxicity Risk Assessment

J. Popp, and D. Threadgill. *Texas A&M University, College Station, TX.*

Cardiotoxicity is often the most sensitive parameter for determining threshold exposure levels of toxicants, but relatively few environmental chemicals have been tested successfully for cardiotoxicity. This is due, in part, to incomplete, although ongoing, development of models of cardiotoxicity, both *in vitro* and *in vivo*. Simplistic *in vitro* models lack receptor diversity, while *in vivo* models usually make use of a homogenous population. Of those chemicals tested, translating findings from current models to human risk assessment is challenging due to the lack of genetic diversity represented in these models, as well as limited epidemiological data to validate translation to humans. Animal models have been the gold standard for risk assessment, and with the use of individuals from a genetically diverse mouse reference population, the Collaborative Cross (CC), we can model the genetic diversity present in the human population. In 31 strains of mice, electrocardiogram measurements indicate a high strain-dependent variability ranging from 300 BPM to 800 BPM as well as significant differences in QT interval duration. Comparing cardiac high frequency ultrasounds acquired in both conscious and unconscious mice, strain-dependent effects of isoflurane on cardiac function were observed. Results demonstrate inter- and intrastrain variability in unexposed mice. While the goal is to create a powerful diverse testing panel whose baseline phenotypes are characterized before and after exposure to several chemicals, these baseline measurements are crucial for identifying the ideal model for testing toxicity, ultimately allowing more informative risk assessments.

3092 Triptolide Induces Cardiotoxicity by p53 Activation in Cardiomyocytes

Y. Xi, F. Shen, and Z. Huang. *Sun Yat-sen University, Guangzhou, China.*

Triptolide (TP), a principal active ingredients extracted from Chinese herb *Tripterygium wilfordii* Hook. F. (TWHF), has attracted wide attention of its therapeutic effects on inflammation and autoimmune diseases. Severe cardiomyocyte toxicity is the main factor hindering its clinical application. Our studies indicated that p53 was indispensable in TP-induced cardiotoxicity. We investigated the role of p53 in TP-induced cardiotoxicity in H9c2 cell lines, primary neonatal rat cardiomyocytes, and $p53^{-/-}$ mice. p53 protein level was elevated by TP *in vitro* and *in vivo*. p53 deficiency effectively prevented heart histology injury, reversed myocardial energy metabolism and decreased serum cardiac troponin I (cTn-I). p53, as a transcription factor, regulates the transcription of its target genes involved in apoptosis, such as Bcl2 family members. On the other hand, p53 activation inhibites IKKβ-NF-κB pathway that regulates glucose transporter (GLUT) expression. Based on these evidences, we investigated the mechanisms of p53 mediated cardiotoxicity from two sides, motochondrial-dependent apoptosis and disturbed glucose metabolism. Immunoblotting and immunofluorescence identified that TP-induced toxicity was dependent on p53 nuclear translocation and transactivation of Bcl2 family genes leading to mitochondrial outer membrane permeabilization. p53 antagonist PFTα counteracted apoptotic gene transcription and improved mitochondrial membrane integrity. Bax inhibitor peptide (BIP) V5 ameliorated TP-induced apoptosis through suppressing membrane depolarization and ROS accumulation. Additionally, depressed glucose consumption and ATP production by TP also contributed to the cardiac damage. ATP improved TP-induced injury. Mechanically, TP suppressed glucose uptake by restriction of IKKβ-NF-κB activation, GLUT1 and GLUT4 expression which was abolished by PFTα treatment. Consistently, in acute heart injury models, *p53* deficiency upregulated IKKβ-NF-κB activation and GLUT1 and GLUT4 protein levels. The present findings indicated that p53 mediated TP-exerted cardiotoxicity by Bax-induced apoptosis and disturbing glucose metabolism through inhibition of GLUT1 and GLUT4 expression.

3093 Cardiovascular Toxicity Assessment of Tris (2-Chloroethyl) Phosphate (TCEP) in *Ex Ovo* Chicken Embryos

K. Kanda[1], S. Ito[1], D. Koh[2], E. Kim[2], and H. Iwata[1]. *[1]Ehime University, Matsuyama, Japan; and [2]Kyung Hee University, Seoul, Korea, Republic of.*

Tris (2-chloroethyl) phosphate (TCEP) is one of pervasive organophosphate flame retardants (OPFRs) that have been used for textiles, industrial materials and furnitures. Some of avian species are top predators in the ecosystem and are exposed to high concentrations of environmental contaminants through the food web. TCEP has been detected from tissues and eggs of wild birds. However, there are fewer studies regarding the effects of TCEP on avian embryos. In *in ovo* exposure test of avian embryonic development, *in situ* observation has been difficult because avian embryos develop within untransparent eggshell. A novel shell-less incubation system for chick embryos that enables to visualize *in situ* the development of chicken embryos has been developed in 2014. Here, we assessed the developmental toxicity of TCEP exposure on chicken embryos in the shell-less incubation system. Fertilized chicken (*Gallus gallus domesticus*) eggs were treated with 50, 250 and 500 nmol/g egg of TCEP (TCEP-L, -M and -H, respectively) or DMSO (control) at the beginning of incubation. Survival rates started to be greatly reduced from 3rd incubation day and were significantly decreased until 9th day in TCEP-M and TCEP-H groups. The heart rate was significantly decreased on 5th day in TCEP-M and on 5th and 6th days in TCEP-H. The length and number of extra-embryonic blood vessels were significantly decreased on 4th day in TCEP-M and TCEP-H embryos. Digital gray image values of the extra-embryonic artery, an indicator of the number of red blood cells, were significantly decreased on 4th and 5th days in TCEP-M and on 4-7th days in TCEP-H. The cardiac transcriptome analysis and the following transcription factor enrichment analysis intimated that activation of NFKB1, SP1, SP3, GLI1, CTNNB1 and SMAD4 by TCEP exposure were critical molecular initiating events. Protein-protein interaction network analysis showed the dysregulation of genes related to muscle filament sliding and Ca^{2+} transport. In KEGG pathways, expression levels of ryanodine receptor 2 (RYR2) and, myosin genes were changed, suggesting altered cardiac muscle contraction. These results indicate that TCEP exposure to chicken embryos may induce decreases in heart rate and survival rate by altered expression of genes related to myocardial contraction.

3094 Effects of Small Molecule Protein Kinase Inhibitors on Isolated Rat Heart Mitochondria

Q. Shi[1], L. Ren[1], L. Yi[1], X. Yang[2], L. K. Schnackenberg[1], and W. B. Mattes[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]US FDA/NCTR, Silver Spring, MD.*

As of October 2019, the FDA has approved 53 small molecule kinase inhibitors (KIs), with 30 of them (57%) having warnings for cardiotoxicity in the labeling, 3 being boxed warnings. To better understand the mechanisms of KI cardiotoxicity, the mitochondrial liabilities of KIs were examined in isolated rat heart mitochondria. Freshly prepared mitochondria were treated with KIs at concentrations normalized to the peak blood concentrations (Cmax) in humans, and then oxygen consumption, inner membrane potential, swelling, cytochrome c release and reactive oxygen species were measured. In general, it was found that KIs, including ceritinib, lorlatinib and encorafenib, caused either significant inhibition of state 3 respiration or remarkable increases in state 4 respiration, indicating these drugs are either respiratory chain inhibitors or uncouplers. For the three KIs with boxed warnings for cardiotoxicity, only vandetanib remarkably inhibited oxygen consumption, and the other two drugs, nilotinib and ponatinib, showed no effects, suggesting the involvement of alternative mechanisms for their cardiotoxicity. A notable finding is that regorafenib caused almost complete uncoupling at concentrations 2-fold Cmax, and its two pharmacologically active metabolites, M2 and M5, whose blood levels are the same as regorafenib, were remarkably less toxic to the mitochondria, indicating that regorafenib cardiotoxicity is likely mainly associated with the parent drug but not the metabolites. These data suggest that off-target effects on mitochondrial functions may contribute to KI induced cardiotoxicity.

3095 Cardiac Toxicity Comparison of Roundup and Glyphosate on Human-Induced Pluripotent Stem Cells Derived Cardiomyocytes

R. Printemps, and S. Guilbot. *PhysioStim, Lautrec, France.* Sponsor: R. Printemps, Safety Pharmacology Society

Pesticides are widely widespread in agriculture but their use is suspected of hazardous health effects. Evaluate the safety and potential health risks from exposure to pesticides is a major challenge. Roundup® is an herbicide formulation based on an active ingredient, glyphosate, and adjuvants. Roundup® and glyphosate were compared using human cell based model to evaluate their impacts on cardiovascular function after exposition. Several concentrations of Roundup® and glyphosate were recorded on iCell² cardiomyocytes (derived from Human induced Pluripotent Stem Cells, Fujifilm) using the xCELLigence RTCA cardio ECR platform. Cardiac contractility (impedance) and electrophysiology (MEA) were simultaneously monitored during acute and chronic expositions (up to 24h). No modification of cardiac contractility nor electrical activity or cell viability have been observed in the presence of glyphosate even at the highest concentration of 100µM. At the same concentration of Roundup®, iCell² cardiomyocytes stopped beating and cell index was rapidly and drastically affected (-55% after 24h), corresponding to partial cardiomyocytes death. The absence of effects of glyphosate on cardiac function indicates that the cardiotoxicity observed with Roundup® could be attributed to Roundup® adjuvants. This predictive and sensitive assay can be very useful for cardiotoxicity assessment of pesticides using a human cell based model. This work also demonstrates that the evaluation of pesticides' adjuvants is also necessary to better address the safety of pesticides which can also be enlarged to a broader class of molecules.

3096 Arsenic Is a Unique Modulator of Macrophage Polarization toward Pro-Atherogenic Phenotypes

K. Makhani[1], N. De Jay[1], C. Charpy[2], L. Silva[1], M. Lemaire[2], C. Kleinman[1], and K. Mann[1]. *[1]McGill University, Montreal, QC, Canada; and [2]Jewish General Hospital, Montreal, QC, Canada.*

Arsenic toxicity is a global health concern and is correlated with adverse cardiovascular outcomes, including atherosclerosis. Atherosclerotic plaque formation is a complex process with macrophages being major players in both its initiation and progression. Macrophages accumulate lipids and modulate the microenvironment through secreting cytokines and recruiting other immune cells to the site. There is phenotypic heterogeneity of macrophages residing in plaques, the most prevalent of which are broadly characterized as M1 (pro-inflammatory) and M2 (anti-inflammatory) subtypes in response to microenvironmental cues. Here, we hypothesized that arsenic exerts proatherogenic effects by skewing the relative abundance of pro- and anti-inflammatory macrophages towards pro-inflammatory M1 macrophages. To test this hypothesis, we cultured bone marrow derived macrophages from C57BL/6 mice *in vitro* and differentiated them into M1 (IFNγ) or M2 (IL-4) phenotypes in the presence or absence of 50 ppb arsenic over 48 hours. Gene expression was assessed by RNA sequencing. The principle component analysis showed that unpolarized (M0), M1, and M2 macrophages could easily be distinguished. Surprisingly, arsenic did not result in a separate population of "arsenic-exposed macrophages", but rather altered different gene expression within each subtype. Within M2 macrophages, many chemokines were altered by arsenic. In particular, CCL17 and CCL22 mRNA and secreted CCL17 and CCL22 protein levels were decreased in the presence of arsenic. These anti-inflammatory chemokines recruit Tregs leading to the plaque resolution. We will correlate arsenic exposures with decreased CCL17/22 to decreased Tregs and increased plaque size *in vivo*.

3097 Transient and Sustained Antioxidant Protection in Progeny following Gestational Engineered Nanomaterial Inhalation Exposure

A. Kunovac, Q. A. Hathaway, A. D. Taylor, M. V. Pinti, W. T. Goldsmith, G. K. Fink, A. J. Durr, T. R. Nurkiewicz, and J. M. Hollander. *West Virginia University, Morgantown, WV.*

Increased utilization of engineered nanomaterials (ENM) necessitates thorough investigation into the systemic toxicological events associated with inhaled exposure. Of particular concern are vulnerable populations, such as the developing fetus, which may experience more detrimental alterations following maternal exposure. This study aimed to determine whether targeting antioxidant defense to the mitochondrion via overexpression of mitochondria phospholipid hydroperoxide glutathione peroxidase (mPHGPx) could diminish cardiac dysfunction in fetal and adult progeny following maternal exposure to nano-TiO_2 during gestation. To gain insight into the importance of maternal vs progeny regulated mitochondrial antioxidant protection during development, two strategies were employed. Wild-type (WT) and transgenic (mPHGPx) female mice were bred with transgenic and WT males, respectively. Pregnant dams were exposed to sham air or nano-TiO_2 (primary particle size = 21 nm, mass concentration = 12 mg/m^3) for 6 hrs/day over 6 days. Echocardiography performed at the fetal stage (GD 14) revealed that maternal antioxidant protection significantly enhanced cardiac output by 86% and stroke volume by 43% compared to pups of nano-TiO_2-exposed

WT dams. At the adult stage (11 wks), transgenic offspring of WT dams presented with significantly higher ejection fraction (8%) and fractional shortening (29%) compared to WT offspring of nano-TiO_2-exposed transgenic dams. Therefore maternal antioxidant protection, in the absence of the transgene in the offspring, may not be sufficient for complete protection into adulthood. Mitochondrial respiration revealed a >3 fold higher respiratory control ratio in transgenic offspring of transgenic dams compared to transgenic offspring of WT dams. N^6-methyladenosine (M^6A) abundance, which can be induced by elevated ROS, was significantly decreased in the WT offspring of transgenic (0.046 ± 0.007) and WT dams (0.050 ± 0.009) when compared to WT sham-exposed offspring (0.091 ± 0.008). These data present the potential of antioxidant defense during fetal development and adulthood for ameliorating cardiac dysfunction following gestational ENM exposure, yet highlight the pivotal role of antioxidant delivery context.

PS 3098 Sex-Biased Differences in Circulating microRNAs in Doxorubicin-Treated Mice

V. Vijay, T. Han, C. L. Moland, A. Azevedo-Pouly, B. Phanavanh, K. Sivakumar, J. C. Fuscoe, and V. G. Desai. *US FDA/NCTR, Jefferson, AR.*

Despite a severe side effect of cardiotoxicity, doxorubicin (DOX) remains one of the most widely used anticancer drugs. There is evidence that males are more susceptible to DOX-induced cardiotoxicity than females. While a majority of animal studies have focused on heart tissue, information on sex-biased circulating microRNAs (miRNAs) is lacking. Circulating miRNAs are widely considered as potential markers of many cardiac diseases or toxicities because of their role as key regulators of gene expression and important biological processes. We have previously shown that a cumulative dose of 24 mg/kg DOX caused cardiac pathology and significantly altered miRNA expression in male B6C3F1 mouse heart. Therefore, male and female B6C3F1 mice (n=8) were treated with a weekly dose of 3 mg/kg DOX or saline (SAL) via tail vein for 8 weeks (resulting in 24 mg/kg cumulative dose). At necropsy one week after the last dose, plasma samples were collected to evaluate sex difference in the level of circulating miRNAs in response to DOX-treatment leading to cardiotoxicity. MiRNA sequencing was performed on Illumina NextSeq system using Edgeseq Whole Transcriptome Assay for 273 mouse miRNAs. With a cutoff of FDR<0.1, 143 plasma miRNAs were significantly altered (DOX vs. SAL) in males, while only 1 miRNA was significantly altered in female mice. Six miRNAs (miR-130a, miR-19b, miR-21, miR-221, miR-23b, miR-34a) had at least 1.8-fold higher transcript level (DOX vs. SAL) in male plasma and these were also significantly upregulated (FDR<0.1) in the hearts of male mice treated with the same dose of DOX. Enrichment analysis of 143 significantly altered miRNAs in males and their mRNA targets revealed involvement of many plasma miRNAs (such as miR-21, miR-19b, miR-221) in cardiac hypertrophy, fibrosis, necrosis and apoptosis. Supporting these findings, a greater susceptibility of male hearts to DOX compared to females was indicated by a 3.6-fold increase in plasma cardiac troponin T in male mice compared to females and cytoplasmic vacuolization only in male hearts. These circulating miRNAs may shed light on the mechanisms of differential sex-biased susceptibility to DOX toxicity and may have potential in predicting early-onset of DOX cardiotoxicity.

PS 3099 Prediction of Drug-Induced Cardiotoxicity and Liver Toxicity Using Chemical Structure and *In Vitro* Assay Data

L. Ye, R. Huang, J. Zhao, L. Zhang, S. Sakamuru, T. Zhao, M. Xia, and R. Huang. *NIH, Rockville, MD.*

Drug-induced cardiotoxicity and liver toxicity (DILI) are major adverse effects encountered by many clinically important drugs especially antineoplastic agents. To provide an alternative to *in vivo* toxicity testing, the US Tox21 program has screened a collection of ~10K compounds, including drugs in clinical use, against ~70 cell-based assays in a quantitative high-throughput screening (qHTS) format. In this study, we evaluated the potential of Tox21 assay data in comparison with chemical structure information in building optimal prediction models for human *in vivo* cardiotoxicity and DILI. Models were built with a number of machine learning algorithms (e.g., random forest, SVM, MLP) and model performance was evaluated by area under the receiver operating characteristic (ROC) curve (AUC) and Matthews Correlation Coefficient (MCC). Chemical structure based models showed moderate predictive power for cardiotoxicity (AUC = 0.69±0.04) and better predictive performance for DILI (AUC = 0.77±0.05). Tox21 assay data alone only showed better than random performance with AUCs around 0.6. Combining assay data and structure information significantly improved the performance of the cardiotoxicity prediction model (AUC = 0.79±0.06) but did not have a positive impact on DILI prediction. The suboptimal predictive performance of the assay data is likely due to insufficient coverage of an adequately-predictive number of toxicity mechanisms. Tox21 is currently expanding the coverage of biological response space with additional assays that probe toxicologically-important targets and under-represented pathways that may improve the prediction of *in vivo* toxicity such as DILI and cardiotoxicity.

PS 3100 Protective Effect and Mechanism of Metallothionein on Heart Damage Induced by High-Fat Diet and Therapeutic Dose of Arsenic Trioxide

T. Ge[1], Y. Yu[1], L. Cai[1], and J. Cui[2]. *[1]Pediatric Research Institute, Louisville, KY; and [2]Cancer Center, Changchun, China.*

Arsenic trioxide is a common clinical anti-tumor drug. However, the cardiotoxicity caused by its application seriously hindered the strategy of treatment. Unfortunately, patients with tumors also commonly suffer from heart damage induced by a high-fat diet or abnormal lipid metabolism, which greatly limits the choice of arsenic trioxide as an anti-tumor treatment. Metallothionein is an effective endogenous antioxidant, which can effectively protect cardiac myocytes from oxidative stress injury. Therefore, the purpose of this study was to prove whether metallothionein can protect cardiac myocytes and inhibit the occurrence of cardiac toxicity under the double attack of high-fat diet and treatment dose of arsenic trioxide. MT-TG transgenic and WT mice were exposed to a high-fat diet and a normal diet. Subsequently, arsenic trioxide (5mg/kg/day) was injected for one month. Metallothionein has a protective effect on myocardial oxidative stress injury, which may be achieved by directly inhibiting oxygen free radicals. In addition, metallothionein protects myocardial cell apoptosis by inhibiting the P53 signaling pathway and inhibiting myocardial cell apoptosis. Finally, metallothionein can inhibit the recruitment of immune cells by inhibiting the activation of the NF-kB inflammatory signaling pathway and inhibiting its downstream inflammatory cytokines, adhesion molecules and chemokines, thus achieving the protective effect of myocardial inflammatory response and fibrosis. 1.High-fat diets increases the sensitivity of ATO leading to heart damage. 2.MT inhibits cardiomyocyte fibrosis, apoptosis, inflammatory response, and oxidative stress injury induced by high-fat diets and therapeutic doses of ATO.3.The protective mechanism of MT on the heart may be achieved by directly reducing oxygen free radical production.

PS 3101 Effects of Polysorbate 80 as a Vehicle: Species Comparison in Beagle Dogs, Cynomolgus Monkeys, and Göttingen Minipigs

S. Authier[1,2], T. Zabka[3], J. Maher[3], P. Paula Juliana Brizuela de Seadi Pereira[1], L. Miraucourt[1], and R. Kubaszky[1]. *[1]Charles River, Laval, QC, Canada; [2]Université de Montréal, Saint-Hyacinthe, QC, Canada; and [3]Genentech Inc., San Francisco, CA.*

Polysorbate 80 is a nonionic surfactant and emulsifier commonly used as a vehicle in non-clinical formulations. Polysorbate 80 has been associated with IgE independent anaphylactoid reactions in various species including humans, with dogs recognized as the most susceptible species. Polysorbate 80 at 3 mg/kg (0.15%, 2 mL/kg, 15 min IV infusion) was administered to Beagle dogs, Göttingen minipigs and cynomolgus monkeys. Dogs were also treated with Polysorbate 80 at 3 mg/kg as a 15 min IV infusion with diphenhydramine (1 mg/kg, SC) pre-treatment. Additionally, Polysorbate 80 at 10 mg/kg was administered orally to Beagle dogs. All animals were monitored for clinical signs or cardiovascular changes by telemetry. No clinical signs, histamine level changes or cardiovascular effects were observed in cynomolgus monkeys or Göttingen minipigs. In dogs, a 3 mg/kg 15 min IV infusion was associated with a body temperature decline reaching a -2 Celsius nadir at 45 min post-dose and recovery to baseline comparable values by 105 min post-dose. Hypotensive effects were transient but chronotropic changes were sustained. Parallel to the cardiovascular changes, mean plasma histamine levels were maximal at 20 min post-dose at 3 mg/kg and diphenhydramine was associated with a 3-fold reduction in histamine release and a significant attenuation of cardiovascular effects. Oral administration of Polysorbate 80 at 10 mg/kg was associated with facial edema in 33% of dogs but without any cardiovascular changes. Polysorbate 80, at 3 mg/kg as 15 min IV infusion was not associated with any signs of anaphylactoid reaction in cynomolgus monkeys or Göttingen minipigs. In dogs, skin edema was observed prior to cardiovascular changes and diphenhydramine pre-treatment significantly attenuated cutaneous and cardiovascular changes. Overall, these results confirm the high susceptibility of Beagle dogs to Polysorbate 80 mediated anaphylactoid reactions with differences between dosing routes.

3102 Weighted Gene Coregulation Network Analysis (WGCNA) to Decipher Temporal Dynamics in Cardiotoxicity

A. Rahman[1], D. Svoboda[2], P. R. Bushel[1], B. R. Berridge[1], and S. S. Auerbach[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; and [2]Sciome LLC, Durham, NC.*

Cardiotoxicity can be elicited through a variety of mechanisms, which lead to complex, temporally regulated compensatory processes at the molecular level. The sequence of molecular processes has evolutionary roots that, at a regulatory level, are analogous to highly complex agent-based models with self-organized behavior. One approach to delineating the evolved, self-organizational framework is to characterize the coordinated expression genes across a diverse set of toxicological perturbations using WGCNA. Here we describe a cartographic exercise that uses WGCNA of the DrugMatrix heart gene expression data (1-5 days in duration, 88 test articles) from rat to reveal a map of gene-level co-expression relationships that are rooted in compensatory/adaptive processes associated with cardiotoxic stress. In total, the map reveals sets of genes tightly linked to well document biological processes such as cell cycle and ribosomal biogenesis, but also identifies sets of genes that are reflective of changes in cellularity and processes central to the differentiate functions of cardiac cells. We use the co-expression map as a base framework to explore the temporal dynamics of cardiotoxicity of a variety of prototype agents such as anthracyclines, corticosteroids, and kinase inhibitors. The exercise reveals early agent specific behavior that evolves into a general compensatory process that is likely intrinsic to the reparative function of the heart and is conserved across most test articles. We believe this analysis serves as molecular level point of reference that can be used to understand the capabilities and limitations of *in vitro* systems for modeling cardiotoxicity.

3103 A Targeted Metabolomics-Based Assay Using Human-Induced Pluripotent Stem Cell-Derived Cardiomyocytes Identifies Structural and Functional Cardiotoxicity Potential

J. A. Palmer[1], A. M. Smith[1], M. R. Colwell[1], V. Gryshkova[2], E. L. Donley[1], J. Valentin[2], and R. E. Burrier[1]. *[1]Stemina Biomarker Discovery Inc., Madison, WI; and [2]UCB Biopharma SPRL, Braine L'Alleud, Belgium.*

Implementing screening assays that identify functional and structural cardiotoxicity earlier in the drug development pipeline has the potential to improve safety and the cost and time required to bring new drugs to market. In this study, a metabolic biomarker-based assay was developed that predicts the cardiotoxicity potential of a drug based on changes in the metabolism and viability of human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CM). Assay development and testing was conducted in two phases: (1) biomarker identification and (2) targeted assay development. In the first phase, metabolomic data from hiPSC-CM spent media following exposure to 66 drugs was used to identify biomarkers that identified both functional and structural cardiotoxicants. Four metabolites that represent different metabolic pathways (arachidonic acid, lactic acid, 2′-deoxycytidine, and thymidine) were identified as indicators of cardiotoxicity. In phase two, a targeted, exposure-based biomarker assay was developed that measured these metabolites and hiPSC-CM viability across an eight-point concentration curve. Metabolite-specific predictive thresholds for identifying the cardiotoxicity potential of a drug were established and optimized for balanced accuracy or sensitivity. When predictive thresholds were optimized for balanced accuracy, the assay predicted the cardiotoxicity potential of 81 drugs with 86% balanced accuracy, 83% sensitivity, and 90% specificity. Alternatively, optimizing the thresholds for sensitivity yields a balanced accuracy of 85%, 90% sensitivity, and 79% specificity. This new hiPSC-CM-based assay provides a paradigm that can identify structural and functional cardiotoxic drugs that could be used in conjunction with other endpoints to provide a more comprehensive evaluation of a drug's cardiotoxicity potential.

3104 The Effects of Inhaled Multiwalled Carbon Nanotubes on Systemic Blood Pressure and the Autonomic Nervous System in Spontaneously Hypertensive Rats

T. South, W. McKinney, M. L. Kashon, and H. Kan. *NIOSH, Morgantown, WV*. Sponsor: J. Antonini

It is well documented that the autonomic nervous system (ANS) plays a critical role in controlling cardiovascular functions including heart rate, cardiac contractility and blood pressure (BP). In previous studies, we reported that inhalation of multi-walled carbon nanotubes (MWCNTs) elevated systemic BP, which was associated with an altered activity in the ANS in normotensive rats. In addition, we also reported that the BP of spontaneously hypertensive (SH) rats was greatly increased in response to pulmonary MWCNT exposure compared to normotensive rats. The available evidence indicates that in essential hypertension, there is a deteriorated balance between sympathetic and parasympathetic activity. The present study investigated the effects of inhaled MWCNTs on the ANS and the role of peripheral neurons in regulation of cardiovascular function after exposure of SH rats to MWCNTs. SH Wistar rats were pre-implanted with a telemetry device and exposed by inhalation to MWCNTs at a concentration of 2 mg/m^3 for 5 h/day for three consecutive days. The real-time EKGs and systemic BP were recorded by a telemetry system at pre-exposure, during exposure, 1 day post-exposure and 7 days post-exposure. The activity of the ANS in response to MWCNT exposure was determined by heart rate variability (HRV) analysis. The non-selective transient receptor potential (TRP) channel blocker, ruthenium red (2.5 mg/kg), was injected intraperitoneally 1 h before MWCNT exposure to study the role of peripheral neurons in regulating cardiovascular function and activity of the ANS after pulmonary MWCNT exposure. Inhalation of MWCNTs elevated systemic BP and increased the variance of the root mean square of successive differences (RMSSD) between adjacent R-R intervals ($p < 0.01$) and the high frequency (HF) power ($p < 0.01$). Both RMSSD and HF are metrics corresponding to autonomic nerve influences on cardiovascular function. Pretreatment with ruthenium red prevented those increases. Our study indicates that pulmonary exposure to MWCNTs significantly altered the activity of the ANS and increased the BP via a peripheral neuron-regulated pathway in SH rats.

3105 Cerebrovascular Dysfunction and Microvessel Density Changes in Offspring of Rat Dams Exposed to Electronic Cigarette Aerosols

E. N. Burrage, E. Aboaziza, S. Reppert, C. Price, J. O'Reilly, L. Hare, P. D. Chantler, and M. Olfert. *West Virginia University, Morgantown, WV.*

Electronic cigarette (E-cig) usage has steadily been increasing and it is even being promoted as a safer option to traditional tobacco cigarettes; however, there is little evidence supporting this theory as it relates to the cerebrovasculature. We examined the effects of maternal E-cig exposure (Joyetech eGrip OLED using 5-sec puffs @17.5 W) on cerebrovascular function and microvessel density in offspring with maternal exposure to ambient air (control, n=6), E-cig with 18 mg/ml nicotine (E-cig18, n=6), and without nicotine (E-cig0, n=7). Exposure consisted of 60 puffs over 1-hour each day, 5 days/week, and resulted in an average daily TPM of ~120 mg/m^3. Maternal exposure was started on gestational day 2 and continued until pups were weaned. Pups themselves we never directly exposed. The middle cerebral arteries (MCA) were obtained from 3-month old pups, isolated and positioned in a pressurized myobath, and exposed to increasing concentrations of acetylcholine (Ach; 10 -9 M to 10 -4 M), serotonin (5-HT; 10 -9 M to 10 -4 M), and sodium nitroprusside (SNP; 10 -9 M to 10 -4 M), in the presence or absence of Tempol (a superoxide dismutase mimetic). Brains were also flash frozen, sectioned, and analyzed for microvessel density (MVD). The MCA dilation of offspring to Ach was impaired in both E-cig0 and E-cig18 by 63% and 62%, respectively, compared to controls (<0.05). Incubation with tempol reversed the cerebrovascular dysfunction seen in both E-cig groups, suggesting the superoxide pathway is involved in the impairment observed in offspring with maternal E-cig use. The MCA dilation to SNP and constriction to serotonin was similar between all groups. Preliminary data (n=2 per group) shows a 12% and 29% decrease in MVD in the cortex of E-cig0 pups and E-cig18 pups, respectively. These data suggest that E-cig usage during pregnancy impairs the cerebrovascular reactivity and induces rarefaction of cortical microvessels in offspring.

3106 Developing Patient-Centric *In Vitro* Cardiovascular Safety Models Applicable to Drug Discovery

L. Starnes[1], A. Hall[2], A. Cavallo[1], D. Etal[1], R. Hicks[1], and A. Pointon[2]. *[1]AstraZeneca, Mölndal, Sweden; and [2]AstraZeneca, Cambridge, United Kingdom.* Sponsor: L. Starnes, Safety Pharmacology Society

Translation of functional and structural toxicity findings from healthy to disease states is a major challenge to providing safe and efficacious drugs. Currently, a range of *in vitro* and *in vivo* model systems are utilized to risk assess cardiovascular safety. Largely, these approaches rely on cells derived from 1-2 healthy donors or healthy animals that do not recapitulate patient's co-morbidities, pathophysiology of disease, drug treatment history or genetic variability. Critical to cardiomyocyte function is calcium signalling for which genetic variability within key calcium handling genes in the population exists. We hypothesized that hiPSC-CMs containing SNPs or reduced expression levels of a critical calcium handling gene, *RYR2* would display differential pharmacological responses compared to isogenic controls. This model would

allow, elucidation of the impact of genetic variability in calcium handling on the manifestation of drug-induced cardiotoxicity. hiPSCs were transfected with Cas9-GFP and gRNA plasmids +/- ssODN, followed by single cell FACS sorting, expansion and verification of genotype by Amplicon/Sanger sequencing. The isogenic lines obtained (2 heterozygous knockouts (Het KO), 1 SNP1 and WT parental) contained 95-98% Oct4 and SSEA4 double positive cells as measured by FACS and immunofluorescence indicating a pluripotent state, had normal G-banding karyotype and could differentiate to beating hiPSC-CMs containing 70-90% of cTnT positive cells. In addition, the resulting hiPS-CMs expressed α-actinin, PLN and SERCA2. Furthermore, western blot analysis confirmed that Het KO *RYR2* lines had 2-fold reduction of RYR2 expression. Functional characterisation confirmed a stable beat rate and amplitude, in addition, WT and Het KO cells responded to electrical stimulation up to 2Hz. hiPSC-CMs were analysed for contractility changes in response to selected inotropes. For example, WT, Het KO or SNP1 cells were treated with the L-type calcium channel inhibitor, verapamil or vehicle control and beat rate IC_{50} values were determined. SNP1 cells displayed increased sensitivity compared to WT and Het KO cells. In conclusion, a novel patient-centric *in vitro* cardiovascular safety model was developed which displays differential cardiotoxic susceptibility response to drug treatment. This provides a proof of principle for patient-centric *in vitro* human models in cardiovascular safety.

3107 QA Interval Heart Rate Correction: Multispecies Comparison of an Indirect Ventricular Contractility Biomarker

R. Kubasky, M. V. Accardi, Y. Zhong, E. Boulay, and S. Authier. *Charles River, Laval, QC, Canada.*

Ventricular contractility parameters are influenced by multiple factors (e.g. preload, afterload and heart rate). Recently, we described the value of using a multi-parameter correction on a key contractility parameter (i.e., dP/dt_{max}) for enhancing data interpretation in non-clinical drug safety assessments. To further refine cardiac contractility measurement strategies, we have assessed the potential utility of a heart-rate corrected QA interval (QAI) to that of dP/dt_{max} across three non-clinical animal species (rats, n = 13; dogs, n = 5; non-human primates, n = 13). The QAI is the time interval from the Q wave on the electrocardiogram (ECG) to the initiation of the upstroke in aortic pressure and represents an indirect measure of cardiac function, inversely proportional to direct cardiac contractility measures, and may act as a useful indirect index of cardiac contractility. As expected, higher heart rate values were associated with shorter QAI across all three species whereas dP/dt_{max} values were positively correlated to heart rate as previously reported. The correlation between the QAI and dP/dt_{max} evaluated by linear regression suggest that in non-human primates ($y = 32.24*x + 61.25$) and dogs ($y = 26.49*x + 18.18$) heart rate related changes in QAI are nearly independent of dP/dt_{max} whereas in rats a strong negative correlation exists between the two parameters ($y = -704.1*x + 5.113$). Upon application of a heart-rate corrected formula, both QAI and dP/dt_{max} displayed strong individual corrections reducing the slope of each respective trend line to near 0. Interestingly, corrected QAI values were noted to be more consistently corrected to values closer to 0 than dP/dt_{max} suggesting that heart-rate corrected QAI values may present a more consistent heart rate dependence. Taken together, heart rate corrected dP/dt_{max} and QAI can improve assay sensitivity to detect drug induced inotropic effects in order to assess drug-mediated effects on cardiac contractile function for use in non-clinical drug safety assessments. This observation maybe critical in the context of the high prevalence of chronotropic effects in drug safety testing.

3108 Developmental Exposure to Environmentally Related Concentrations of PCB126 and TPHP Exhibits Synergistic Effect on Vascular Growth of Zebrafish Embryos

X. Zhong, J. Wu, W. Ke, Q. Zhu, C. Niu, D. Ji, Y. Yu, J. Kang, C. Wang, and Y. Wei. *Sun Yat-sen University, Guangzhou, China.*

Persistent organic pollutant 3'3,4,4'5-pentachlorobiphenyl (PCB126) and organophosphorus flame retardant triphenyl phosphate (TPHP) are ubiquitous organic environmental pollutants. These two chemicals coexist in various environmental media and human samples and thus may have combined effects on human health. However, the vascular toxicity and related mechanism of co-exposure to PCB126 and TPHP remain unknown. High content imaging was performed on embryos at 72 hours post fertilization (hpf). A dose-response relationship was analyzed by benchmark dose (BMD) modeling. The results showed that the growths ofdorsal aorta (DA), subintestinal veins (SIV), and intersegmental vessels (ISV) were affected at doses ranging from 0-300 ug/L of PCB126 or 0-2400 ug/L of TPHP at 72 hpf, while no significant change was shown in common cardinal veins (CCV). DA was the most sensitive among the observed blood vessels to PCB126 or TPHP exposure. The BMD value of PCB126 and TPHP was 0.28 μg/L and 291.4 μg/L respectively. Compare to the exposure of chemical alone, co-exposure to both PCB126 and TPHP resulted in a more reduction of DA diameter and the gene expression of *VEGFA*, *VEGFR2*, as well as the DA diameter of BMD value for PCB126 and TPHP respectively. The results suggest that PCB126 and TPHP exert vascular toxicity and co-exposure led to synergistic effect in vascular development. The study provides new insights into the combined toxicity of exposure to polychlorinated biphenyls and organophosphorus flame retardants.

3109 Acute Effects of Electronic Cigarette Aerosol on Cerebral Perfusion in Mice

S. Reppert, M. Smith, M. Alvi, P. Chantler, and M. Olfert. *West Virginia University, Morgantown, WV.*

Electronic cigarettes (E-cig) have become exceedingly popular with the campaigning notion of being more safe than tobacco cigarettes. However, it remains uncertain whether or not these products are less harmful than tobacco cigarettes. We analyzed the cerebral perfusion flux (CPF) using a Moor Full-Field Laser Perfusion Imager (FLPI)-2 in wild-type C57BL/6 mice by collecting one image every minute for up to 2 hours after exposure. Mice were anesthetized with Isoflurane (5% induction/ 2-3% maintenance). Five baseline (pre-exposure) images were taken prior to exposure to either, French Vanilla flavored E-liquid with 18 mg/ml nicotine (E-cig18, n=4) or without nicotine (E-cig0, n=3), Univ. of Kentucky-reference tobacco cigarette (3R4F, n=2), or ambient air (Sham, n=4). Exposures were for ~5 minutes (total of 10 puffs, with 1 puff every 30 secs). Separate Harvard Apparatus Dual Phase Control Respirator Pumps were used to administer the E-cig aerosol (from 3rd generation tank-style device set at 17.5 W) and cigarette smoke (from one 3R4F cigarette). Baseline images obtained prior to E-cig exposure were averaged and used for comparison to post-vaping values (repeated measures ANOVA). A rapid increase in whole-brain CPF was observed in E-cig0, E-cig18, and 3R4F immediately after vaping, showing peak responses of 13±9%, 12±1%, 9±7%, respectively (mean % change±SEM). CPF returned to baseline at 34 min, 16 min and 16 min in E-cig0, E-cig18, and 3R4F, respectively. There was no significant change in CPF in the Sham group (0 ± 2%) during the same time period as reported for the other exposure groups. The immediate increase in CPF was similar between E-cig (with or without nicotine) and tobacco cigarette, indicating that the cerebral vascular response to vaping is similar to smoking. These data suggest that the cerebral vasculature may not be able to differentiate between E-cig aerosol and cigarette smoke, and therefore is likely to lead to the same cerebral pathologies known to occur with smoking.

3110 Polyethylene Glycol (PEG)-Coated Liposomes Disrupt Endothelial Function via Alterations in Oxidative Stress

V. C. Minarchick, D. Simberg, and J. Brown. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

Polyethylene glycol (PEG) liposomes are being investigated for improvement of drug delivery; however, the vascular toxicity associated with these modified liposomes is largely unknown. Previous research has shown that PEG coated liposomes are associated with vascular tissue up to 3 days post-exposure. Therefore, we hypothesize that this association will result in increased oxidative stress and ultimately impair microvascular function. Microvascular endothelial cells were treated with PEG and non-PEG coated liposomes (3, 50, and 100 ug/ml). Reactive oxygen species (ROS) generation was monitored via a CellROX kinetic assessment. Oxidative stress potential was assessed by analyzing the ratio of glutathione disulfide (GSSG) to glutathione (GSH) via HPLC. For *in vivo* assessments, Balb/C mice were injected with PEG coated or non-PEG coated liposomes (5mM) and mesenteric arterioles were harvested 3 days post exposure. Endothelium-dependent reactivity was assessed with acetylcholine (ACh, 10^{-9}-10^{-4} M) via pressure myography. After initial assessments, superoxide and hydrogen peroxide were scavenged in the presence of the superoxide dismutase mimetic 2,2,6,6-tetramethylpiperidine-N-oxyl (TEMPOL, 10^{-4} M) and catalase (50 U/mL). There was a significant increase in ROS following exposure to PEG-coated liposomes compared to the non-PEG liposomes and control (2.7 ± 0.1% fold-change vs. control 1.7 ± 0.1%). There was also an increase in oxidative stress potential in the endothelial cells exposed to PEG-coated liposomes as determined by an increase in the GSSG:GSH ratio (-229 ± 2 vs. control -118 ± 4). Finally, following only PEG-coated liposome delivery, endothelium-dependent dilation was significantly attenuated (-3.9 ± 24% vs. control 69 ± 4%), and this impairment was resolved following treatment with TEMPOL and catalase (41 ± 19% vs. control 69 ± 4%). Taken together, these results indicate that PEG-coated liposomes induce microvascular dysfunction and these impairments may be due to changes in oxidative stress and/or endothelial cell signaling. The understanding of

liposomes toxicity *in vitro* and *in vivo* is critical, since liposomes are being increasingly used as therapeutic delivery methods and adverse endothelial cell impacts may lead to adverse cardiovascular responses.

PS 3111 Critical Time Point of Gestational Nanomaterial Inhalation Exposure: Alteration of Angiotensin II Response within the Maternal Uterine Microcirculation

K. L. Garner, E. C. Bowdridge, J. A. Griffith, T. P. Batchelor, K. J. Engels, W. T. Goldsmith, S. Hussain, and T. R. Nurkiewicz. *West Virginia University School of Medicine, Morgantown, WV.*

Engineered nanomaterials are utilized in diverse applications yet cardiovascular ramifications of gestational exposure are poorly understood. The aim of this study was to assess microvascular and reproductive consequences of gestational inhalation exposure to nano-titanium dioxide (nano-TiO_2) during distinct trimesters. Our hypothesis was that time-points of gestational exposure cause varying degrees of microvascular dysfunction. Uterine microvascular angiotensin II (ang II) reactivity was assessed, as it is a critical vasoactive hormone involved in the microvascular adaptations to pregnancy. Ang II signaling occurs via the type 1 and type 2 receptors (AT_1R: constriction, AT_2R: dilation). Receptor balance during gestation is critical for maternal and fetal health. Sprague Dawley rats were randomly assigned to 6 nano-TiO_2 exposure groups (early gestational days (GD) 2-6, mid GD 8-12, late GD 15-19, or control groups). Evonik-P25 (primary diameter = 21 nm) was the bulk nano-TiO_2 material utilized. Whole-body exposure (concentration = 12±0.5 mg/m^3) was performed for 6 hours/d for 3 days (cumulative calculated lung burden = 263±16 µg). Rats were euthanized on GD 20. Pup characteristics were assessed and pressure myography was performed on isolated uterine radial arteries. Average dry pup weight of early exposure group was 0.40±0.02 g, 0.50±0.02 g for the mid exposure, and 0.63±0.02 g for the late exposure. All exposure group dry pup weights were significantly different, suggesting the earlier exposures reduce pup weight. Placental efficiency was significantly different among exposure groups (early exposure 3.3±0.2, mid 3.8±0.2, late 7.5±0.4). Radial artery ang II ($1x10^{-13}$ - $^{-4}$ M) reactivity was assessed via pressure myography. Reactivity was significantly different among exposure groups (average difference of max response: 15±5% early vs late, 8±3% early vs mid, 5±2% mid vs late). Experiments are ongoing to assess additional microvascular reactivity data. Additionally, immunohistochemistry is being performed on placental tissues to determine AT_1R and AT_2R distributions, which may account for the altered ang II sensitivity and may help pinpoint the mechanism of dysfunction. *Support: ES015022 (TRN) U54GM104942 (SH).*

PS 3112 High-Fructose Diet Increases Arrhythmia and Alters Ventricular and Hemodynamic Function One Day after a Single Wood Smoke Exposure in Wistar-Kyoto Rats

M. S. Hazari[1], G. Little[2], B. Martin[2], M. Harmon[3], Y. Kim[1], C. King[1], M. I. Gilmour[1], and A. K. Farraj[1]. *[1]US EPA, Research Triangle Park, NC; [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [3]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

It is well established that exposure to air pollution, including smoke from extreme events like wildfires, can worsen cardiovascular function and lead to adverse health responses. On the other hand, it is still not clear how certain diets affect these responses or the risk of developing long-term disease. This study examined the impact of a high-fructose (HF) diet on cardiovascular function and subsequent responsiveness to wood smoke inhalation in rats. We hypothesized that HF diet would lead to baseline cardiovascular mechanical changes and increased electrical dysfunction. Eight-week old Wistar-Kyoto rats were placed on either a normal (ND) or HF diet for seven weeks and then exposed to either filtered air (FA) or 0.5 mg/m^3 of flaming eucalyptus wood smoke (WS) for one hour. One day after exposure, rats were anesthetized, implanted with an intraventricular Millar probe and then challenged with dobutamine to determine cardiac and arterial function under stress conditions. There was no difference in the left ventricular (LVP) and aortic pressures between ND and HF rats, although exposure to WS caused them to increase significantly in both groups. HF rats had significantly higher heart rates (HR), stroke energetics, and stroke volume than ND. Although Tau or time of active relaxation was the same for FA-exposed ND and HF rats, WS caused it to increase more in the latter. On the other hand, WS only increased arterial stiffness in ND rats. During dobutamine challenge, WS increased the HR response in both ND and HF rats compared to controls, but caused a greater increase in LVP in the latter. HF rats had a significantly greater number of cardiac arrhythmias than ND and exposure to WS showed a trend of increase in these counts for both groups. Although these alterations do not necessarily represent the development of disease, they indicate a shift from the normal, which becomes more evident after exposure to WS. A HF diet may predispose the cardiovascular system to greater dysfunction upon a single exposure to wood smoke and has implications for public health impacts during biomass smoke events. *This abstract does not reflect US EPA policy.*

PS 3113 Proarrhythmic Assessment of Drugs Using Chronically Paced Human-Induced Pluripotent Stem Cell-Derived Cardiomyocytes

M. Hong. *Agilent Technologies Inc., San Diego, CA.*

Human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) are commonly used to evaluate cardiac function *in vitro*. In a recently published report (Blinova K et al 2018), ten sites participated in Phase II Comprehensive *in vitro* Proarrhthmia Assay (CiPA) initiative and tested 19 arrhythmogenic and 9 non-arrhythmogenic compounds in 5 electrophysiology platforms and 2 hiPSC-CMs cell lines. Using the results, the authors developed regression models to assess risk probability. Albeit imperfect, these models correctly categorized 22 of the 28 compounds across the 10 participated sites. Depending on the cut-off value, these 9 drugs were miscategorized: bepridil, risperidone, terfenadine, chlorpromazine, clozapine, ranolazine, metoprolol, mexiletine, and loratadine. We investigated if chronic pacing of hiPSC-CMs improves proarrhythmia predictivity of the miscategorized drugs. hiPSC-CMs (iCell2 Fujifilm CDI) were cultured for a week and were subjected to stepwise increase of pacing frequency every 5 days at 1Hz, 1.5Hz, and 2Hz, respectively, using xCELLigence RTCA ePacer (Agilent technologies). 7 hours after termination of the pacing, cells were incubated with the 9 miscategorized drugs for 30 minutes, following the CiPA protocol as described in Blinova et al. Both the field potential and impedance signals were recorded using xCelligence RTCA CardioECR and were analyzed using CardioECR data analysis software (Agilent technologies). Chronic pacing improved the iCell2 response in 3 important ways compared to non-paced iCell2. First, the long-term electrical stimulation reduced the events of quiescence in the high doses of bepridil, risperidone, terfenadine, metoprolol, and mexiletine. Second, it enhanced the cell response as measured by FPD and IBD50 for high risk drugs such as bepridil, risperidone, and terfenadine, which in turn greatly contributes to the divergence of risk probability between intermediate and low risk drugs in the Blinova's 2018 model. In addition, variance of beating rhythm also separated the tested high-risk drugs from low risk drugs. In summary, varied physiological responses due to immaturity of hiPSC-CMs may hinder the predictive capacity of these cells for pro-arrhythmia. Our data shows that electrical stimulation improves proarrhythmia predictivity.

PS 3114 The Inhibitory Effect of Different Solvents on hERG Potassium Channel

X. Ren, X. Deng, and M. Chen. *WuXi AppTec, Suzhou, China.*

Inhibition of hERG (human ether-a-go-go related gene) current may cause QT interval prolongation, which may result in potentially fatal ventricular tachyarrhythmia called Torsade de Pointes. *In vitro* hERG assay is widely used as screening assay to evaluate the potential cardiac safety-concerns for lead compound optimization; GLP hERG assay in drug development has become routine in pharmaceutical industry, which is a critical element of safety pharmacology tests required for IND submission. Solvent is an easily neglected aspect that has significantly impact on results of hERG assay. Poor solubility may underestimate the impact of a compound on hERG channel and lead improperly judgement for potential utilization of a compound. Researchers have put much efforts in selecting different solvents in order to improve compound's solubility. However, the effects of these solvents on hERG channels are rarely reported and thus remain unclear. Our lab provides insight into the blocking characteristics of solvents itself on hERG channels, which hope to arouse more attention to judicious utilization of solvents. We investigated four different solvents, Acetone, DMSO, Tween 80, and Cyclodextrin to evaluate their impact on hERG current. The 0.3% (v/v) working solutions of Acetone, DMSO and Tween 80 were prepared respectively by diluting with extracellular solution, and cyclodextrin was directly dissolved in extracellular solution to obtain 1 mg/ml working solution. The manual patch clamp was used to detect the hERG current. There is no inhibitory effect on hERG current with 0.3% (v/v) DMSO and Acetone, the percentages of inhibition were -0.66% ± 3.29% and -3.74% ± 2.85%, respectively. However, both 0.3% (v/v) Tween 80 and 1 mg/ml Cyclodextrin exhibit inhibitory effects on hERG current with the percentages of inhibition of 66.28% ± 2.30% and 20.50% ± 2.27%, respectively. Treating with 0.3% (v/v) Acetone had shown no obviously impact on hERG current, but it did show slightly cytotoxicity over recording time.

3115 Engineered Cardiac Tissue as an *In Vitro* Platform to Evaluate the Role of Cardioprotective Mechanisms for Acute Toxic Study and Chronic Cardiac Remodeling and Dysfunction

X. Wang[1], B. Keller[2], Y. Zheng[3], and L. Cai[1]. *[1]Pediatric Research Institute, Louisville, KY; [2]University of Louisville, Louisville, KY; and [3]Jilin University, Changchun, China.*

Engineered cardiac tissues (ECTs) serve as robust *in vitro* models to study human cardiac diseases including cardiac toxicity assays due to rapid structural and functional maturation. Advanced glycation end-products (AGEs), either endogenously formatted or through diet, are the proteins or lipids that become glycated as a result of exposure to sugars and found to be an important player in the development or worsening of many degenerative diseases, such as aging and diabetes. To date, the effect of AGEs on cardiomyocytes and underlying mechanisms remains not been fully illustrated; therefore, we generated 3D ECTs culture using neonatal mouse ventricular cells to determine the effect of AGEs on ECT toxicity and function under two serum conditions. We found: (1) ECT structural and functional maturation was similar in 10 % and 15% fetal bovine serum until 14 days after ECT was set up; (2) ECT was resistant to AGEs induced cytotoxic and functional changes under 15% serum, but not under 10% serum condition; (3) Under 10% serum condition, AGEs could induce cell necrotic death at 400 μg/ml (detected by medium Lactate dehydrogenase), apoptotic cell death at 200 μg/ml (detected by cleaved caspase 3), and no cytotoxic effect at the concentration of 150 μg/ml or less; (4) However, AGEs at 150 μg/ml could negatively impact ECT function in time-dependent manner (reduced beating rate and global function); (5) at the same dose AGEs also increased oxidative stress (increased HO-1 and Nrf2), inflammation (increased PAI-1 and TNF-α), fibrotic response (increased transcript expression of Collagen I-α1, Collagen III-α1, CTGF and FN1), hypertrophy (increased transcript expression of ANP, BNP and β-MHC) and autophagic disorder (increased p62) over time. Thus, neonatal murine ECTs can serve as a robust *in vitro* model as a platform to evaluate the role of cardioprotective mechanisms for acute toxic study and chronic cardiac remodeling and dysfunction, which will fill the gap between monolayer cell culture and *in vivo* animal models.

3116 TCDD Alters Dynamic DNA Methylation Patterns Crucial for Cardiomyocyte Maturation and Implicated in Disease

M. K. de Gannes, C. Ko, J. Biesiada, X. Zhang, M. Medvedovic, and A. Puga. *University of Cincinnati College of Medicine, Cincinnati, OH.*

Congenital heart disease (CHD) is the leading birth defect worldwide, yet the precise etiological factors underlying CHD remain largely unknown. Epidemiological studies estimate that <15% of cases of CHD can be traced to known Mendelian inheritance, suggesting that environmental agents may contribute to CHD during development. Exposure to tetrachlorodibenzo-p-dioxin (TCDD) in the young has been associated with disease conditions in adult fish, birds and mammals, including higher incidence of congenital heart abnormalities. TCDD is a potent ligand for the Ah receptor (AhR) - a sensor of environmental signals as well as morphogenic and detoxification pathways. Our lab has previously shown that AhR ablation or activation by TCDD disrupt molecular networks involved in heart formation and function. During development, the heart has to adapt to diverse physiological and pathophysiological needs. Several epigenetic processes have been implicated as modulators of cardiac gene expression in development and disease. Most recently, DNA methylation was shown to be highly dynamic during cardiomyocyte development, postnatal maturation, and disease. To test the hypothesis that TCDD exposure during cardiomyocyte development alters DNA methylation and gene expression patterns important in cardiomyocyte maturation, the stable pNkx2-5PuroIRES2eGFP cell line was established by differentiation from mouse embryonic stem (ES) cells. These cells express the selection markers puromycin resistance and eGFP under control of the Nkx2-5 promoter as well as markers characteristic of cardiomyocytes. These cells were treated with either 5nM TCDD or DMSO (control) after 24, 48, 72, and 96 hours of culture. Cells were harvested in duplicate after 24, 72, and 96 hours of treatment and compared to those treated for 24 hours with DMSO as well as ES cells. To assess genome-wide gene expression and DNA methylation, RNA- and methyl- seq analyses were performed with respect to the 24 hour DMSO control group. Our analyses showed significant correlation between expression and DNA methylation in 122 genes, many of which are involved in toxicological pathways related to cardiac transformation, cardiac hypoplasia, and cardiac damage. Our findings provide a key step towards elucidating the complex epigenetic patterns and mechanisms surrounding the development of congenital heart disease.

3117 Influence of Nanoparticle Inhalation on Cyclooxygenase-2 Metabolites during Gestation

J. A. Griffith, K. L. Garner, E. C. Bowdridge, T. P. Batchelor, W. T. Goldsmith, S. Hussain, and T. R. Nurkiewicz. *West Virginia University, Morgantown, WV.*

Nano-titanium dioxide (nano-TiO_2) is an engineered nanomaterial that is commonly incorporated in diverse advanced materials. We have reported that pulmonary nano-TiO_2 exposure has adverse systemic microvascular effects, but the mechanisms and impacts on reproduction are not well understood. Prostacyclin (PGI_2) and thromboxane A_2 (TXA_2) are derivatives of arachidonic acid (AA) and are critical parts of cardiovascular and reproductive health. PGI_2 is an endothelium-dependent vasodilator, while TXA_2 is a platelet produced vasoconstrictor. Their balance is vital to maintain maternal/ fetal vascular function and adaptation throughout gestation. PGI_2 and TXA_2 reactivity within the microcirculation are fundamental components to maternal and fetal health. In this study, uterine microvascular PGI_2 and TXA_2 reactivity were assessed in uterine arterioles from virgin and pregnant rats after nano-TiO_2 inhalation exposures. Sprague-Dawley rats were either not exposed, naive (n=9) or sham- filtered air (n=9) or exposed to nano-TiO_2 aerosols (n=8) during gestation. Nano-TiO_2 aerosols were generated with Evonik- P25 (primary particle size= 21 nm and a zeta potential= -57 mV). Whole-body inhalation exposure (concentration= 12±0.5 mg/m^3) was performed for 6 hours/day for 6 days (cumulative lung burden= 525±16 μg). The aerosol count mean aerodynamic diameter (182±2 nm) was determined with a high resolution electrical low pressure impactor (ELPI). Rats were euthanized on gestational day 20 (24-hours post final inhalation exposure). Uterine microvascular reactivity was assessed via pressure myography. Naïve group characteristics: age 92±11 d, and mass 252±11 g. Sham-air group characteristics: age 87±2 d, and mass 268±8 g. Nano-TiO_2 group characteristics: age 70±5 d, mass 246±7 g, and MAP 67±9 mmHg. PGI_2 and TXA_2 responsiveness was recorded as diameter changes over increasing concentration ranges of AA derivatives. PGI_2 reactivity was not different between groups. However, TXA_2 reactivity was significantly decreased after nano-TiO_2 inhalation (percent change= 58±14%). Ongoing studies are investigating the impact of this potential deviation of TXA_2 and PGI_2 balance during gestation. *Support: NIH ES015022 (TRN); U54GM104942 (SH).*

3118 Effects of Long-Term Waterpipe Smoke Exposure on Atherosclerosis in ApoE Knockout Mice

R. J. Arechavala, D. Herman, S. Renusch, I. Hasen, A. Ting, and M. T. Kleinman. *University of California Irvine, Irvine, CA.*

Waterpipe smoke (WPS), a type of tobacco smoke, is currently rising in popularity in the United States, specifically with respect to college-aged youths. Despite this alarming trend and waterpipe's centuries-long history, little is known about the long-term impact of chronic waterpipe smoke (WPS) on the development of atherosclerosis. Apolipoprotein E deficient (ApoE$^{-/-}$) mice have been shown to exhibit increased atherosclerotic plaque development in the brachiocephalic artery and the aortic arch. Furthermore, the atherosclerotic build-up in these hyperlipidemic animals appears to become exacerbated by exposure to ambient particulate matter and other forms of particulate pollutants such as cigarette smoke. Therefore, it is reasonable to postulate that other forms of tobacco smoke may also increase atherosclerotic plaque progression. Genetically modified male and female mice were exposed to either diluted WPS (46.46 ± 24.82 mg/m^3) or purified air via nose-only inhalation for 2 hours/day, 4 days/week, for 5 months. The brachiocephalic artery and aortic arch of all animals were excised and transversely sectioned and stained to identify lipid and collagen contents of the arteries. Animals exposed to WPS exhibited differences in the wall thickness and percent lesion intrusion into the arterial lumen compared to air controls indicating a greater degree of plaque formation. Lipid deposition and collagen buildup measured in the exposed cohort also differed compared to controls and provide insights into the compositional differences of plaques found in the different exposure groups. Quantitative assessment of differential staining furthers understanding of lesion severity and translates to the effect of WPS on the exacerbation of atherosclerosis. Previous studies have indicated that long-term inhalation of WPS alters the autonomic nervous system control of the heart by measuring heart rate variability. The current study indicates that WPS can influence the progression of cardiovascular disease in susceptible individuals. Taken together, these studies inform the cardiovascular health effects of WPS exposure in hyperlipidemic individuals.

3119 Development of Heart Block in ApoE (-/-) Mice Chronically Exposed to Waterpipe Smoke

R. Sandhu, D. A. Herman, R. M. Arachevala, S. R. Renusch, and M. T. Kleinman. *University of California Irvine, Irvine, CA.*

Tobacco smoke is an environmental toxicant that has been shown to exacerbate instances of atherosclerosis and CVD. Waterpipe smoke (WPS), a subset of tobacco smoke, is currently rising in popularity in the United States, specifically with respect to college-aged youths. Chronic exposures to WPS in mice have been shown to significantly enhance atherosclerotic biomarkers and plaque formation. However, a limited number of studies to date have examined the abnormalities in cardiac-specific endpoints, such as atrioventricular signaling which may result from WPS-exposure. This study aims to determine whether WPS exposure is associated with irregularities in atrioventricular signaling such as conduction blockages. Genetically modified male mice (n=5) were exposed nose-only to generated WPS (apple flavored) or purified air for 2 hours/day, 4 days/week, for 5 months. These animals were implanted I.P. with cardiac transducers allowing for electrocardiogram (ECG) collection. Waveforms of the mice were collected during the evenings following exposures and analyzed to detect alterations in ECG segments related to atrioventricular conduction (e.g. P-R interval duration, occurrence of non-conductive P-waves, and QRS interval duration). Heart rate variability in these animals was also measured during corresponding time periods using collected ECG signals. Animals chronically exposed to WPS exhibited altered electrical conduction through the atrial compartments of the heart compared to controls. The QRS interval duration in the exposed rodents also showed impairments compared to the air-exposed controls. Additionally, the exposed cohort experienced a statistically significant decrease in heart rate for six consecutive weeks during the first half of the study. Waterpipe usage has increased significantly in recent years. Determining cardiac malfunctions resulting from WPS inhalation is imperative for providing accurate health care to current and past users.

3120 Heart Rate Variation and Human Body Burdens Environmental Mixtures: Results from the Nituuchischaayihtitaau Aschii Multi-community Environment-and-Health Study in Eeyou Istchee

E. N. Liberda[1], A. M. Zuk[2], and L. J. Tsuji[2]. *[1]Ryerson University, Toronto, ON, Canada; and [2]University of Toronto, Toronto, ON, Canada.*

Heart rate variability (HRV), the examination of beat-to-beat fluctuations in heart rate, is a measure of cardiac autonomic regulation. Unexposed persons generally show increased HRV compared to their contaminant exposed counterparts. While many exposure-based studies have examined the effects of air pollution on HRV, few have examined the association between contaminant body burdens, such as, persistent organic pollutants or metals, and HRV. None have examined these effects as a mixture. Using data collected from the Multi-Community Environment-and-Health Study in *Eeyou Istchee*, we assessed HRV in two time domain measures; root mean square of successive differences (RMSSD) and standard deviation of the N-N (R-R) intervals (SDNN); and in three frequency domains; high frequency (HF), low-frequency (LF), and very-low frequency (VLF). Subjects with any cardiovascular disease or stroke were excluded from analysis and only adults aged 19 to 79 were assessed (n=440). We first examined mixture effects of twenty one organic and metal contaminants using principal component analysis (PCA) followed by multivariable general linear regression, adjusting for age, sex, body mass index, smoking status, and kidney disease. We then chose the significant response variables of the previous analysis and performed a Bayesian kernel machine regression (BKMR) to examine individual contaminant contribution as well as entire mixture effects on HRV. Significant and negative associations were found between HRV and principal component axis 2, which highly and positively loaded for PBDE-47 and PBDE-153, and negatively loaded for nickel. The association was found for RMSSD and SDNN, but not HF, LF, or VLF. BKMR showed a mixture effect trend of decreasing RMSSD and SDNN as exposure concentration quantile increased. No single contaminant was, by itself, significantly and solely responsible for the overall negative trend observed in the BKMR analysis, but rather, several contaminants appear to work in concert to exert their effects on the cardiac autonomic regulation. Taken together, this analysis shows that PBDE-47 and some oragnochlorines may be driving the observed reductions in HRV while some contaminants such as nickel appear to temper this effect. The combined mixture effects of the contaminant is suggestive of a negative trend in both time domain measurements. This study expands our knowledge of the effects of environmental contaminant mixtures on HRV using novel statistical methods (PCA and BKMR).

3121 Methylmercury Accelerates Monocyte Adhesion to the Endothelial Cells by the Induction of Cytokine and Intercellular Adhesion Molecules

J. Fowler, M. T. Tsui, S. Belperain, A. Dunphy, and Z. Jia. *University of North Carolina at Greensboro, Greensboro, NC.*

The development of cardiovascular disease (CVD) has many facets ranging from unhealthy lifestyle choices to unavoidable environmental toxins. Among these toxins that contribute to CVD, environmental, and dietary exposure to organic mercury, in the form of methyl mercury (MeHg), presents a considerable cause for concern. While traditionally labeled a neurotoxin, MeHg has been epidemiologically linked to CVD pathologies; however, its role in development and promotion of atherosclerosis, an initial step in more immediately life-threatening CVDs, remains unclear. This study was conducted to examine the role that MeHg plays in the adhesion of circulating monocytes to vascular endothelial cells, a critical step in atherosclerosis, and attempts to clarify the underlying mechanisms. MeHg treatment significantly induced the adhesion of monocyte to Human microvascular endothelial cells (HMEC-1), while also upregulating the production of proinflammatory cytokines interleukin-6 (IL-6), interleukin-8 (IL-8). Further, MeHg treatment also upregulated the chemotactic cytokine monocyte chemoattractant protein-1 and intercellular adhesion molecule-1 (ICAM-1). Our results further demonstrated that MeHg stimulated a significant increase in NF-κB activation as measured by the eLUCIdate™ NF-κB reporter cell line. These findings suggest that NF-κB signaling pathway activation by MeHg is an important factor in the binding of monocytes to endothelial cells. This study provides new insights into the molecular actions of MeHg that can lead to endothelial dysfunction, inflammation and subsequent atherosclerotic development. The results of this study also contribute to our understanding of the detrimental effects of human exposure to MeHg which remains an important human health concern in a rapidly industrializing world.

3122 Electrophysiology Testing in Drug Development: Evaluation of Intracardiac Conduction Parameters in Dogs

B. M. Roche, T. Vinci, K. Beachy, D. Tracey, J. Shaffer, and B. Borders. *Charles River Laboratories Ashland LLC, Ashland, OH.*

Atrial fibrillation (AF) affects about 3 million people in the US, 30% of whom experience no symptoms at all. AF is one example of a cardiac arrhythmia that can cause a disturbance in normal electrical conduction of the heart. Electrophysiology testing (ET) is routinely performed in human medicine to assess arrhythmias, such as AF, and identify any sites within the conduction system for blocks or delays. However, this common human technique is rarely performed during nonclinical drug development. The objective of this study was to evaluate the cardiac conduction times and effective refractory periods (ERP) from the sinus node through to the ventricles in male beagle dogs. Six dogs (10 to 12 kg) were anesthetized (isoflurane 2-5%) and intracardiac electrode catheters were placed, percutaneously, through the jugular veins (coronary ostium (CO) and high right atrium (HRA)) and femoral vein (HIS bundle and right ventricular apex) under fluoroscopic guidance. A surface ECG and femoral artery pressure catheter were also placed. ET was conducted in a passive (intrinsic rhythm) and dynamic phase (atrial and ventricular pacing). Continuous atrial pacing for 30 seconds at three cycle lengths (CL; 400, 330 and 300) was used to determined sinus node recovery time. ERPs of the atria, AV node and ventricles were assessed at the same CLs in a standard train of 8 impulses and 1 premature impulse at progressively shorter coupling intervals. The following parameters were measured; intra-atrial conduction time, PA interval; interatrial conduction time, HRA-left atrium or CO; HRA-HIS, AH; HIS-ventricles, HV; sinus node recovery time (SNRT) and SNRT corrected; and atrial, AV and ventricular ERPs. The SNRT was 790±284, 681±208, 639±161, SNRT corrected was 171±121, 166±110, 125±65, AH interval was 55±6, 60±3, 50±4, HV interval was 38±19, 58±19, 52±21, atrial ERP and AVERP were similar with values of 220±84, 141±25, 153±26, and VERP was 155±10, 150±6, 150±5. Values are presented for 400, 330 and 300 msec CLs, respectively, and are expressed as mean±SEM. Intracardiac placement of the electrode catheters and experience with conducting pacing studies are critical to the success of collecting intracardiac conduction times and effective refractory periods in dogs. The results of this study demonstrate both the comprehensive electrical evaluation of the heart and repeatability of the ET protocol for arrhythmia generation and safety evaluation of new chemical and biological entities.

3123 A Mouse Model of Doxorubicin-Induced Subclinical Cardiotoxicity

V. G. Desai[1], T. Han[1], C. L. Moland[1], V. Vijay[1], B. Phanavanh[1], T. Lee[2], K. C. Stine[3], and J. C. Fuscoe[1]. *[1]US FDA/NCTR, Jefferson, AR; [2]Korea University, Sejong-si, Korea, Republic of; and [3]University of Arkansas for Medical Sciences, Little Rock, AR.*

Subclinical cardiotoxicity at low cumulative doxorubicin (DOX) doses can manifest into irreversible cardiomyopathy in some long-term cancer survivors. However, the underlying mechanisms are still less clear. To get better insights, echocardiographic assessment of cardiac function was performed in adult $B6C3F_1$ male mice at 1-, 4-, 10-, 17-, and 24-week after receiving 6, 9, 12, or 24 mg/kg cumulative DOX dose or saline to examine progression toward late-onset cardiotoxicity. In these mice, 24 mg/kg dose resulted in a significant decline in systolic function (Left Ventricular Ejection Fraction (LVEF) and Fractional Shortening (FS)) from 4- to 24-week after treatment compared to saline-treated counterparts. While there was no statistically significant effect elicited by lower cumulative doses (6 and 9 mg/kg) in systolic function at any time during the 24-week recovery, a significant time-dependent decline in both %LVEF and %FS was observed during the recovery period. At 24-week after 6 – 24 mg/kg total DOX, a significant dose-related decrease was observed in the transcript levels of ryanodine receptor 2 and sarco/endoplasmic reticulum calcium ATPase 2, with a significant 1.47- and 1.27-fold decline, respectively, at the highest cumulative dose. These genes encode proteins crucial in regulating intracellular calcium concentration within cardiomyocytes essential for contractility of cardiac muscle. These mice also showed a significant dose-related increasing trend in the total number of apoptotic cells with a significant 1.9- to 3.5-fold elevated level after exposure to 6 to 24 mg/kg total DOX dose compared to concurrent saline-treated controls. Altogether, subclinical cardiotoxicity in our mouse model was associated with molecular changes relating to calcium homeostasis and apoptosis even at low cumulative doses later in life. In long-term cancer survivors with underlying cardiovascular risk factors, such molecular changes in the heart may potentially lead to irreversible cardiac damage.

3124 Protective Role of Roflumilast against Cadmium-Induced Cardiotoxicity through Inhibition of Oxidative Stress and NF-κB Signaling in Rats

K. M. Alharthy, M. Ganaie, and M. Ansari. *Prince Sattam Bin Abdulaziz University, Alkharj, Saudi Arabia.*

Cadmium (Cd), a potent cardiotoxic environmental heavy metal, induces oxidative stress and membrane disturbances in cardiac myocytes. Phosphodiesterase (PDEs) retards the positive inotropic effects of β-adrenoceptor activation by decreasing levels of cAMP via degradation. Hence, PDE inhibitors sensitize the heart to catecholamine and are therefore, used as positive inotropic agents. The present study was designed to probe the potential attenuating effects of the selective PDE4 inhibitor (Roflumilast, ROF), on cardiac biomarkers, lipid profile, lipid peroxidation products, antioxidant status and histology of cardiac tissues against Cd-induced cardiotoxicity in rats. Rats were randomly distributed into four different groups: group 1, served as the normal control group. Group 2, served as the toxic control group and were administered Cd (3 mg/kg, i.p.) for 7 days. Groups 3 and 4, served as treatment groups that received Cd with concomitant oral administration of ROF doses (0.5 and 1.5 mg/kg), respectively for 7 days. Results showed Cd significantly increased the serum lactate dehydrogenase (LDH) and creatine phosphokinase (CPK) levels by 333.24 ± 14 and 213.63 ± 5.8 (IU/L), respectively. Both ROF doses significantly reduced Cd-induced LDH and CPK levels in dose dependent manner. Also, ROF doses significantly reversed the Cd-induced TC, TG, LDL VLDL serum levels of 233.06 ± 8.05, 114.42 ± 2.35, 186.92 ± 8.68 and 22.88 ± 0.47 (mg/dl), respectively. The reduction of HDL serum level by Cd treatment (23.25 ± 1.22 mg/dl) was significantly counteracted by both ROF co-treatment to 29.10 ± 2.14 and 32.33 ± 1.47 mg/dl, respectively. Moreover, Cd causes a significant increase in myocardial malondialdehyde (MDA) contents and decrease in cardiac glutathione (GSH) level, superoxide dismutase (SOD) and catalase (CAT) enzyme activities. Whereas both doses of ROF, significantly reversed the Cd effects on these oxidative stress markers and antioxidant enzymes. Western blot analysis showed a significant induction of non-phosphorylated and phosphorylated form of NF-κB p65 expressions, and a significant reduction of glutathione-S-transferase (GST) and NQO1 expressions mediated by Cd treatment compared to control group in the heart tissue. These effects were significantly reversed by ROF treatments. Histopathological changes were also improved by ROF administration as compared to Cd treated rats alone. In conclusion, Roflumilast exhibited attenuating effect against Cd-induced cardiac toxicity.

3125 Determination of Blood Pressure Liabilities through Assessment of Vessel Reactivity Using a Tissue Myograph System

J. Ross[1], D. Zhang[2], Y. Lu[1], T. Ardrey[1], M. Waines[1], P. Hooper[1], and B. Roche[1]. *[1]Charles River, Ashland, OH; and [2]Michigan State University, East Lansing, MI.*

Pharmacologically induced hypertensive and hypotensive disorders are leading causes of post-approval adverse vascular events. Chronic hypertension is associated with heart disease, arterial stiffening, stroke, kidney disease, and glomerular disease. Acute hypotension can cause dizziness, fainting, nausea, fatigue, and in severe cases; life threatening conditions such as oxygen deficiencies in the heart and brain or shock. Testing for potential blood pressure liabilities preclinically is required for IND approval of small molecules (ICH S7A) and is typically performed in parallel or following IND-enabling toxicology studies. Attrition at this stage in development is costly and can be detrimental to the success of a pharmaceutical development program. Screening for potential blood pressure effects early in drug development can help identify these liabilities and aid in candidate selection during lead optimization. Testing isolated rodent superior mesenteric (SM) arteries in the *ex vivo* myograph system provides an inexpensive method which allows early screening of direct pharmacologic effects on vessels. In this study, four vasoactive pharmaceutical agents were tested to assess vessel reactivity. The SM arteries were treated with escalating concentrations of epinephrine (0.01, 0.1, and 1 μM) and phenylephrine (0.01, 0.1, and 1 μM) to assess vasoconstriction. Vasodilation was assessed by treating these vessels to escalating concentrations of sodium nitroprusside (0.1, 1, and 10 μM) and minoxidil sulfate (0.05, 0.5, and 5 μM). Epinephrine and phenylephrine produced dose dependent responses, increasing tension at the highest concentrations by approximately 4- and 2-fold, respectively. Sodium nitroprusside and minoxidil sulfate produced dose dependent responses in pre-constricted vessels, decreasing tension at the highest concentrations by approximately 2-fold. To assess how these effects on the vasculature affect blood pressure *in vivo*, a single dose of epinephrine (4 μg/kg, i.v.), phenylephrine (50 mg/kg, oral), isosorbide mononitrate (250 mg/kg, oral), or minoxidil (10 mg/kg, orally) was administered to telemetered rats and blood pressure was monitored continuously. Epinephrine and phenylephrine caused a marked increase in mean arterial blood pressure. Isosorbide mononitrate and minoxidil caused a marked decrease in mean arterial blood pressure. This study demonstrates the ability of the myograph system to detect vessel reactivity *ex vivo* as well as the translatability to an *in vivo* model. Early screening for these potential blood pressure effect can aid in identifying liabilities and developing de-risking strategies.

3126 Establishing the Mode-of-Death of Combined Methamphetamine and Fentanyl by Leveraging an *In Vivo* Model for the Simultaneous Assessment of Diaphragmatic Force and Cardiovascular Parameters

S. Roof, and R. Hamlin. *QTest Labs Ltd., Columbus, OH.*

Over the past decade, traces of fentanyl (FENT) has been found, at alarming rates, in persons whose deaths have been attributable to cardiovascular collapse from methamphetamine (METH). FENT reduces, principally, respiratory drive that may lead to concomitant cardiovascular consequences. In theory, METH's stimulatory effect should protect against the depressant effects of FENT, therefore the cause of death (cardiovascular or respiratory) is puzzling and has yet to be established. Elucidating the combined cause of death is paramount for future preventative or therapeutic measures. Male Sprague Dawley anesthetized (2.5% isoflurane) rats were ventilated mechanically and instrumented to simultaneously assess left ventricular hemodynamics as well as diaphragmatic force. In this setting, the dose-dependent effects of FENT (5-40 ug/kg IV bolus) and METH (0.1-1 mg/kg IV bolus) were studied. METH alone, dose-dependently, increased force of diaphragmatic contractions 3 minutes post dose by 4, 18, and 27% with 0.1, 0.2, and 0.4 mg/kg and negligible effects on peak left ventricular pressure (LVPmax). Administration of 0.6 and 1.0 mg/kg elicited completed cardiovascular collapse and death. FENT alone transiently decreased diaphragmatic contractions (peak reduction of -65, -79, -85, and -94% and LVPmax (-22, -29, -33, and -38%) with 5, 10, 20, and 40 ug/kg. To assess the effect when administered in combination, FENT (10 ug/kg) was administered twice (with and without METH (0.4 mg/kg)) separated by a 1-hour washout period. FENT alone decreased force of diaphragmatic contractions by -63% and LVPmax by -19%. FENT+METH resulted in an unexpected greater reduction (-88%) in diaphragmatic force and similar changes in LVPmax. A similar study was performed to control for the administration FENT twice in an experiment. Contrast to FENT+METH, the second dose of FENT alone resulted in less of a respiratory depression compared to the first dose. Taken together, combinations of FENT and METH result in greater reduction in force of diaphragmatic contractions than FENT alone and

likely results in a greater chance of intoxication. This study demonstrates that potential *in vivo* cardiovascular and respiratory liabilities of opioids and other abused drugs can be assessed simultaneously.

PS 3127 A Rodent Model to Examine the Impact of Sleep on Cardiovascular Responses to Environmental Stressors

W. K. Martin[1], M. C. Schladweiler[2], B. L. Martin[2], M. S. Hazari[2], and A. K. Farraj[2]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

Cardiovascular (CV) disease remains the preeminent cause of premature death worldwide. Among the contributors to CV disease, poor sleep is among the most common with more than 1/3 of Americans habitually sleeping suboptimal lengths of time necessary to promote health. Critically, perturbed sleep patterns (e.g., insomnia, short sleep duration) alter CV function and increase risk of CV diseases such as atherosclerosis, stroke, and hypertension. Apart from overt impacts, acute sleeplessness may also prime the CV system to increased sensitivity to environmental stressors in the short term, even in healthy people. For example, acute sleep loss has been linked to altered CV responses to subsequent mental stress and cold sensation in young, healthy people. Thus, this paradigm has the potential to reveal subtle impacts of sleeplessness including its impact on responsiveness to environmental stressors such as air pollution. While models of sleep loss have been proposed, a robust analysis of the CV impacts of one night of poor sleep has not been undertaken in a rodent model. To that end, we disrupted the sleep of rats by gentle handling for 5 s every 30 min for 5 h during the normal sleep cycle (09:00 - 14:00). CV function, including heart rate (HR), blood pressure (BP), the electrocardiogram, and core body temperature (T) was constantly monitored using implanted telemeters. Telemetry also allowed monitoring of locomotor activity, which was used as an indirect metric of sleep. Sleep disruption elevated activity levels during the disruption period relative to normal undisrupted sleep (~7x, p=0.0003), and caused activity levels that mirrored those of the preceding waking period. Importantly, sleep disruption also increased BP (systolic +7mmHg, p<0.0001; diastolic +4mmHg, p=0.005), HR (+27 bpm, p<0.0001), and T (+0.3^{0} C, p=0.0007), and decreased QA interval (-1.9 ms, p=0.0002), an inverse metric of cardiac contractility. Analysis of HR and BP variability, baroreceptor sensitivity, and systemic inflammation and stress are forthcoming. Given that nocturnal hypertension is a key driver in the long-term cardiovascular adversity associated with sleeplessness, this approach may prove useful in assessing the role of BP dysregulation in the interactive effects of sleeplessness and environmental factors. *This abstract does not reflect US EPA policy.*

PS 3128 Revisiting ICH S7B: Enabling Effective Clinical Evaluation Strategies Using a Science-Based Nonclinical *In Vivo* QT Model Based on Detection Sensitivity and Quality Criteria

M. J. Engwall, J. Baublits, and H. M. Vargas. *Amgen Inc., Thousand Oaks, CA.* Sponsor: T. Monticello

The ICH S7B guideline describes the non-clinical evaluation of human therapeutics for pro-arrhythmic risk, i.e. Torsades de Pointes (TdP). The two principal models highlighted in guidance are the *in vitro* I_{Kr} (hERG) and *in vivo* QT assays. The guideline has been invaluable in identifying and driving the use of these test systems to evaluate hERG blockade-mediated QTc prolongation, given that drugs known to cause TdP inhibit hERG function *in vitro* and prolong the QTc interval *in vivo*. A limitation of the guideline is the absence of any details on study design requirements, assay sensitivity, or the definition of quality, especially the QT analysis. It is possible that the absence of such detail may have led to an unintentional consequence: not leveraging the full value of the *in vivo* QT assay for informing the need for routine or extensive (ICH E14) QTc evaluation. We obtain statistical analyses on all cardiovascular assessment studies that inform on the quality the study performed. Our approach to performing cardiovascular telemetry studies in nonrodent species includes an evaluation of study quality, defined as the ability to detect a predefined magnitude of change in QTci (QT corrected with an individual animal heart rate correction factor). Using a retrospective power analysis of multiple studies (n=14 dog; n=6 NHP), we determined the mean power for a specific study design (N=8 per group) in both canines and cynomolgus monkey (NHP). The output of the power analysis is the minimal detectable effect at a specific probability level of 80%. The double Latin-square cross-over design provided an average sensitivity to detect a 2% (5 msec) change in QTci in canines and 2% (7 msec) in NHP. These findings indicate that this experimental approach has a consistent and reproducible sensitivity level that enables a robust QTci risk evaluation and inform the safe progression of new agents, e.g., create an integrated pro-arrhythmia risk assessment. The inclusion of power analysis (sensitivity) data in a regulatory submission provides key information to critical stakeholders about the quality of the *in vivo* QT assessment and value for human safety testing.

PS 3129 An *In Vitro* Human Population Model for Screening Environmental Chemicals for the Cardiotoxicity Hazard

S. D. Burnett[1], A. D. Blanchette[1], F. A. Wright[2], W. A. Chiu[1], and I. Rusyn[1]. *[1]Texas A&M University, College Station, TX; and [2]North Carolina State University, Raleigh, NC.*

Adverse effects on the cardiovascular system are a major liability for pharmaceuticals, so the potential for cardiotoxicity is carefully assessed. However, environmental chemicals are seldom tested for their cardiotoxic potential, as no *in vivo* or *in vitro* cardiotoxicity tests are required for non-pharmaceutical compounds. Thus, with the exception of particulate matter and a few well-studied substances, the extent to which the chemicals in commerce and the environment may contribute to human cardiovascular disease morbidity is essentially unknown. Human induced pluripotent stem cell (iPSC)-derived cardiomyocytes have become an important organotypic *in vitro* model for cardiotoxicity testing because they demonstrate biological relevance, high sensitivity and specificity, and consistent reproducibility of both baseline and treatment-induced characteristics. Importantly, iPSC-derived cardiomyocytes have been derived from multiple individuals and have previously demonstrated a reproducible and clinically-relevant model for *in vitro* testing of population responses to drugs and chemicals. Therefore, we hypothesized that a population-based model of iPSC-derived cardiomyocytes from a diverse set of normal human donors can be used to assess environmental chemicals for their potential cardiotoxicity hazard. To test this hypothesis, we conducted concentration-response screening of more than 1000 diverse chemicals (pharmaceuticals, industrial chemicals, pesticides, flame retardants, PAHs, and food constituents) in iPSC-derived cardiomyocytes from 5 humans that vary in their baseline and treatment-induced cardiophysiologic characteristics. We quantified kinetic calcium flux and high-content imaging data following chemical exposure, examined a panel of cardiophysiologic and cytotoxicity phenotypes, and calculated point-of-departure (POD) values for each chemical and donor. We observed chemical-specific variation in both potency and degree of population variability. These results show the potential for various environmental chemicals to affect the beating function of iPSC-derived cardiomyocytes. Ultimately, this study demonstrates the feasibility of using an organotypic population-based human *in vitro* model for rapid, high-throughput screening to quantitatively assess the cardiotoxic potential of chemicals for which little cardiotoxicity information is available.

PS 3130 Genotoxicity in the Heart-Brain Axis following Inhalation of Hexavalent Chromium [Cr(VI)] in a Rat Model

J. P. Wise Jr. *University of Louisville, Louisville, KY.*

As our global population continues to grow and live longer, diseases of heart and brain are becoming more prevalent. In order to better tackle the medical problems associated with aging bodies, we need better understanding about how our bodies are united. Decades of research have characterized the roles of individual organs in diseases and organ responses to chemical insults, but in most cases we are still lacking disease-modifying therapies. Here, we aim to bridge the traditional fields of neurotoxicology and cardiovascular toxicology to better understand how these two organs are physiologically connected. We are particularly focused on how DNA damage in both heart and brain contributes to systemic inflammation and associated diseases. We are using Cr(VI) as a model to induce DNA damage, given its known genotoxic effects. Cr(VI) is a known human carcinogen and listed among the Top 25 environmental pollutants by the Environmental Protection Agency. Most research investigating the toxic effects of Cr(VI) focus on known target organs (e.g. lungs, liver, kidneys), though there is a growing body of literature that describes the toxic effects in the heart and brain. Rodents studies demonstrate that up to 46% of inhaled of Cr(VI) can reach the brain and induces widespread neurodegeneration, though it is unclear how this may contribute to neurological diseases. Several human studies have linked occupational Cr(VI) exposure or chromium metallosis with neuropsychological disorders and brain tumors. Hence, there is a need to better understand how Cr(VI) affects heart and brain individually, as well as effects on their interconnected health. Our comet assay shows increases in DNA damage in the heart and different regions of the rats exposed to Cr(VI), with different dose-response profiles among organs and regions as well as sexes; therefore, we aim to evaluate how Cr(VI) inhalation accumulates in heart and brain tissues, induces DNA damage and repair pathways, and contributes to systemic inflammation. *This work was supported by NIEHS*

3131 Predicting Putative Cardiotoxic Chemicals Using Tox21 qHTS Data

S. Krishna, B. Berridge, and N. Kleinstreuer. *NIEHS, Morrisville, NC.*

Cardiovascular (CV) disease is the leading cause of death for people of most ethnicities in the United States and is a major source of pharmaceutical drug attrition. A potentially significant but underappreciated risk factor contributing to the development and severity of CV disease is exposure to bioactive substances in our environment. The heart and vascular system have been shown to be vulnerable to several environmental agents such as pesticides, flame retardants, polycyclic aromatic hydrocarbons (PAHs), plasticizers, ambient air pollution and metals. There is an urgent need to evolve the predictive toxicological testing paradigm to identify environmental chemicals that might be contributing to CV disease. In this study, we are designing a strategic paradigm to screen for potential environmental chemical cardiotoxicity that may also help in preclinical testing to identify pharmaceutical CV safety liabilities. To screen compounds for potential CV effects, we are leveraging *in silico* tools and *in vitro* high-throughput screening (HTS) data. The US federal consortium on toxicology in the 21st century (Tox21) providing broad chemical coverage, and the EPA toxicity forecaster program (ToxCast) providing broad biological coverage, produce quantitative HTS data on thousands of chemicals across a wide range of assays covering critical biological targets and cellular pathways. Using these data, we have designed a CardioToxPi, which is a visualization tool and a ranking system in which we have prioritized chemicals by bioactivity score against molecular and cellular targets known to mediate bioactivity in the CV system. We are working to generate *in silico* predictive models that can provide predictions of CV toxic events across large numbers of chemicals. The computational toxicology methodology applied here aims to include diverse data streams, toxicity mechanisms & pathways, and derive thresholds that could be applied to specific decision contexts. This method will be applied to screen and prioritize chemicals with constrained or no toxicity information for further assessment.

3132 Perfluorobutanoic Acid (PFBA) Affects Larval Weight Changes in the Beet Armyworm *Spodoptera exigua*

E. W. Omagamre, S. A. Zebelo, and J. S. Pitula. *University of Maryland Eastern Shore, Princess Anne, MD.*

Toxicological studies on long chained perfluorinated compounds (PFCs) in a number of organisms suggest that they are endocrine disruptors. Perfluorobutanoic acid (PFBA), one of the replacement compounds for long chained PFCs, have been shown to accumulate in plants. To evaluate the endocrine disruptive potential of PFBA on the development and plant interaction of insect pests, its dietary effect on the larval weight of the Beet armyworm, *Spodoptera exigua* was investigated. Second instar larvae were fed with PFBA spiked artificial diets and leaves from soybean plants grown on soils spiked with PFBA solution. Spiked PFBA concentrations were ~200 ug/kg and 10 mg/kg respectively on the artificial diets and the soils. The artificial diet larval weight experiment was observed until the larvae commenced pre-pupal inactivity while the soybean plant leaf diet exposure study was observed for 3 days. For the artificial diet study, the treatment groups showed consistently increased weight over the Controls from 1 - 7 days post treatment (dpt). The ratio of weight gain of this treatment group over the Controls ranged from 1.08 to 1.39. The differences in weight gain were significant from 3-7 dpt ($p < 0.05$). The study involving the soybean leaf diet showed increased larval weight of the exposed over the controls for all three days with the ratio of weight gain ranging from 2.53 to 5.71. The leaf morphology showed damage of 27.01±2.45 and 22.52±2.26 % by the Beet armyworm for the PFBA treatments and controls respectively at 2dpt. Taken together, the data suggests that the PFBA perturbed the weight gain of the exposed larvae as they transited from the second to fifth instar. The implications of these findings are the possibilities of plants' uptake of this PFC influencing the development and the plant damage potential of the Beet armyworm. Further studies are ongoing to understand the dose response relationship with respect to weight changes. Correlation of weight changes with transcriptomic changes is also being carried out to gain better insight into the findings here reported.

3133 Exposure to Perfluoroalkyl Substances (PFAS) in the Placenta and Altered Expression of Epigenetic Machinery-Associated Genes

C. X. Plazas, J. T. Bangma, C. J. Meakin, J. T. Szilagyi, and R. C. Fry. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Per- and poly-fluoroalkyl (PFAS) substances are chemicals that are found in a variety of products including nonstick pans, cleaning supplies, fire-fighting foams, and water-repellent fabrics. While perfluorooctanoic acid (PFOA) and perfluorooctanoic sulfate (PFOS) are no longer used in the United States, their persistence continues to be an environmental and health concern. In addition, a replacement PFAS, 2,3,3,3-tetrafluoro-2- (hepta fluoropropoxy) propanoate (GenX) is also present in waterways and air emissions as an environmental toxin. There is supportive evidence that exposure to PFAS results in adverse human health outcomes such as preeclampsia and reduced infant birth weight. Studies have also shown an association between PFAS including PFOA to epigenetic changes including hypomethylation in cord blood. However; the effects of perfluoroalkyl substances (PFAS) on the expression of genes that play a role in epigenetic regulation in the placenta are poorly understood. This study seeks to determine whether the expression of genes that play a role in epigenetic regulation (epigenetic machinery genes; EMGs) are altered in the placenta with PFAS exposure. Specifically, *in vitro* trophoblast JEG-3 cells were treated with PFOA, PFOS, and Genx (10-100 ng/mL), in serum or serum free media. A total of 96 EMGs involved in histone phosphorylation, ubiquitination, CpG methylation, deacetylation, acetyltransferases, and methyltransferases were assessed for mRNA expression changes through PT-PCR. Western blots were used to assess changes in protein expression in relation to PFAS treatments. The results revealed significant alterations after PFAS treatments in the expression of EMGs, including Aurora A kinase, *AURKA,* and Protein Arginine Methyltransferase 3, *PRMT3.* The results suggest that exposure to PFAS in the placenta is associated with the altered expression of key genes that play a role in epigenetic regulation in JEG-3 cells, specifically related to histone phosphorylation, demethylation, and deacetylation. There is a need for additional research to determine long-term human health effects due to PFAS exposure and the role of EMGs.

3134 Hexafluoropropylene Oxide Dimer Acid (HFPO-DA): GenX Induces Apoptosis in Liver Cells

H. Yoo, M. Pyo, and K. Lee. *Korea University College of Life Sciences and Biotechnology, Seoul, Korea, Republic of.*

Ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)-proponate (Hexafluoropropylene oxide dimer acid, HFPO-DA) is a type of perfluorinated alkyl substances (PFASs), also known as GenX. PFASs are nonvolatile substances that are easily released into the environment during manufacture and use, so they are easily implemented in drinking water, soil, and air. GenX, unlike other PFASs, has a relatively short carbon length and has recently been used as a new alternative because of its ability to be released into the body. However, it has recently been detected in water sources in many countries, including the USA. The mechanisms and human intoxication directly attributed to GenX have not been elucidated. Therefore, the aim of the study was to investigate the apoptotic potential of GenX in human liver cells, HepG2. HepG2 cell was exposed to GenX (40-500 μg/mL) for 48 h showed a decrease in cell viability and significantly increased apoptosis rate. GenX was also induced oxidative stress in a dose-dependent manner indicated by increasing the production of intracellular reactive oxidative species (ROS). Quantitative real-time PCR results showed the mRNA expressions of apoptosis markers were up-regulated in the GenX-treated group. Compared with the untreated control group, mRNA expression level of BAX, caspase-3, caspase-9, and p53 was increased by 3.1, 1.2, 1.4, and 2.5-fold in the 500 μg/mL-treated group, respectively. In addition, similar tendencies were observed in protein expression level of apoptosis-related factors through western blotting. This study suggests that GenX induces apoptosis through oxidative stress in liver cells.

3135 A Comparison of PFAS Serum Concentrations in the General Population to Points of Departure Used in Regulatory Guidance

S. R. Boomhower, L. E. Kerper, J. Chien, and B. D. Beck. *Gradient, Boston, MA.*

Per- and polyfluoroalkyl substances (PFAS) are a group of chemicals of growing concern to regulatory agencies. In deriving guidance values for PFAS in drinking water, agencies typically use a rodent serum PFAS concentration associated with a key toxicological effect as the point of departure (POD) to

estimate a human-equivalent dose. A comparison of agency PODs with serum concentrations in the general population would provide perspective on the toxicological significance of the exposures of the general population to PFAS. We first conducted an analysis of the serum concentration PODs from both national and state agencies with finalized drinking water health-based values for perfluorooctanoate (PFOA), perfluorooctane sulfonate (PFOS), perfluorononanoic acid (PFNA), perfluorohexane sulfonate (PFHxS), perfluorodecanoic acid (PFDA), and perfluorobutane sulfonic acid (PFBS). Using PFAS serum concentrations measured in the most recent NHANES, we then conducted a margin of exposure (MOE) analysis to compare POD serum concentrations with those of both the geometric mean and 95th percentile of adults and children in the general US population. Agencies' PODs varied greatly for any given PFAS, and this was due to differences in selection of key studies, key toxicological effects, and model assumptions. For example, US EPA and the Minnesota Department of Environmental Protection estimated the highest POD as 38,000 ng/mL PFOA, whereas the New Jersey Department of Environmental Protection and New Hampshire Department of Environmental Sciences estimated the lowest POD as 4,351 ng/mL PFOA. MOE values also varied greatly depending on the agency and PFAS. For example, MOEs for the general population with PFOA serum concentrations at the 95th percentile (4.17 ng/mL) and geometric mean (1.56 ng/mL) ranged from 1,000-9,100 and 2,800-24,000, respectively. Similarly, MOEs for children aged 3-11 years in the general population with PFOA serum concentrations at the 95th percentile (4.19 ng/mL) and geometric mean (1.92 ng/mL) ranged from 1,000-9,100 and 2,300-20,000, respectively. Our analysis underscores the uncertainties in evaluations of PFAS toxicity. It further shows that current serum levels in the general population are well below any exposures that could potentially be associated with health effects.

PS 3136 Computational Association of PFAS Exposure and Hypothyroidism

K. Albers, A. Ni, B. Ramirez, S. Ruiz, H. Skrehot, and D. E. Johnson.
University of California Berkeley, Berkeley, CA.

Perfluoroalkyl substances (PFAS) are a group of man-made chemicals that are known contaminates of drinking water, particularly in communities surrounding military bases. Some studies, such as Project Viva, a longitudinal Prebirth Cohort, have concluded that exposure to some PFAS influence and may disrupt thyroid function in both mothers and infants. This study investigates whether there is an association between PFAS exposure and thyroid dysregulation using a systems toxicology approach to identify a probable molecular initiating event (MIE) in a proposed adverse outcome pathway (AOP). In addition, the populations most susceptible to thyroid dysregulation when exposed to PFAS in drinking water were proposed. Various computer programs, including online databases, data networks, biomonitoring data, and the literature were used to establish proposed chemical-gene-disease associations. The iodothyronine deiodinase 3 (DIO3) gene, which catalyzes the inactivation of triiodothyronine (T3) and thyroxine (T4), was of primary interest because it affects two thyroid hormones that are crucial in maintaining the body's metabolism. The proposed MIE suggests that PFAS bind to the DIO3 nuclear receptor, increasing the gene expression of DIO3. This leads to the deactivation of T3 and T4, ultimately resulting in hypothyroidism. Additionally, to determine if those who have autoimmune diseases are more susceptible to hypothyroidism when exposed to PFAS, this study examined the connection between Hashimoto's Disease and exposure to PFAS. Hashimoto's Disease is caused by the increased production of antibodies against thyroid peroxidase (TPO), an enzyme normally found in the thyroid gland that plays an important role in the production of thyroid hormones T3 and T4. Research suggests that an increase in transforming growth factor beta (TGFB) also inhibits TPO mRNA and protein expression in humans, and over stimulates DIO3. PFOS and PFOA are hypothesized to decrease TPO by increasing TGFB, further increasing the activity of DIO3 in patients with Hashimoto's. The results of this study suggest that there is a connection between PFAS and hypothyroidism, and that those who already have Hashimoto's Disease are even more susceptible to PFAS exposure.

PS 3137 Proteomic Analysis Reveals Perfluoro-(3,5,7,9-tetraoxadecanoic) Acid (PFO4DA) Induced Hepatotoxicity via Activation of PPARs in Male Mice

J. Dai, H. Guo, and N. Sheng. *Institute of Zoology, Chinese Academy of Sciences, Beijing, China.*

Perfluoropolyether carboxylic acids (PFECAs, $CF_3(OCF_2)_nCOO-$, n = 2-5), including perfluoro (3,5,7,9-tetraoxadecanoic) acid (PFO4DA), are emerging per- and polyfluoroalkyl substances (PFASs). PFO4DA has been recently detected in human blood samples in US and the environmental matrix. However, their potential toxicities for humans are unclear. In this study, we assess the hepatotoxicity of PFO4DA on male mice, especially its effects on liver lipid metabolism. Male mice were exposed to 0, 0.4, 2, or 10 mg/kg/d PFO4DA continuously for 28 d. We first measured and compared the liver weight, relative liver weight and serum biochemical parameters that indicating acute liver injury. Compared to control group, changes in liver injury index in 0.4 and 2 mg/kg/d PFO4DA groups did not exceed 20%. After 10 mg/kg/d PFO4DA exposure, relative liver weight and liver injury index including alanine aminotransferase, glutamic oxaloacetylase and alkaline phosphatase were significantly increased, suggesting acute liver injury. Liver and serum lipid content were then detected to assess the effects of PFO4DA on lipid metabolism. No change in triglyceride (TG) and total cholesterol (TCHO) content was observed in both three exposed groups, while in the liver of 10 mg/kg/d PFO4DA exposed mice, TG and TCHO levels were significantly decreased. Furthermore, differentially expressed liver proteins (DEPs) between the control and 10 mg/kg/d groups were identified using isobaric tags for relative and absolute quantification (iTRAQ) and bioinformatics analysis to explore the possible mechanism for PFO4DA toxicity. Western blotting was performed to verify iTRAQ results and analyze the expression levels of key proteins and nuclear receptors. Results showed that exposure to 10 mg/kg/d of PFO4DA led to 198 DEPs (56 down-regulated, 142 up-regulated) that were mainly involved in fatty acid metabolism, fatty acid degradation, peroxisome, and the PPAR signaling pathway, highlighting urea cycle disorder and stimulation of lipid metabolism in mice liver. The significantly increased PPARα and the downstream proteins after 10 mg/kg/d PFO4DA exposure might be mainly responsible for the decreased lipid content in liver. PFO4DA exposure could cause hepatotoxicity and decreased lipid content in mice liver, with PPAR pathway activation being a significant contributor to the observed toxicity. Our data implied that PFO4DA may not be a suitable alternative to PFOA. Considering that PFO4DA has been detected at much higher concentrations than PFOA in raw water samples, efforts to remove or at least decrease its occurrence in drinking water should be made urgently.

PS 3138 Perfluorinated Compounds Decrease Expression of a Key Steroidogenic Enzyme in Leydig Cells

T. Fadlou Allah[1], C. Zheng[1], P. Bu[2,1], and X. Cheng[1]. *[1]St. John's University, New York, NY; and [2]Rosalind Franklin University of Medicine and Science Department of Pharmaceutical Sciences, North Chicago, IL.*

Background: Perfluorinated compounds (PFCs) are synthetic chemicals, which were once widely used for industrial purposes. Because of their extraordinary resistance to degradation, PFCs are universally detected in environmental media, as well as in humans and wild life. As a result, environmental exposure to PFCs and their accumulation in human body present toxicological concerns. Over the past several decades, male reproductive functions have been declining in human and wildlife. The present study aims to investigate whether exposure to PFCs adversely impact the functions of male reproductive system. Hypothesis: Exposure to PFCs interferes with the expression of key steroidogenic enzymes in Leydig cells, which then results in a reduction in testosterone production. Method: A panel of four most commonly detected PFCs (PFDA, PFNA, PFOA and PFOS) were screened on three mouse Leydig cell lines (MLTC-1, MA10, and TM3) for interference on the expression of key enzymes involved in testicular steroidogenesis. Results: Perfluorinated carboxylates (PFDA, PFNA, and PFOA) at a concentration of 10 micromolar decreased expression of hydroxysteroid dehydrogenase 3 beta 6 (Hsd3b6) more than 50% in MLTC-1 cells but perfluorooctane sulfonate (PFOS) did not. Using PFDA as a representative of the perfluorinated carboxylates, we showed that PFDA similarly decreased Hsd3b6 expression (≥ 50%) in two additional Leydig cell lines (MA10 and TM3). PFOS decreased Hsd3b6 expression only in TM3 cells but not in MA10 cells. Concentration-response studies of PFDA (0.1-100 micromolar) in all three Leydig cell lines revealed that higher concentration of PFDA caused greater reduction in Hsd3b6 expression. In contrast, concentration-response study of PFOS in MLTC-1 cells showed an irregular concentration-response curve with reduction in Hsd3b6 expression only observed at the highest concentration tested. Conclusions: PFCs decreased the expression of Hsd3b6, which is a conserved and key enzyme, in male gonadal steroidogenesis. In comparison to PFOS, the three perfluorinated carboxylates (PFDA, PFNA, and PFOA) seem to have greater impact on Hsd3b6 expression at lower concentrations and exhibit consistent concentration-response effect in Leydig cells.

3139 A Model Template Approach for Rapid Evaluation of PBPK Models for Use in Human Health Risk Assessments

A. Bernstein[1], P. Schlosser[2], and D. Kapraun[2]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [2]US EPA, Research Triangle Park, NC.*

Physiologically based pharmacokinetic (PBPK) models can significantly reduce uncertainty in components of a human health risk assessment (e.g., dose extrapolation across species) but evaluating PBPK models to meet quality assurance standards can be a slow process, particularly when model code is not readily available. In order to allow for faster evaluation of PBPK models, and thus faster evaluation of chemicals for human health risk assessments, we developed a model "template" that allows one to quickly implement various chemical-specific PBPK models. To test this approach, we created a template PBPK model applicable to multiple per- and polyfluoroalkyl substances (PFAS). This PFAS PBPK model template allows for representation of models with varying numbers of tissue compartments, oral and intravenous exposures, and multiple elimination pathways, including urinary, biliary, and fecal routes. The template also includes an option for renal resorption, which impacts clearance rates for some PFAS. We parameterized the PFAS template model using values from published PBPK models for perfluorohexanesulfonate (PFHxS), perfluorononanoic acid (PFNA), and perfluorodecanoic acid (PFDA). We first verified that the template reproduced the published model results, then attempted to validate the model using independent data sets not used to calibrate model parameters. Following this template approach, only one primary model file needed to undergo quality assurance review. Subsequent model evaluation for individual PFAS only required the input files containing model-specific parameters to be reviewed. This greatly reduced the amount of time necessary to review the PBPK models for the three PFAS we evaluated. This template will allow for faster evaluation of PBPK models for use in assessing the potential human health effects of PFAS exposure and a more efficient quality assurance process, and it demonstrates a generalizable approach that could be applied to broader classes of chemical-specific PBPK models.

3140 *In Vitro* Binding of Human and Rat PPAR Alpha, Beta/Delta, and Gamma Receptors to PFAS, Fatty Acids, and Clofibric Acid

N. Evans, M. Cardon, P. Hartig, E. Medlock-Kakaley, V. S. Wilson, J. M. Conley, and L. E. Gray. *US EPA, Research Triangle Park, NC.*

The molecular mechanism by which some per- and polyfluorinated alkyl substances (PFAS) exert toxicity has largely been attributed to activation of peroxisome proliferator-activated receptor alpha (PPARα). Less attention has been given to PPAR beta/delta (PPARβ/δ) or PPAR gamma (PPARγ). Further, it is unknown how, or if, PFAS activation of PPAR paralogs differs between rats and humans. We utilized *in vitro* luciferase reporter assays with either human or rat PPARα, β/δ, or γ ligand binding domains hybridized with a Gal4 DNA binding domain to evaluate 9 PFAS (hexafluoropropylene oxide-dimer acid ammonium salt (GenXAS) and free acid (GenXFA), nafion byproduct 2 (NBP2), perfluorooctanoic acid (PFOA), perfluorooctane sulfonate (PFOS), perfluorobutane sulfonate (PFBS), perfluorononanoic acid (PFNA), 6:2 fluorotelomer alcohol (6:2 FTOH), and perfluoromethoxyacetic acid (PFMOAA)), 3 endogenous fatty acids (oleic, linoleic, and octanoic), and the drug metabolite clofibric acid at 30 µM -1 mM. We also tested all chemicals for estrogen (ER), androgen (AR), and glucocorticoid receptor (GR) transcriptional activation using previously established stable transfection (ER) and viral transduction (AR, GR) luciferase reporter assays. All compounds, except 6:2 FTOH, activated both PPARα and PPARγ in both human and rat. EC_{10} values were calculated due to low fold induction for several compounds. Oleic and linoleic acid were the most potent human PPARα activators, while PFMOAA had the lowest EC_{10} and PFOS had the lowest fold induction (13% of max). For rat PPARα, GenX was the most potent activator (no difference between GenXFA and GenXAS), while NBP2, PFMOAA, PFBS, and PFOS all had very low fold induction (≤6% of max). For PPARγ, all compounds had similar potency in the human and rat receptor assays (log EC_{10} ranges: -3.33 - -3.86 versus -3.07 - -3.80), except for PFMOAA which only reached 3% and 1% of max fold induction, respectively. In contrast, the only compounds that activated both human and rat PPARβ/δ were oleic and linoleic acid; however, NBP2 weakly activated (~10% of max) rat PPARβ/δ at 300 µM. No compounds displayed *in vitro* AR or GR transcriptional activation. Only 6:2 FTOH exhibited weak ER agonism. Overall, all PFAS studied, except 6:2 FTOH, displayed both human and rat PPARα and γ activity, with some having similar potency to endogenous free fatty acids. Thus, it is likely that both PPARα and γ activation contribute to the adverse *in vivo* effects observed for PFAS. *Abstract does not necessarily reflect US EPA policy.*

3141 Comparative Evaluation of Mouse Mammary Gland Development and Pathways of Gene Expression following Prenatal Exposure to PFOA and GenX

C. A. Love[1], H. A. Cope[1], B. E. Blake[1,2], T. P. Phan[1,3], and S. E. Fenton[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [3]North Carolina State University, Raleigh, NC.*

Legacy per- and polyfluoroalkyl substances (PFAS) are a group of contaminants known to be highly persistent in the environment and in humans. Previous studies have shown that gestational exposure to perfluorooctanoic acid (PFOA) impairs development of the female mouse mammary gland. The purpose of this study was to compare changes in mammary gland morphology and pathways of gene expression from *in utero* exposure to PFOA and a replacement PFAS, GenX (ammonium perfluoro-2-methyl-3-oxahexanoate), which is thought to exhibit more rapid elimination. Time-pregnant CD-1 mice were dosed with PFOA (0.l, 1.0, or 5.0 mg/kg) or GenX (0.2, 1.0, 2.0, or 10.0 mg/kg) from gestation day 1.5 to 17.5. Mammary glands were collected from offspring at weaning (PND 21 or 22) or during puberty (PND 36). Developmental scores between 1 and 4 were assigned to female and male mammary gland whole mounts by three evaluators blinded to treatment, based on a set of criteria for normal development at weaning or puberty. RNA was isolated from PND 22 female glands and changes in gene expression were assessed with an Affymetrix Mouse Clariom D transcriptome array and Ingenuity Pathway Analysis. Histopathology and internal dosimetry are underway. There were significant dose-dependent reductions in developmental score for female glands exposed to PFOA and GenX ($p<0.01$) and male glands exposed to GenX ($p<0.05$) (Jonckheere-Terpstra test). All female dose groups except 0.2 mg/kg GenX had mean scores significantly lower than control glands but no male dose groups differed from the control (Dunn's test). Preliminary evidence indicates 40 genes that are similarly changed (vs control) by PFOA and GenX, and a much larger number that exhibited treatment specific regulation. Among commonly regulated genes are those involved in insulin receptor, growth factor, PPARα, and p38 MAPK signaling as well as regulation of adipose browning and the epithelial mesenchymal transition. Altered expression of these pathways suggests dysregulation in the stromal portion of the gland may be responsible for delayed development of mammary epithelial tissue. Together, these data indicate that, despite more rapid elimination of GenX, both chemicals induce sex-specific impairment of female mammary gland development that may be modulated by prenatally-triggered changes in gene expression.

3142 Perflurooctane Sulfonate (PFOS) Alters Gut Microbiota Composition and Function in Mice

B. Rimal[1], L. Zhang[1,2], R. G. Nichols[1], Y. Tian[1], J. M. Peters[1], and A. D. Patterson[1]. *[1]Pennsylvania State University, State College, PA; and [2]Chinese Academy of Sciences, Wuhan, China.*

Perfluorooctane sulfonate (PFOS) is a persistent environmental chemical that is toxic to human endocrine, reproductive, and immune systems. Toxicity can be mediated by multiple mechanisms. Recently, the gut microbiome has been reported to alter the fate and activity of environmental chemicals on the host. However, whether PFOS directly influences the gut microbiome community structure and function remains unknown. In this study, 6-8 weeks old male C57BL/6J mice were fed a control diet with and without 0.003%, 0.006% or 0.012% PFOS. 16S rRNA gene sequencing of cecal contents revealed that PFOS caused marked changes in the gut microbiota composition relative to control. For example, there was a significant increase in the relative abundance of Bacteroidetes ($FC=1.36$, $p<0.05$) and significant decrease in the relative abundance of Firmicutes ($FC=1.34$, $p<0.05$). Further, flow cytometry and ^{1}H NMR-based metabolomic profiling of cecal contents revealed the direct effects of PFOS on the gut microbiome metabolism and physiology. PFOS caused a significant dose-dependent decrease in CFDA (a proxy for metabolic activity) stained bacteria (63% ± 3.27 to 26.4% ± 0.87%, $p<0.0001$) indicating decreased metabolic activity of bacteria. ^{1}H NMR metabolic profiling revealed a significant increase in the uracil ($FC=1.6$), inosine ($FC=2$), hypoxanthine ($FC=2.14$), xanthine ($FC=1.5$), and uridine diphosphate ($FC=2$) after PFOS treatment. Overall, PFOS altered the gut microbiome composition and its function. These findings provide new insights and understanding of the mechanisms that may modulate the effects of PFOS and suggest new mechanisms to understand PFOS toxicity.

3143 Development of Gestational and Lactational Physiologically Based Pharmacokinetic (PBPK) Model for Perfluorooctane Sulfonate (PFOS) in Rats and Humans within a Bayesian Framework to Derive Health-Based Toxicity Values

W. Chou, and Z. Lin. *Institute of Computational Comparative Medicine (ICCM), Kansas State University College of Veterinary Medicine, Manhattan, KS.*

Perinatal exposure to perfluorooctane sulfonate (PFOS) has been associated with developmental toxicity in animal and human studies. However, risk assessment and derivation of health-based toxicity values for PFOS are conflicted due to the lack of tools for species extrapolation underling the toxicokinetics of gestational and lactational transfer and tissue distribution. To address this challenge, this study aimed to develop a gestational and lactational PBPK model in rats and humans to derive the human equivalent dose (HED) and reference dose for PFOS. Available animal toxicokinetic and human biomonitoring data were used for model calibration and optimization, and independent datasets were used for model evaluation. A Bayesian framework with Markov chain Monte Carlo (MCMC) simulation was applied to improve model performance and to characterize the variabilities and uncertainties of chemical-specific parameters during pregnancy and lactation. Model simulations were within two-fold of observed PFOS concentrations in fetal, neonatal, and maternal plasma. Estimated HEDs based on selected critical toxicity studies in rats following US EPA's guidelines ranged from 0.053 to 0.060 μg/kg/day, which are lower than the HEDs estimated by US EPA (1.6 μg/kg/day). Our results suggest that the derivation of health-based toxicity values based on developmental toxicity study should consider species differences in gestational/lactational dosimetry. This study provides insights into a complete risk characterization of PFOS and may help regulatory agencies in the reevaluation of PFOS risk in sensitive subpopulations, including fetuses, neonates, pregnant and lactating women. The validated gestational and lactational PBPK model can be used to improve risk assessment for other per- and polyfluoroalkyl substances (PFAS).

3144 *In Vivo* Toxicological Investigation of Per- and Polyfluoroalkyl Substances (PFAS) to Elucidate Structure-Bioactivity Relationships and Investigate Modes of Action

Y. Rericha, L. Truong, and R. Tanguay. *Oregon State University, Corvallis, OR.*

Per- and polyfluoroalkyl substances (PFAS) are persistent compounds frequently detected in the environment, biota, and humans. In recent years, toxicological studies have addressed a wider range of PFAS, however, there are still thousands yet to be assessed. To investigate PFAS toxicity, we are conducting *in vivo* testing to better understand structure-activity relationships and to discern mechanisms of action. We developed a high-throughput screening (HTS) platform using early life stage zebrafish to evaluate the biological activity of individual PFAS of a variety of chain lengths and functional head groups. Initial investigation has focused on the carboxylate class. We identified and acquired a complete chain length series of PFAS with a single carboxylic acid head group and fully fluorinated chains from 4 (perfluorobutanoic acid) to 14 carbons (perfluorotetradecanoic acid). The purities of acquired PFAS were characterized and used to make stock solutions in dimethyl sulfoxide. Dechorionated embryos were statically exposed at 6 hours post fertilization (hpf) in individual wells of 96-well plates. We measured 22 morphological and 2 behavioral endpoints at 24 and 120 hpf. For each member of the carboxylate class (11 PFAS), we first conducted a preliminary concentration-response study, using a broad concentration range (0-100 μM, n= 12) to define the bioactivity of each PFAS. For each PFAS, we completed subsequent definitive testing with 36 fish at each concentration to calculate the EC_{10}, EC_{50}, EC_{80}, etc. We are using these concentration-response curves to investigate associations between PFAS carbon chain length and resulting biological activity. To begin to identify the mode of action of the carboxylate class PFAS, we also exposed embryos to the respective EC_{80} and conducted full-genome RNA sequencing using RNA collected from 48 hpf larvae. Collectively, through *in vivo* screening, structure-activity analysis, and transcriptomics, we aim to collect sufficient empirical data to allow us to predict the toxicity of the carboxylate class PFAS. Future work will utilize the outlined experimental design to investigate the sulfonate, sulfonamide, and telomer sulfonate PFAS categories.

3145 Gene Expression Changes Associated with Environmentally Relevant Doses of PFAS in an *In Vitro* Placental Trophoblast Model

J. Bangma, J. Szilagyi, J. Rager, and R. Fry. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Per- and poly-fluoroalkyl substances (PFAS) are a group of chemicals that have been widely used in stain repellents, paints, polishes, protective coatings, and firefighting foams. While some of these chemicals, including perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA), have been discontinued in the United States, their persistence in the environment and continued use internationally make them a toxicological concern. Moreover, GenX, a modern replacement for PFOA, has recently contaminated drinking water in the Cape Fear River in the Wilmington, NC area, warranting immediate analysis of the associated risks. While prior reports have shown that PFAS can cross the placenta, there is little understanding of how this class of compounds can impact placental function itself. Therefore, this study aimed at understanding the effects of PFAS exposure on placental gene expression and ultimately placental function. HTR-8/SVneos, an *in vitro* trophoblast cell line, were treated with an environmentally-relevant dose (10 ng/ml) of PFOS, PFOA, or GenX for 24 hours and mRNA/whole transcriptome sequencing was performed. To evaluate changes in gene expression profiles associated with PFAS exposure, genome-wide RNA sequencing count data were processed and statistically assessed. Genes showing differential expression associated with each PFAS exposure were prioritized based statistical significance. Pathway analysis on resulting genes revealed both PFOS and GenX induce changes in the expression levels of similar gene sets. Specifically, impacted pathways included cell movement and apoptosis with altered genes including but not limited to Tumor Necrosis Factor (*TNF*), Thiosulfate Sulfurtransferase (*TST*), Matrix Metallopeptidase 9 (*MMP9*), Nuclear Factor Erythroid 2-Related Factor 2 (*NFE2L2*), and Insulin Like Growth Factor 1 Receptor (*IGF1R*). PFOA, on the other hand, impacted different gene sets with dysregulation of artery and vein development signaling, most significantly Ephrin Type-B Receptor 2 (*EPHB2*). Several of these genes including but not limited to *MMP9*, *NFE2L2*, and *EPHB2* have published relationships to dysregulated signaling observed in preeclamptic placentas. Ultimately, this is among the first studies to look at whole genome PFAS impact on placental signaling at environmentally-relevant levels and highlights the need for additional research.

3146 Environmentally Relevant PFAS Exposures in a Zebrafish Model: Health Effects and Transcriptomic Assessment

A. Haimbaugh, B. B. Baker, and T. R. Baker. *Wayne State University, Detroit, MI.*

Per- and polyfluoroalkyl substances (PFAS) are mainly used as industrial or commercial surfactants and are present in many common household products, including nonstick cookware, popcorn bags, and cosmetics. PFAS consist of over 5,000 chemicals, all of which have a similar fully-fluorinated carbon chain that renders these chemicals extremely resistant to degradation, leading to environmental persistence and bioaccumulation. Despite phased out production in the United States, two of the most environmentally common PFAS compounds, perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS), are still found in the ug/L range in blood samples from the general population. This range exceeds the EPA lifetime health advisory (HA) for PFOA, PFOS, or a mixture of these chemicals in drinking water, which is 70 ng/L (70 parts per trillion). Though most research to-date has focused on PFOA or PFOS alone, environmental exposures more typically include multiple chemicals at once. In fact, our lab detected PFOA and PFOS concurrently in the Lake Huron-to-Erie corridor at maximum levels of 4ng/L and 3ng/L, respectively. Previous research has linked high doses of PFAS to endocrine-related issues in adults, among other health concerns, but little is known about chronic, low level exposures during early development or to PFAS mixtures. Thus, we exposed embryonic zebrafish (*Danio rerio*) to environmentally relevant levels of PFOS, PFOA, and a 50:50 mixture of each compound at 0, 7, 70, and 700 ng/L from 4 to 120 hours post-fertilization. We then assessed developmental abnormalities, behavioral response to light/dark cycles to screen for neurobiological alterations, and genome-wide transcriptomic changes. We found significant behavioral changes that were chemical- and mixture-dependent, as well as altered gene expression in endocrine- and cancer-related pathways.

3147 Effects of Perfluoroalkyl Phoshinic Acid (PFPiA) on Behavior, Neurodevelopment, and DNA Methylation in Developing Zebrafish

S. Kim[1], K. Stroski[1], M. Simcik[2], and B. W. Brooks[1]. *[1]Baylor University, Waco, TX; and [2]University of Minnesota, Minneapolis, MN.*

While recent studies have reported potential neurotoxicity and epigenetic alteration associated with exposure to several perfluoroalkyl substances (PFASs), the information is not only limited to only a few well-known compounds, but also their underlying mechanism are less understood. In the present study, we investigated the effects of 8:8 perfluoroalkyl phoshinic acids (8:8 PFPiA), one of the emerging PFASs but relatively under-studied, in early life zebrafish. We exposed different concentrations of 8:8 PFPiA (30, 100, 300, 1000, 3000, 10000 nM) to 4 hpf zebrafish embryos for 144 h. Although there were no significant changes in survival, hatchability, and malformation, the larvae exposed to PFPiA showed a decreased locomotor speed at 120 hpf comparing with controls. At 144 hpf, whole body samples were collected to examine the expression of genes involved in neurotoxicity. Genes related to thyroid hormone disruption and oxidative stress were also included considering its relationship with neurodevelopment and the findings from previous relevant studies. In addition, we estimated the alteration in global DNA methylation by ELISA method and specific gene methylation using bisulfite pyrosequencing assay, in order to understand the molecular mechanisms. The results of this study would enhance the understanding the adverse effects and molecular pathway of PFPiA and contribute to preventing risk of other similar PFASs.

3148 Gene Expression Changes in Maternal, Fetal, and Neonatal Tissues from Exposure to Hexafluoropropylene Oxide-Dimer Acid (HFPO-DA, GenX)

C. Lambright, N. Evans, M. Cardon, E. Kakaley, V. Wilson, J. Conley, and E. Gray. *US EPA, Durham, NC.*

The specific molecular mechanisms by which per- and polyfluorinated alkyl substances (PFAS) exert developmental toxicity in laboratory animals are not well described. Existing literature has focused on activation of peroxisome proliferator-activated receptor alpha (PPARα) and perturbation of the developing fetal tissues. Here, we utilized reverse transcriptase quantitative PCR (RT-qPCR) gene expression profiling arrays covering multiple signaling pathways to identify key genes and target tissues from pregnant Sprague-Dawley rats and offspring impacted by PFAS exposure as part of a set of broader experiments on the adverse effects of *in utero* PFAS exposure. Dams were dosed with hexafluoropropylene oxide-dimer acid (HFPO-DA; i.e., GenX) via oral gavage (water vehicle) from gestation days (GD) 14-18 (1-500 mg/kg/d) or GD 8 - postnatal day (PND) 2 (10-250 mg/kg/d) with maternal liver and fetal tissues (liver, heart, lung, kidney, thymus) collected on GD 18 and neonatal livers collected on PND 0. Maternal, fetal, and neonatal livers all displayed significantly altered expression of genes in the PPAR signaling pathway associated with all three PPAR isoforms - α, β/δ, γ. Each life-stage had distinct expression profiles; however, 7 genes (*Acadm, Acox1, Cpt1b, Ech1, Ehhadh, Fabp1*, and *Rxrg*) were significantly upregulated in maternal, fetal, and neonatal livers. Only neonatal livers displayed genes that were significantly downregulated (*Fabp2* and *Slc27a5*). Neonatal livers were also assessed for glucose metabolism signaling and 17 genes were significantly downregulated including *Ugp2*, *Aldob*, and *Agl*. Preliminary data on PPAR pathway gene expression changes in additional fetal tissues indicated that the overall rank order of tissues based on number of highly affected genes was: liver>thymus>heart>lung>kidney. The liver appears to be a key target tissue for toxic effects with multiple signaling pathways involved, not exclusively PPARα, and the specific genes affected are life-stage dependent. Ongoing research is investigating the maternal, fetal and neonatal liver expression of PPAR and glucose metabolism pathway genes from gestational exposure to a second understudied PFAS, Nafion byproduct 2 (NBP2), and a mixture of three PFAS (GenX, NBP2, and perfluorooctane sulfonate [PFOS]). *Abstract does not necessarily reflect US EPA policy.*

3149 Public Health Evaluation of PFAS Exposures and Breastfeeding: A Systematic Literature Review

L. Hoadley, M. Watters, R. Rogers, L. Werner, B. Anderson, K. Markiewicz, T. Forrester, and E. McLanahan. *CDC/ATSDR, Atlanta, GA.*

The Agency for Toxic Substances and Disease Registry (ATSDR) is working to address concerns from community members exposed to per- and polyfluoroalkyl substances (PFAS). Nursing mothers and health professionals have raised concerns about PFAS exposures through breastmilk. Fetuses and young children may be exposed to PFAS through trans-placental transfer and breastmilk, respectively. Longer breastfeeding duration is associated with greater levels of some PFAS in serum. ATSDR recommends that mothers who have been exposed to PFAS continue to breastfeed their infants; this is in accordance with guidance from American Academy of Pediatrics and the Centers for Disease Control and Prevention. The risks of exposure to environmental pollutants are unlikely to outweigh the well documented health benefits of breastfeeding for both mothers and infants. However, a formal review of evidence documenting any health effects associated with exposure to PFAS through breastmilk was not available. ATSDR is conducting a systematic review of observational human and experimental animal literature published through February 2018 to answer the following questions: (1) What is the evidence that exposure to PFAS through breastfeeding leads to a health outcome in humans or animals? and (2) Under what circumstances, if any, would a clinician recommend that a mother consider not breastfeeding her child? ATSDR followed the National Toxicology Program's Office of Health Assessment and Translation protocol to identify key questions using a PECO (population, exposure, comparator, outcome) framework and formulate criteria for inclusion and exclusion of published studies. ATSDR identified 4,297 unique records from 7 databases and included 37 articles for full-text review and some level of data extraction. The review included 8 animal studies in which the contribution of lactational exposure could be isolated from gestational exposure. This review will inform ATSDR's recommendations to nursing mothers using state-of-the-science evidence of the contribution of exposure to PFAS in breastmilk to health outcomes in infants and children. *The findings in this presentation have not been formally disseminated by the ATSDR and should not be construed to represent any agency determination or policy.*

3150 Elucidating Relationships between Internal Dose, Thyroid Hormones, and Hepatic Gene Expression Altered by Perfluoroalkyl Substances in Rats following 28-Day Oral Exposure

M. Huang, K. Shockley, F. Parham, N. Sipes, S. Auerbach, and C. Blystone. *NIEHS/NTP, Research Triangle Park, NC.*

Perfluoroalkyl substances (PFAS) are persistent in our environment and have been associated with numerous adverse health effects. The National Toxicology Program (NTP) recently evaluated the toxicity of seven perfluorinated chemicals to facilitate comparisons of toxicity across the chemical class and between sexes (NTP Toxicity Reports 96 and 97). Briefly, male and female Sprague-Dawley rats (N=10/exposure group/sex) were exposed to varying concentrations (5-1000 mg/kg/day) of either perfluorobutane sulfonic acid (PFBS), perfluorohexane sulfonate potassium salt (PFHSKslt), perfluorooctane sulfonic acid (PFOS), perfluorohexanoic acid (PFHxA), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), or perfluorodecanoic acid (PFDA) for 28 days via oral gavage. Clinical pathology, thyroid hormones, hepatic gene expression, acyl-CoA oxidase activity, histopathology, plasma concentrations, and liver concentrations (males only) were evaluated at the end of the study. Key findings include dose-dependent decreases in thyroxine (T4) and triiodothyronine (T3), with minimal changes in thyroid stimulating hormone (TSH). Liver was a target organ, evidenced by increased liver weight, induction of hepatic *Acox1, Cyp4a1, Cyp2b1,* and *Cyp2b2*, histological lesions, and increased serum biomarkers of hepatobiliary injury. Using these data, we further investigated the relationship between these observations. In male animals, plasma and liver concentrations were strongly correlated (Pearson's $r \geq 0.88$) for all PFAS. Liver:plasma ratios ranged between 0.3 to 25 and tended to decrease with increasing dose, except for PFHxS where liver:plasma ratio increased with increasing dose. Hepatic gene expression was generally negatively correlated with T4 and T3, but not TSH, and more strongly in males than females. Significant correlations were seen more consistently among sulfonate PFAS. Thyroid hormones and liver endpoints were also examined in the context of all the measured endpoints to identify previously unidentified interactions. Overall, these analyses present efforts to better understand the health effects of PFAS, particularly the relationship between thyroid and hepatic effects.

3151 Perfluorinated Compounds Disrupt Wound-Healing Responses in Human Lung Fibroblasts (HFL-1)

J. H. Lucas, Q. Wang, and I. Rahman. *University of Rochester, Rochester, NY.*

Perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) are persistent environmental contaminants that were used in fire retardants, food packaging, and textiles for decades. Despite phase-out of PFOS and PFOA, exposure from drinking water and dietary intake continues to be a health risk.

Detectable levels of PFOS and PFOA have been found in most people tested, raising concerns about their potential long-term health effects. Studies have demonstrated that PFOS and PFOA can accumulate in the lung and are associated with a higher risk of developing asthma, respiratory infection, and decreased lung function. However, the mechanisms underlying these potential health risks are unknown. We hypothesized that the harmful effects of PFOS and PFOA might be due to the dysfunction of normal wound healing responses by inhibiting fibroblast differentiation and inducing senescence. Human lung fibroblasts (HFL-1) were exposed to 50μM PFOS and PFOA alone or combined with 5ng/mL transforming growth factor-β (TGF-β) for 72h. Scratch assay was applied for measuring the wound healing response. Protein targets related to fibroblast-myofibroblast differentiation and senescence were determined as well. Using the scratch assay, wound closure was significantly inhibited by PFOS at both 48h (n=4, p<.001) and 72h (n=4, p<.05) compared to the TGF-β group. Furthermore, fibronectin and type-1 collagen induced by TGF-β were significantly reduced with PFOS (n=3, p<.001), but not PFOA. Moreover, there was no significant difference in α-smooth muscle actin (α-SMA). Interestingly, PFOS exposure resulted in increased p53, plasminogen activator inhibitor-1 (PAI-1), and p21, suggesting that PFOS may promote cellular senescence. Together, our data suggest that dysregulated wound healing processes might be a result of disturbing TGF-β signaling and promoting senescence by PFOS exposure. Future studies will examine PFOS modulation of TGF-β signaling and cellular senescence in order to understand how PFOS is negatively impacting lung health. *Supported by T32 ES007026.*

PS 3152 Developmental Toxicity of Perfluoroalkyl Substances Using Zebrafish

O. Wasel, H. King, K. Thompson, and J. Freeman. *Purdue University, West Lafayette, IN.*

Perfluoroalkyl substances (PFAS) are synesthetic compounds that are used in food packaging products, firefighting materials, electronics, cookware, carpets, furniture, clothing, and many other applications. PFAS are composed of a fluorinated carbon chain. PFAS are persistent in environment and bioaccumlative in organisms. The concerns of PFAS toxicity led to voluntarily phasing out of perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) by their manufacturer. PFOA and PFOS are both composed of 8 carbon chain (C8). Shorter chain chemicals (such as perfluorobutyrate (PFBA, C4) and perfluorobutane sulfonate (K-PFBS, C4)) and compounds with chemical modifications (such as GenX, C6) were used as a replacement to the long chain PFAS, (>C7 for COO^-- containing PFAS or >C6 for SO_3^-- containing PFAS), in order to increase their degradability potential. In this study, we compared toxicity of five PFAS in order to assess the role of chain length, functional group and chemical structure in their toxicity. We compared the toxicity of K-PFOS (CAS# 2795-39-3), PFOA (CAS# 335-67-1), K-PFBS (CAS# 2940-49-3), PFBA (CAS# 29420-49-3), and GenX (CAS# 13252-13-6) using Zebrafish (*Danio rerio*). To determine LC50 of each chemical, zebrafish embryos were exposed to a range of concentrations of each chemical within 1-hour post fertilization (hpf) for 120 hpf. The toxicity of these compounds was assessed by monitoring the survivability every 24 hours through 120 hpf. 120hpf-LC50 were determined using SPSS-23 software. In addition, behavioral analysis using a visual motor response test was performed. For behavioral analysis, we used concentrations of 0, 4, 40, 400, and 4000 part per billion (ppb). The exposure was terminated at 72hpf and the test was done at 120hpf. Results showed that the 120hpf-LC50s are 24.04 part per million (ppm) for PFOS, 451.15 ppm for PFOA, 2578.08 ppm for PFBS, >10000 ppm for PFBA, and >7000 ppm for GenX. Toxicity ranking is K-PFOS> PFOA> K-PFBS >PFBA, GenX. Based on these results, we can conclude that toxicity increases with increasing the chain length. Also, presence of sulfonate group increased toxicity for PFAS of a given chain length. Behavioral analysis showed that embryonic exposure to K-PFOS, PFOA or GenX induced hyperactivity in larvae, while PFBA and K-PFBS caused hypoactivity. Future work is identifying the mechanism behind the observed behavioral changes.

PS 3153 A Comparison of Effects and Modes of Action of Perfluorooctanoic Acid (PFOA) and Hexafluoropropylene Oxide Dimer Acid (HFPO-DA, or GenX) in Liver and Placenta from CD-1 Mice Exposed during Pregnancy

B. E. Blake[1], H. Cope[1], S. Hall[2], R. Keys[1], B. Mahler[1], J. McCord[3], B. Scott[1], H. Stapleton[2], M. Strynar[3], S. Elmore[1], and S. Fenton[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; [2]Duke University, Durham, NC; and [3]US EPA/CCTE, Durham, NC.*

Perfluorooctanoic acid (PFOA) is a perfluoroalkyl substance (PFAS) associated with adverse pregnancy outcomes in mice and humans, but little is known regarding one of its replacements, hexafluoropropylene oxide dimer acid (HFPO-DA or GenX). GenX was selected to replace PFOA due in part to its quicker elimination in both human and rodents but has received public scrutiny in North Carolina after reports of high levels of GenX contamination in the Cape Fear River. We compared the toxicity of PFOA and GenX in pregnant mice and their developing embryo-placenta units. Pregnant CD-1 mice were exposed daily to PFOA (0, 1 or 5 mg/kg) or GenX (0, 2 or 10 mg/kg) via oral gavage from embryonic day (E) 1.5 to 11.5 or 17.5. Maternal clinical chemistry, maternal liver and placental histopathology, embryo and placental weight, internal dosimetry, and placental thyroid hormones were measured. Accumulation of GenX in maternal serum, amniotic fluid, and whole embryos was comparable to levels in mice exposed to PFOA, but GenX accumulated to a much lesser extent than PFOA in the maternal liver (5 mg/kg PFOA: 159.2 ± 22 μg/g; 10 mg/kg GenX 14.2 ± 8 μg/g). GenX exposure recapitulated many known effects of PFOA on the liver/metabolic system, including significantly increased gestational weight gain, reduced serum triglycerides and 100% incidence of hepatocellular cytoplasmic alteration. Subcellular changes induced by PFOA and GenX in hepatocytes included reduced glycogen, increased mitochondria and peroxisomes, and altered rough endoplasmic reticulum. Incidence of placental lesions was similar for both 5 mg/kg PFOA (68%) and 10 mg/kg GenX (83%), but lesion subtype incidences were compound-specific. Placenta labyrinth atrophy was more common in GenX-exposed placentas (10 mg/kg GenX: 46%; 5 mg/kg PFOA: 7%) and labyrinth congestion was more common in PFOA-exposed placentas (5 mg/kg PFOA: 57.5%; 10 mg/kg GenX: 23%). Placental thyroxine was disrupted in mice exposed to 10 mg/kg GenX, but not altered in mice exposed to PFOA. Taken together, these data suggest that PFOA and GenX likely utilize divergent mechanisms of toxicity in the placenta. Transcriptomic analyses of maternal livers, placentas, and embryo livers are in progress to characterize the shared and divergent molecular pathways used by PFOA and GenX to exert toxic effects in the maternal-embryo-placental unit.

PS 3154 Development of an AOP Network for the Developmental Effects of Exposure to the PFAS

L. E. Gray, Jr, C. Lambright, N. Evans, M. Cardon, E. M. Kakaley, V. Wilson, and J. Conley. *US EPA, Research Triangle Park, NC.*

There is growing global concern about the health effects of PFAS due to widespread exposure from a variety of sources. We are developing an AOP network for PFAS from the literature and from our own developmental studies with rats. The goal is to link *in vitro* Molecular Initiating Events (MIEs) and *in vivo* Key Events (KEs) to adverse fetal and postnatal effects of individual PFAS and mixtures of PFAS. *In vitro* data demonstrate that the PFAS (HFPO-DA, PFNA, PFOS, PFOA, PFBS, PFMOAA and nafion byproduct 2 (NBP2)) and fatty acids (FA) (oleic, linoleic, octanoic) are PPAR α and γ agonists but 6:2 FTOH is not. Only FA activated PPAR δ. None of the PFAS or FA are AR or GR agonists, whereas 6:2 FTOH appears to be a weak ER agonist. In order to identify KEs related to PFAS developmental toxicity, we dosed pregnant rats from gestational day (GD) 14 to 18, we found that HFPO-DA (GenX) altered fetal and maternal liver mRNA expression for genes in the PPAR and lipid pathways, increased maternal but not fetal liver weight, altered maternal serum lipid profiles, and reduced maternal serum T3 and T4. We also are examining the effects of PFAS on gene pathways in other fetal tissues including the thymus, heart, lung, brain and placenta. Although fetal viability and body and liver weight were unaffected by GD 14 to 18 exposure, in a pre-postnatal study dosed from GD 8 to postnatal day 2, HFPO-DA reduced pup weight and viability at dose levels that did not induce overt maternal toxicity. HFPO-DA also increased liver PPAR gene expression and liver weight in the dam and pups and reduced neonatal liver glycogen storage, which by itself could result in neonatal mortality. Similar studies on the effects of NBP2 and a PFAS mixture (HFPO-DA, NBP2 and PFOS) are ongoing. To date, we have found that NBP2 and the mixture of PFAS (dose additive) also reduced neonatal survival and growth. Taken together, these data indicate that PFAS act via multiple MIEs, disrupting multiple KEs that result in diverse effects in fetal, neonatal and maternal tissues. MIEs include, but may not be not limited to, PPAR α and γ and ER agonism. The *in vitro* PPAR agonism EC_{50}s did not correlate well with the reduced neonatal viability following *in utero* exposure and PFAS-induced hepatomegaly and induction of the liver PPAR pathways also were poorly correlated with neonatal mortality. In summary, tissue- and life-stage-specific AOP networks that account for multiple MIEs likely will be needed to accurately describe the developmental effects of *in utero* PFAS exposure. *This abstract does not reflect Agency policy.*

3155 Impact of Environmentally Relevant Concentrations of PFAS on Global Methylation Patterns in a Placental *In Vitro* Model

J. T. Bangma, C. Meakin, J. Szilagyi, C. Plazas, S. Kepper, and R. C. Fry. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Per- and polyfluorinated compounds (PFAS) are a class of fluorinated compounds human populations are routinely exposed to. Common routes of exposure include drinking water, non-stick pans, carpets and other surfaces treated with PFAS to repel water. The ATSDR has acknowledged that exposure to PFAS, including perfluorooctanesulfonic acid (PFOS) and perfluoro-n-octanoic acid (PFOA), is linked to adverse developmental outcomes such as preeclampsia and low infant birth weight. Recently, a newly developed PFAS, ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)-propanoate, also known by the trade name GenX, has been found in abnormally high concentrations in drinking water sourced downstream of an industrial production facility in the Cape Fear river basin in North Carolina. In light of ongoing exposure and the established link between PFAS and adverse developmental outcomes, it is essential to determine the developmental impact of newly developed PFAS such as GenX. Since epigenetic changes play a crucial role in regulating cellular processes during development, it is important to understand how PFAS impact epigenetic regulatory mechanisms. To answer this question, we analyzed whether exposure to varying concentrations of PFAS affect genome-wide 5mC methylation patterns in JEG3, an *in vitro* trophoblast model. Cells were treated using 100 ng/ml and 1000 ng/ml of PFOS, PFOA and GenX in serum and serum free media for 24 hours; genomic DNA was harvested; and an Enzyme-Linked Immunosorbent Assay (ELISA) was used to analyze global LINE-1 DNA methylation. While no significant differences from the control were observed at $p<0.05$, dose-dependent trends were observed. Specifically, increasing PFOS levels led to decreasing global methylation. Additionally, PFOA exhibited the opposite trend, with increasing PFOA levels leading to increasing global methylation. Further research is needed to elucidate the specific impact of PFOS, PFOA and GenX on global methylation patterns and on methylation patterns of specific genes and regulatory elements.

3156 Development of a Gas Chromatography-Mass Spectrometry Method for Simultaneous Determination of Various Per- and Polyfluoroalkyl Substances (PFAS) in Biological Media

M. A. Silinski[1], J. Licause[1], D. M. Crizer[2], M. J. Devito[2], J. C. Blake[1], R. A. Fernando[1], and S. Waidyanatha[2]. *[1]RTI International, Research Triangle Park, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

Per- and polyfluoroalkyl substances (PFAS) are a large yet diverse class of compounds that are widely used for their stain-resistant, waterproofing, and friction-reducing properties. In general, PFAS compounds are persistent in the environment and bioaccumulate in wildlife and humans. Exposure occurs primarily through ingestion of drinking water but can also occur through inhalation and skin absorption. Despite widespread exposure, the toxicity data for PFAS are limited, particularly for some of the shorter and branched chain compounds that are increasing in production and use. The objective of this work was to develop a method to simultaneously quantitate various PFAS in support of studies investigating the clearance of PFAS in hepatocytes. Sixteen PFAS were selected, including fluorotelomer alcohols, polyfluorinated alcohols, a fluorotelomer-based methacrylate, a polyfluoroalkyl ether, a polyfluoroalkyl ether alcohol, a perfluoroalkyltrifluoromethane-sulfonate, and an *N*-alkylperfluoroalkane sulfonamidoethanol. The analytes were 4:2 fluorotelomer alcohol, 6:2 fluorotelomer alcohol, 8:2 fluorotelomer alcohol, 4:4 fluorotelomer alcohol, 11:1 fluorotelomer alcohol, heptafluorobutanol, 1H,1H,5H-perfluoropentanol, 3-(perfluoropropyl)propanol, dodecafluoroheptanol, 1-pentafluoroethylethanol, hexafluoroamylene glycol, 6:2 fluorotelomer methacrylate, tris[(trifluoroethoxy)methane], 1H,1H,8H,8H-perfluoro-3,6-dioxaoctane-1,8-diol, 2,2-difluoroethyl triflate, and *N*-ethyl-N-(2-hydroxyethyl)perfluorooctane sulfonamide. Media standards (0.1 to 10 µM) were prepared by adding 10 µL solution containing the analyte mixture to 100 µL of hepatocyte incubation media containing Williams E media with 15 mM HEPES and extracting with 90 µL of ethyl acetate. Following centrifugation, the organic layer was analyzed by gas chromatography-mass spectrometry, using single ion monitoring. A DB-WAX column was used with oven temperature ramped from 40°C to 230°C in 19 min. Different columns and instrument conditions were evaluated to optimize chromatography and ionization, and the extraction process was optimized using different solvents, ratios, and degree of centrifugation. Multi-point calibration curves were assessed in solvent and media to evaluate sensitivity, linearity, recovery, and matrix effects. Media standard curves were linear ($r \geq 0.99$) over the range 0.1 to 10 µM for all analytes. Mean recoveries were 93-115%, and matrix effects were minimal. These data demonstrate that the method is suitable for the analysis of 16 PFAS in hepatocyte suspension, in support of *in vitro* screening studies.

3157 Perfluoroalkyl Carboxylic Acids Are Substrates of the Bile Acid Transporter NTCP

H. Miller[1], M. Ruggiero[1], J. D. Zitzow[2], J. Y. Akakpo[1], P. J. Sandoval[1], S. Chang[2], and B. Hagenbuch[1]. *[1]University of Kansas Medical Center, Kansas City, KS; and [2]3M, Saint Paul, MN.*

Sodium/taurocholate cotransporting polypeptide (NTCP) is a sodium-dependent bile acid transporter located at the basolateral membrane of hepatocytes, important for the enterohepatic circulation of bile acids. We previously had demonstrated that NTCP can transport several perfluoroalkyl sulfonates. In addition, our previous results demonstrated that organic anion transporting polypeptides (OATPs) 1B1, 1B3 and 2B1 can transport perfluoroalkyl carboxylates with 8 and 9 carbon atoms. In the current study we determined to what extent the perfluoroalkyl carboxylates perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), or perfluorodecanoic acid (PFDA) are substrates of NTCP. Human embryonic kidney cells (HEK293) stably expressing NTCP were plated on poly-D-lysine-coated 24 well plates, and uptake of sodium-dependent ^{3}H-taurocholate was measured as a positive control. Time- and concentration-dependent uptake of PFOA, PFNA, and PFDA was quantitated by LC-MS/MS. Protein concentrations were determined by BCA assay. PFOA, PFNA, and PFDA inhibit NTCP. In addition, all compounds are transported by NTCP. Uptake is time- and concentration dependent. Kinetic experiments suggest that PFOA, PFNA and PFDA are transported with relatively low affinities. Similar to perfluoroalkyl sulfonates, PFOA, PFNA, and PFDA can inhibit NTCP-mediated taurocholate uptake and all three compounds are also substrates of NTCP. In addition to our previous data that demonstrated liver-expressed OATP1B1, 1B3 and 2B1 can transport PFOA and PFNA, our current study provided additional evidence that NTCP is also important for the enterohepatic circulation of PFOA, PFNA, and PFDA.

3158 Transcriptomic Responses in Livers of GenX-Treated Mice Demonstrate Upregulation of PPAR Signaling and Related Pathways

G. A. Chappell[1], L. C. Haws[2], and C. M. Thompson[3]. *[1]ToxStrategies Inc., Asheville, NC; [2]ToxStrategies Inc., Austin, TX; and [3]ToxStrategies Inc., Katy, TX.*

GenX was developed as an alternative to long-chain per- and poly-fluoroalkyl substances (PFAS). It has been postulated that the underlying mechanism of GenX-induced liver lesions in mice involves PPARα activation. To investigate alterations in PPARα signaling at the mRNA level, as well as other potential molecular signals related to GenX-induced liver effects, transcriptomic analysis was conducted in liver sections from male and female mice previously exposed to up to 5 mg/kg bw GenX by oral gavage for 90 days (2010). The RNA sequencing platform TempO-Seq, which is amenable to FFPE tissue sections, was used to identify differentially expressed genes for each treatment group. Pathway enrichment analysis was conducted using gene sets that represent biological states and known canonical pathways. There was no significant gene set enrichment at 0.1 mg/kg, while significant enrichment of PPAR signaling was prominent in both sexes at 0.5 and 5 mg/kg. PPAR signaling and fatty acid metabolism were among the most significantly enriched genesets, and two genesets specific to the PPARα subtype were significantly enriched. Benchmark dose modeling was conducted, and PPAR signaling pathways were again found to be significantly enriched among dose-responsive genes, as were mitotic cell cycle gene sets. Additionally, down-regulation of coagulation cascade proteins was observed in both sexes at 0.5 and 5 mg/kg, which has been reported to occur during hyperplasia-mediated liver proliferation in mice. The original histopathological analysis of these liver sections (2010) reported increased 'hepatocyte single cell necrosis' in the liver at 5 mg/kg; however, updated diagnostic criteria recommend that 'single cell necrosis' be diagnosed as either necrotic or apoptotic cell death. A reevaluation of liver tissue from the same FFPE tissues demonstrated that liver lesions previously diagnosed as 'single cell necrosis' were in fact apoptosis, a finding that was corroborated by immunostaining for activated caspase-3. GenX also increased mitosis in the liver at the same doses as apoptosis, which is consistent with rodent-specific cell cycle changes induced by PPARα activators. These results indicate that the liver changes observed in GenX-treated mice occur via a mode of action (MOA) involving PPARα, a finding important for risk assessment as this MOA has been determined to not be relevant to humans.

3159 Development of a Maximum Allowable Dose Level for Perfluorooctanoic Acid and Comparison of Exposures from Consumer Products, Drinking Water, and Natural Food Sources

K. M. Scaife, S. Pham, S. West, J. M. Cybulskie, and L. A. Haighton. *Intertek Group plc, Mississauga, ON, Canada.*

Perfluorooctanoic acid (PFOA), a polyfluoroalkyl substance, which is used in the production of fluoropolymers, is an environmentally persistent industrial contaminant. The US EPA concluded that PFOA may be developmentally toxic to humans based on toxicology studies, and, thus, PFOA was added to the California Proposition 65 (Prop 65) list by the authoritative bodies mechanism. As there is no safe harbor level (SHL or Maximum Allowable Dose Level, MADL) for PFOA, the current work was undertaken to: derive a MADL; determine if PFOA exposure from consumer products, drinking water, or natural food sources would be likely to exceed the MADL; and, determine which sources of exposure would be of greatest concern. Prop 65 requires businesses to provide a clear and reasonable warning if they sell products or discharge effluent into drinking water sources that would result in exposures above a SHL. From the most sensitive PFOA developmental study, a Lowest-Observed-Effect Level (LOEL) of 0.3 mg/kg/d was identified based on findings of increased femoral periosteal area and decreased mineral density in tibias. A MADL of 1.7 mcg/d was calculated from the LOEL [(0.3 mg/kg/d/10)/1000 x 58 kg x 1000 mcg/mg]. Data from the Unregulated Contaminant Monitoring Rule were used to determine average (0.028 mcg/L) and maximum (0.053 mcg/L) concentrations of PFOA in CA drinking water which corresponded to exposures of 0.056 and 0.106 mcg/day (assuming 2 L/d), respectively. Fruits, vegetables, and flour substantially contributed to PFOA intake from the diet and median and high-level intakes from these sources were determined to be 0.2 and 0.5 ng/kg bw/d, respectively, or 0.0116 and 0.029 mcg/day. A worst-case exposure scenario to PFOA from consumer products was determined for standard 10″ pans coated with polytetrafluorethylene (PTFE) resulting in both oral exposure from eating the cooked food and dermal contact from handling and cleaning the pan. The sum of oral and dermal exposure to PFOA from use of the PTFE-coated pan was determined to be 0.042 mcg/day. Based on this work, exposures to PFOA from cooking pans (a worst-case scenario), drinking water, or natural food sources would not be expected to exceed the calculated MADL for PFOA. Exposure to PFOA from drinking water sources resulted in the highest level of exposure which may be a target for future efforts to reduce PFOA exposures to average Californians.

3160 Evaluation of Perfluorooctanoic Acid (PFOA) Replacement Chemicals on Pancreatic Toxicity

L. M. Kamendulis, J. M. Hocevar, and B. A. Hocevar. *Indiana University, Bloomington, IN.*

Per- and polyfluoroalkyl substances (PFAS) are used in a variety of industrial applications including production of surface repellant coatings, fire-fighting foams, and fluoropolymer synthesis. Due to their environmental persistence, bioaccumulation, and toxicity of the legacy PFAS, such as perfluorooctanoic acid (PFOA), other perfluoroether carboxylic acids (PFECAs) have been introduced to replace PFOA as a processing aid in fluoropolymer production. Previously, we demonstrated that PFOA triggered ductal hyperplasia, oxidative stress and inflammation in the mouse pancreas after a 7 day exposure. In addition, we have shown that PFOA induces endoplasmic reticulum (ER) stress, triggering the unfolded protein response (UPR) in the mouse pancreatic acinar cell line 266-6 and *in vivo* in the mouse pancreas. While the toxicity profiles of the legacy PFAS have been studied, little is known of the toxicities caused by exposure to the alternative products, for which environmental and biological contamination has been documented globally. In comparison to PFOA, we evaluated the effects of two PFECA compounds on pancreatic toxicity *in vitro* and *in vivo*: ammonium perfluoro(2-methyl-3-oxahexanoate) (GenX) and perfluoro(2,5-dimethyl-3,6-dioxanonanoic acid) (HFPO-TA). In the 266-6 cell line, GenX exhibited less effects on cell viability as compared to PFOA, while HFPO-TA caused a greater cytotoxicity. This same rank order was observed when stimulation of the UPR was monitored by ATF4 and CHOP mRNA induction. *In vivo*, mice were exposed to 5 and 10 ppm GenX, 0.5 and 1.5 ppm HFPO-TA, and 5 ppm PFOA in drinking water for 7 days. To measure the effects on the pancreas, serum lipase and amylase were measured. While no changes were observed in lipase levels, exposure to 10 ppm GenX increased amylase, while 1.5 ppm HFPO-TA exposure decreased amylase levels. Examination of mRNA levels demonstrated that all three PFAS altered markers of ER and oxidative stress in the pancreas, with HFPO-TA exhibiting the strongest effect. As pancreatic damage, ER and oxidative stress have been linked to chronic diseases such as diabetes and pancreatic cancer, our findings suggest that further toxicological evaluation of the replacement PFAS with respect to pancreatic toxicity are warranted.

3161 The Interaction with and Transport of Three Perfluoroalkyl Sulfonates by Renal Organic Anion Transporters

P. J. Sandoval[1], J. D. Zitzow[2], S. Chang[2], and B. Hagenbuch[1]. *[1]Kansas University Medical Center, Kansas City, KS; and [2]3M, Saint Paul, MN.*

Perfluoroalkyl and polyfluoroalkyl substances (PFAS) are persistent environmental chemicals and some have long serum elimination half-lives in humans. There is evidence suggesting that some PFAS such as perfluorooctane sulfonate (PFOS) and perfluorohexane sulfonate (PFHxS) are actively reabsorbed by the tubules of the kidney which could be a contributing factor to their long half-lives. The aim of this study is to determine the role of several renal organic anion transporters (OAT1, OAT3, OAT4, URAT1, and OATP1A2) in the reabsorption of selected PFAS by the kidney. We undertook this study to measure the inhibitory effects of perfluorobutane sulfonate (PFBS), PFHxS, and PFOS against the activity of these transporters, which were transiently expressed in HEK293 cells, using radiolabeled probe substrates. We also quantitatively measured the time-dependent uptake of PFBS, PFHxS, and PFOS using LC-MS/MS. Our preliminary data suggested that, for the most part, PFBS and PFHxS inhibited the transport activity of these selected transporters to a greater extent than PFOS, with the greatest inhibition observed in the transport activity of OAT3 and OAT4. In addition, we also observed that: 1) OAT1 and OAT4 transported PFBS, PFHxS and PFOS; 2) OAT3 and URAT1 transported PFBS and PFHxS; and 3) OATP1A2 transported PFOS exclusively. These results demonstrate that the renal organic anion transporters interact with and transport perfluoroalkyl sulfonates and is consistent with these transporters having a role in the reabsorption of these compounds by the kidney.

3162 iPSC-Derived Hepatocytes and Transcriptomics Reveal Mechanisms of PFOA- and PFOS-Induced Developmental Hepatotoxicity

D. R. Robarts, S. Griffith, S. Gunewardena, I. Huck, J. Draper, J. L. Vivian, and U. Apte. *University of Kansas Medical Center, Kansas City, KS.*

Perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) are persistent organic pollutants with myriad of toxic effects including developmental toxicity and hepatotoxicity. Our studies have shown that PFOA and PFOS degrade HNF4α, the main hepatic differentiation factor, resulting in significant hepatotoxicity. Given that HNF4α is critical for liver development and the fact that PFOA and PFOS can cross placenta, we hypothesized that PFOA and PFOS affect embryonic liver development. We investigated the effects of PFOA and PFOS on embryonic liver development using human iPSC-derived hepatocyte model, which mimics all stages of human liver development. iPSC cells were exposed to PFOA and PFOA at 10 μM concentration starting from either definitive endoderm stage, hepatic endoderm stage or hepatotoblast stage till mature hepatocyte stage. Transcriptomic changes were determined using RNA sequencing (RNAseq) and IPA analysis. PFOA induced significantly more gene expression changes than PFOS and affected all three stages of liver development. PFOA inhibited genes involved in thyroid hormone synthesis, cAMP, glutamate receptor, and integrin signaling; and activated gene involved in lipid, sterols, cholesterol transport, NRF2 pathway, and ROS-mediated signaling over the differentiation period. Target genes of HNF4α and several related transcription factors including HNF1α and CEBP/β were suppressed whereas targets of NR5A1, FOXA3, SIRT1, and CBX5 were induced by PFOA treatment during hepatic differentiation. The major effect of PFOS was to inhibit several pathways during hepatoblast to hepatocyte maturation period. PFOS inhibited genes in cAMP, eNOS, Gas, FGF, calcium, glutamate, and Apelin signaling pathways; and induced genes in melatonin and nicotine degradation pathways and citrulline biosynthesis. Interestingly, PFOS inhibited genes in cancer and cell movement, and induced genes in glucuronidation of sterols. PFOS inhibited target genes of VEGF, GLI, FGF2, CREB, NF-κB, SP1, and several other transcription factors involved in hepatocyte maturation while inducing expression of PXR and NUPR1 targets. Taken together, these data indicate PFOA and PFOS have significant and specific effects on embryonic liver development, which should be considered in risk assessment.

3163 Low-Dose PFOS Exposure Alters the Placental Transcriptome in C57BL/6 Mice

J. Agudelo[1], M. Pfohl[1], E. Marques[1], L. Aleksunes[2], and A. Slitt[1]. [1]*University of Rhode Island, Kingston, RI; and* [2]*Rutgers, The State University of New Jersey, Piscataway, NJ.*

The placenta plays a vital role in fetal development and health. As the primary conduit for fetal development, the placenta mediates nutrient transfer, waste elimination, gas exchange, hormone production, and development of the fetal immune system. Per- and polyfluoroalkyl substances (PFAS) are a class of man-made, ubiquitous environmental toxicants known to cause adverse health effects. Perfluorooctanesulfonic acid (PFOS), the most prevalent PFAS member, consists of a synthetic perfluorinated eight-carbon backbone with a sulfonic acid head group. Evidence suggests that PFOS can induce developmental toxicity in humans and rodents following placental transfer and has been associated with low birth weight in humans. Furthermore, PFOS is detected in both human and rodent umbilical cord blood and in breast milk. The overarching hypothesis of the work is that PFOS exposure impacts placental health and function through modulation of the placental transcriptome. The aim of this study was to elucidate the effects of developmental PFOS exposure at 3 ppm (~0.3 mg/kg/day) or 30 ppm (~3 mg/kg/day) per day in feed on the placental response *in vivo* using 10-week old C57BL/6 timed-pregnant dams. On gestational day 1 (GD1), dams were assigned to one of the following blinded experimental diets and fed *ad libitum*: 1) Standard chow diet, 2) 3 ppm PFOS (w/w) or 3) 30 ppm PFOS (w/w). Dams were euthanized at GD17 and placentae collected. Fetal weight collection confirmed statistical significance in low birth weight association to PFOS exposure with a more robust weight reduction in the 3 ppm PFOS-treated. RNA integrity was confirmed, libraries were prepared, and next-generation sequencing (RNA-Seq) was performed to investigate the impact of PFOS exposure on the placental transcriptome. Our studies indicate upregulation of Phospholipase C signaling, Actin Cytoskeleton Signaling, Rho Family GTPase, EIF2 Signaling, Oxidative Phosphorylation signaling pathways, with 3 ppm PFOS inducing a more robust transcriptional response. In addition, at 3 ppm PFOS elicited a fold change of ~2.0 in the Gzmf, Emilin1, Gzmg, Slit1, and Lrp1 genes. Interestingly, gene Hsd3b1 resulted in a fold change of ~2.0 within the PFOS-treated. Hsd3b1 is responsible for the conversion of pregnenolone to progesterone in the placenta. In summary, our data suggest that PFOS, at relatively low concentrations in diet, can induce a significant placental response.

3164 Exposure of Perfluorooctanesulfonic Acid (PFOS) as a Potential Risk Factor for Late-Onset Alzheimer's Disease (LOAD)

V. Basaly[1], B. Alansi[1], J. Hill[1], A. Slitt[1], and N. Zawia[1,2]. [1]*University of Rhode Island, Kingston, RI; and* [2]*George and Anne Ryan Institute for Neuroscience, Kingston, RI.*

Poly- and perfluoroalkyl substances (PFAS) are a class of emerging persistent organic pollutants (POPs) linked to neurotoxicity and are considered major risks to the ecosystem and human health. Of particular concern is the legacy PFAS perfluorooctanesulfonic acid (PFOS), which has been widely used in industrial, commercial and household applications due to its unique physicochemical and amphipathic properties. PFOS is very stable in the environment as it is resistant to biodegradation, direct photolysis, hydrolysis and photo-oxidation. Furthermore, PFOS cannot be metabolized and is not well excreted, leading to an elimination half-life in humans at about 5.4 years. Even though levels of PFOS exposure have decreased over the last decade, its toxicity is attracting a lot of attention, particularly because of the ability of PFOS to cross the brain blood barrier, placenta and into breast milk. Studies suggest that early life exposure to environmental toxicants influences the pathogenesis of neurodegenerative diseases later in life. Alzheimer's disease (AD) is a progressive neurodegenerative disorder that accounts for 60-70% of dementia cases worldwide according to the World Health Organization. Two physiological features of AD are extracellular senile plaques consisting of β-amyloid (Aβ) peptide that is cleaved from a larger protein called the amyloid precursor protein (APP), and intracellular neurofibrillary tangles (NFTs) containing hyperphosphorylated tau protein. This hyperphosphorylation of tau protein is regulated by activated kinases such as glycogen synthase kinase-3 beta (GSK3β). Thus, the aim of this study is to investigate the association between PFOS exposure and AD-related biomarkers. Differentiated SH-SY5Y neuroblastoma cells were exposed to PFOS concentrations of 0-100 μM for 24, 48, and 72 h. After 48 h, PFOS treatment at 50 μM resulted in an increase of GSK3β protein expression and phosphorylated tau (P-tau) at ser 404 by 1.29- and 1.69-fold vs control respectively. Data presented herein suggests that PFOS exposure may perturb AD-related biomarkers such as tau, P-tau, and GSK3β, indicating that PFOS is a potential risk factor for Alzheimer's disease. *In vivo* studies are underway to validate these findings.

3165 Perfluorooctanoic Acid Alters the Function and Global Proteome of Differentiating Primary Human Villous Trophoblasts

H. Chen, P. Liu, K. E. Williams, M. Kapidzic, E. Kwan, A. San, S. J. Fisher, and J. F. Robinson. *University of California San Francisco, San Francisco, CA.*

Perfluorooctanoic acid (PFOA) is a widely used industrial surfactant and a major contaminant of developmental concern due to its environmental persistence. In humans and rodents, maternal PFOA exposure has been linked to adverse pregnancy outcomes, however the specific cellular and molecular mechanisms are unclear. The human placenta is the interface between the maternal and fetal compartments, and is a potential target of various environmental stressors including PFOA. Placental cytotrophoblasts (CTBs) play critical roles in implantation, uterine infiltration, and vasculature development, and perturbations in CTB function underlie common pregnancy complications (*e.g.,* preeclampsia, preterm birth). *In vitro*, primary human villous CTBs differentiate towards an invasive phenotype, correlating with their *in vivo* characteristics. We previously demonstrated the utility of this model system (on functional and transcriptomic levels) to evaluate the toxicity of persistent pollutants such as brominated flame retardants. To test the hypothesis that CTBs are sensitive to PFOA exposure, we assessed primary human CTB differentiation using functional and proteomic approaches. Second trimester CTBs were treated with vehicle (0.1% DMSO) or PFOA (25 μM, 100 μM) for 39 hr and invasion was assessed using the Transwell assay. PFOA significantly increased the invasive ability of CTBs at concentrations independent of cytotoxicity. To identify the molecules driving these observed changes, protein homogenates of CTBs treated with vehicle or PFOA (100 μM) were collected during differentiation (24 hr). The global proteome was profiled using sequential window acquisition of all theoretical mass spectra (SWATH-MS). Signaling molecules associated with invasive and inflammatory processes were differentially expressed after PFOA exposure, including ITGA6/B4 (integrin alpha 6/beta4), COX2 (cyclooxygenase-II), MIF (macrophage migration inhibitory factor), and GPX7 (glutathione peroxidase 7). Our results suggest that PFOA alters key proteins involved in CTB differentiation and functionality *in vitro*, via induction of cellular invasion.

3166 Toxicokinetic Processes Differ between Perfluorinated Alkyl Acid Carboxylates and Sulfonates in Zebrafish Embryo

C. Vogs[1,2], G. Johanson[1], A. Nilsson[3,4], M. Shariatgorji[3,4], P. E. Andrén[3,4], and E. Wincent[1]. [1]*Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden;* [2]*Sveriges lantbruksuniversitet, Uppsala, Sweden;* [3]*Uppsala Universitet, Uppsala, Sweden; and* [4]*Science for Life Laboratory, Uppsala Universitet, Uppsala, Sweden.*

Perfluorinated alkyl acid carboxylates and sulfonates (PFAA) are a group of extremely persistent organofluorine chemicals. PFAAs have been found to accumulate in wildlife and human globally. To date, understanding is still limited how the various PFAA structures (e.g. alkyl chain length, functional group) impact the toxicokinetics (TK) and, consequently, the toxicity. We studied the TK processes of perfluorooctanesulfonate (PFOS), perfluorooctanoic acid (PFOA), perfluorohexanesulfonic acid (PFHxS) and perfluorobutanesulfonic acid (PFBA) using the zebrafish (*Danio rerio*) embryo (ZFE) model. To this end, we exposed ZFE from two hours post fertilization (hpf) until 120 hpf to each of the four PFAAs at two or three different concentrations. We measured exposure concentrations in the medium and internal concentrations in the whole ZFE at nine time points using UPLC-MS/MS. Additionally, we sampled 120 hpf old ZFE exposed to PFOS, PFOA and PFHxS to visualize distributions in ZFE. ZFE were embedded in a mixture of 5% carboxymethyl cellulose (w/w) and 10% gelatin (w/w). Embedded tissues were frozen, cut in 18 μm thick slides and mounted on glass slides. The lateral distribution of PFAA was determined using MALDI-MS imaging. Determined bioconcentration factors differed four orders of magnitude with PFOS (4000 L/kg) > PFHxS (200 L/kg) > PFOA (50 L/kg) > PFBA (0.8 L/kg). The apparent toxic potency varied about three orders of magnitude between these four PFAAs when based on effective external concentrations. However, after correction for bioconcentration, the effective internal concentrations became similar, reducing the differences in toxic potency to only three-fold difference. Moreover, PFOS and PFHxS tended to accumulate in the ZFE brain, while PFOA tended to accumulate in the vascular system. These differences in distribution may explain reported organ-specific toxicity of PFAAs. In summary, our data indicate that both alkyl chain length and the functional group of PFAAs influence the TK processes, which in turn directs toxic potency and target organ toxicity.

3167 Interspecies Extrapolation of Toxicity Data for Perfluorohexanoic Acid (PFHxA)

A. Luz, and P. DeLeo. *Integral Consulting Inc., Annapolis, MD.*

It is the practice of the US EPA to use a margin of exposure (MOE) approach in its human health risk characterization of new chemicals under the Toxic Substances Control Act. EPA compares the MOE of the new chemical to a benchmark (acceptable) MOE derived by applying a combined uncertainty factors (UF) based on (1) interspecies extrapolation (UFA); (2) intraspecies extrapolation (UFH); and (3) LOAEL-to-NOAEL extrapolation (UFL). Default UFs of 10 are commonly applied such that the benchmark MOE for a new chemical is typically 100 or 1,000. The interspecies UF can be subdivided into pharmacokinetic (PK) and pharmacodynamic (PD) components, and each component is customarily assigned a value of 3. However, if chemical- and species-specific data are available, the PK component of the interspecies UF can be replaced with a data-derived extrapolation factor (DDEF). In 2015, the EPA Risk Assessment Division developed a DDEF for interspecies extrapolation of toxicity data for perfluorohexanoic acid (PFHxA) of 768 and a subsequent benchmark MOE of 23,000. The derived DDEF was based upon the ratio of volumes of distribution between humans and rats (estimated to be 1), and the ratio of serum elimination half-lives for humans ($t_{1/2}$ = 768 hours) and male rats ($t_{1/2}$ = 1.0 hours). However, toxicokinetic data for PFHxA demonstrate that serum elimination half-lives for PFHxA are proportional to body weight across mice, rats, monkeys, and humans. This finding supports the use of allometric body weight scaling to the ¾ power for the PK component of the interspecies UF, consistent with recent assessments of PFHxA by other authoritative bodies. Use of allometric body weight scaling supports a much lower benchmark MOE, closer to 100, for PFHxA. These results highlight how different interspecies extrapolation methods can lead to disparate benchmark MOEs, which could ultimately lead to different decisions regarding the need for risk management.

3168 PFOA, PFOS, and PFNA Affect Cholesterol Metabolism in Human HepaRG Liver Cells

J. Louisse[1], D. Rijkers[1], G. Stoopen[1], A. W. Janssen[1], S. Kersten[2], R. L. Hoogenboom[1], and A. A. Peijnenburg[1]. *[1]Wageningen Food Safety Research, Wageningen University and Research, Wageningen, Netherlands; and [2]Nutrition, Metabolism and Genomics Group, Division of Human Nutrition and Health, Wageningen University and Research, Wageningen, Netherlands.*

Per- and polyfluoroalkyl substances (PFASs) are omnipresent, very persistent in the environment and present in the food chain. Epidemiological studies have shown an association between serum levels of perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) and increased total and LDL serum cholesterol levels. These human data have been used by the EFSA to derive a tolerable weekly intake for these chemicals. However, causality has been questioned, amongst others given that animal studies, as well as a human phase 1 dose-escalation trial (both at high doses), show a PFAS-induced decrease of serum cholesterol levels. Also, although PFASs have been shown to act as PPAR agonists, the role of PPAR activation in PFAS-induced changes in cholesterol metabolism is not known. Studies with human cell models can provide more insight in the mode of action underlying PFAS-induced effects on cholesterol metabolism, enabling better interpretation of the human epidemiological data. The present study assessed the effects of PFOA, PFOS and perfluorononanoic acid (PFNA) on whole genome gene expression in human HepaRG liver cells using DNA microarray analysis. Gene set enrichment analysis (GSEA) of the microarray data pointed to several cellular processes affected upon PFAS treatment. Gene sets related to cholesterol biosynthesis were downregulated for PFOA, PFOS and PFNA. Gene sets related to PPAR signalling were only enriched upon PFOA treatment, but the expression of a number of PPAR responsive genes was also significantly induced by PFOS and PFNA. Concentration-response analyses for selected genes related to cholesterol biosynthesis and PPAR signalling indicated that PFNA appeared to be the most potent inhibitor of cholesterol biosynthesis, whereas PFOA appeared to be the most potent PPAR activator, suggesting that PFOA-, PFOS- and PFNA-induced decrease of cholesterol biosynthesis is not directly related to PPAR activation. Besides effects on cholesterol biosynthesis and PPAR signalling, the present study also points to other gene sets in common for PFOA, PFOS and PFNA, which are related to PERK/ATF4 signalling (upregulated), tRNA aminoacylation (upregulated), amino acid transport across the plasma membrane (upregulated), and glycolysis/gluconeogenesis (downregulated). These data indicate possible other cellular processes that may also play a role in PFAS-induced adverse effects.

3169 *In Vitro* Hepatic Clearance of Per- and Polyfluoroalkyl Substances (PFAS)

J. R. Rice[1], D. M. Crizer[1], Z. Zhou[1,2], K. S. Lavrich[1], S. Ramaiahgari[1], M. Rosentsvit[1], S. Waidyanatha[1], B. A. Wetmore[3], S. S. Ferguson[1], and M. J. DeVito[1]. *[1]NIEHS/NTP, Research Triangle Park, NC; [2]Southern Medical University School of Public Health, Guangzhou, China; and [3]US EPA/ORD, Research Triangle Park, NC.*

Per- and polyfluoroalkyl substances (PFAS) are man-made chemicals that have been used in a variety of industries throughout the world. The two most studied PFAS compounds are perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) which have both been shown to be persistent in both the environment and in humans as neither is broken down in the environment or metabolized in humans. To better understand the significance to public health a two sets of 75 PFAS compounds was selected to cover different classes of PFAS. The goal of this work was to determine whether or not these compounds are hepatically cleared via metabolism using primary human hepatocytes (PHHs). Allowing for the potential assessment of the persistence of these chemicals in humans. In total, 27 of the 75 PFAS in set 1 were amenable to liquid chromatography mass spectrometry (LCMS) using ESI. These 27 PFAS compounds were subjected to an initial screen for hepatic clearance where 10-donor pooled primary human hepatocytes (PHHs) were incubated with 10 µM of PFAS for 0 and 4 hours at 37 C. Heat inactivated PHHs were also incubated with 10 µM of PFAS for 0 and 4 hours at 37 C as a control. Comparison of peak area ratios (4 hours/0 hours) for the active and heat inactivated PHHs was completed and a t-test was used to determine whether or not there was a significant difference between active and inactive PHHs. In total, 23 of the 27 PFAS compounds studied were shown to have statistically significant hepatic clearance. To further investigate *in vitro* hepatic clearance, those PFAS compounds found to be cleared in the initial screen are being evaluated in more detail via incubations with 50-donor pooled primary human hepatocytes at 0, 15, 30, 60, 90, 120, and 240 minutes. For these 23 PFAS compounds, half-lives ranged from 19 to > 2,400 minutes with corresponding intrinsic hepatic clearance values of 0.04 - 4.9 mL/min/kg. Finally, metabolites for each parent PFAS compounds were predicted using ADMET Predictor/MedChem Studio. This information will be used to assist in the metabolite profiling of the hepatically cleared PFAS compounds to identify, at this time, unknown PFAS metabolites. Additional studies are ongoing to analyze an additional 31 PFAS compounds via LCMS, with the remaining PFAS compounds being analyzed using GCMS.

3170 Risk Assessment of Oral Intake of PFAS from US FDA's Total Diet Study

A. Schmidt[1], M. McAfee[1], J. Kind[2], and A. Perez[1]. *[1]CTEH, Portland, OR; and [2]CTEH, Little Rock, AR.*

Per- and polyfluoroalkyl substances (PFAS) are a large group of synthetic compounds that are ubiquitous in the environment due to their widespread use and resistance to degradation. PFAS are detected in drinking water and food products in the United States. In 2019, FDA sampled 91 food products for 16 PFAS compounds, of which 14 samples had measurable concentrations of 5 PFAS. Perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) were detected in 10 samples. Several food products, such as produce and baked goods, had quantifiable concentrations of less commonly studied PFAS, including perfluorohexane sulfonate (PFHxS), perfluoropentanoic acid (PFPeA), and pentafluorobenzoic acid (PFBA). The current assessment aims to calculate human health risk using a Hazard Index (HI) approach resulting from ingestion of PFAS-containing food. Food intake estimates were adapted from both EPA and USDA databases. PFAS intake was compared against EPA reference doses (RfDs) for PFOS and PFOA and against RfD estimates for PFHxS, PFBA, and PFPeA. All PFAS were assumed to be 100% bioavailable from oral ingestion. Meat products (red meat and poultry) had the highest concentrations of PFOS. The estimated daily intake of PFOS was approximately 1.1E-6 mg/kg/day, which is below the RfD of 2E-5 mg/kg/day. The hazard index was estimated as 5.7E-2, or below 1 for PFOS intake from meat. The daily PFOS ingestion from seafood was estimated as 1.3E-7 mg/kg/day. For cumulative meat and seafood, daily PFAS ingestion was 1.3E-6 mg/kg/day. These results indicate that daily PFOS intake from meat and seafood consumption is not associated with an increased risk of adverse health effects. Cumulative consumption of PFOS from other contaminated foods may lead to an exceedance of the RfD and is discussed relative to the FDA diet study data. Further sampling of food products for PFAS will strengthen exposure assessments. Additional studies on atypical dietary intake of meat (e.g., Paleo diet) may help further characterize PFAS oral exposure risk.

3171 Using ToxCast and Reactome to Evaluate Toxicity of PFAS

A. Massarsky[1], J. A. Parker[1], M. T. Hoang[1], E. S. Fung[1], and K. M. Unice[2]. *[1]Cardno ChemRisk, Aliso Viejo, CA; and [2]Cardno ChemRisk, Pittsburgh, PA.*

Per- and polyfluoroalkyl substances (PFAS) are ubiquitous in the environment due to their wide use in consumer products, as well as their slow degradation. The environmental fate and human health effects of two commercially successful PFAS, perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS), have been extensively studied. There is strong evidence that hepatotoxicity, immunotoxicity, and developmental toxicity observed in PFOA/PFOS-exposed rodents involve the activation of peroxisome proliferator-activated receptor-α (PPARα); however, studies in PPARα-null mice suggest that PPARα-independent mechanisms also contribute to hepatotoxicity and immunotoxicity. During the prior decade, manufacturing uses of PFOA and PFOS were phased out as part of global stewardship programs; however, thousands of newer PFAS that are less well-characterized are currently used in consumer products. Consequently, there is the need to better understand the toxicity of newer PFAS to ensure their safety. To this end, this study explored an *in silico* approach to assess toxicity of PFAS. In order to validate this approach, the study focused on PFOA and PFOS, whose toxicity has been well characterized. Specifically, ToxCast was used to gather data available for human liver HepG2 cells, in order to identify genes that are upregulated or downregulated upon exposure to PFOA or PFOS. The identified genes were then analyzed using Reactome, in order to understand which biological pathways are impacted. Subsequently, the results were discussed in the context of the known biological effects of PFOA and PFOS. This study demonstrated that several biological pathways identified through ToxCast-Reactome were found to be impacted in the literature on PFOA and PFOS. Thus, this *in silico* approach could be used in assessing the toxicity of the newer PFAS, as well as other toxicants.

3172 Antigenic, Inflammatory DHP-Lysine Adducts Are Induced by Aldehydes in the Vapor of Both Flavored and Unflavored E-cigarettes and Heated Tobacco Products

J. Nakamura[1], M. Kawanishi[2], T. Yagi[2], T. Okada[1], and N. Kunugita[3]. *[1]Osaka Prefecture University, Izumisano, Japan; [2]Osaka Prefecture University, Sakai, Japan; and [3]University of Occupational and Environmental Health, Japan, Kitakyusyu, Japan.*

E-cigarettes and heated tobacco products (HTPs) are believed to produce fewer toxic chemicals than traditional tobacco smoke due to the lack of need for combustion. However, we recently demonstrated the presence of several carbonyl compounds in eluates from the mainstream vapor of HTPs (Uchiyama, *et. al.* (2018) *Chem. Res. Toxicol*. 31, 585-593). These carbonyl products cause toxicity through direct adduction to proteins as well as indirect oxidative stress. Oxidative stress further results in the formation of reactive aldehydes including malondialdehydes (MDA). We recently discovered that the antigenic, inflammatory 1,4-dihydropyridine (DHP)-type lysine adducts (M2FA) were produced by the reaction between MDA, formaldehyde, and lysine. These adducts consist of two molecules of MDA, one molecule of formaldehyde and lysine. As vapor from e-cigarettes and HTPs includes various aldehydes and can lead to formation of MDA in the lung, here we tested whether such aldehydes produce complexed lysine adducts in the presence of MDA. Aldehydes utilized in this study include formaldehyde, acetaldehyde, acrolein, methylglyoxal, glyoxal, diacetyl, cinnamaldehyde, and vanillin, all of which are found in the vapor of e-cigarettes and HTPs. Each aldehyde was incubated with 6-ACA, a lysine analog, in the absence or presence of MDA in PBS at 37°C. MDA markedly enhanced the complexity of lysine adduct formation in addition to the formation of very stable products. We detected formaldehyde-, acetaldehyde-, and methylglyoxal-derived DHP lysine adducts. In addition, we found that other aldehydes also likely produce DHP-lysine adducts, as determined by both UV-absorbance and fluorescence properties. The structure of these products will be analyzed via a LC-MS method. In the independent study, interestingly, we found that endogenous DHP-lysine adducts were abundant in type-II alveolar epithelium and bronchial epithelium in normal lung tissues. This result suggests that formaldehyde-derived DHP lysine adducts may be present in surfactant molecules. We now hypothesize that a combination of endogenous and inhaled exogenous aldehydes produce complex DHP lysine adducts, which may lead to chronic lung inflammation and diseases such as chronic obstructive lung disease.

3173 *In Vivo* Inhalation Study for 28 Days to Investigate the Effects of Propylene Glycol, Water Mist, and Their Sequential Combination on Sprague Dawley Rats

T. Hirata[1], R. Díaz San Pedro[2], K. Oishi[3], H. Suzuki[3], S. Onami[3], J. Illán[4], R. Fujita[3], H. Ito[3], A. König[4], and M. Sakimura[1]. *[1]Japan Tobacco Inc., Tokyo, Japan; [2]Vivotecnia, Madrid, Spain; [3]Japan Tobacco Inc., Yokohama, Japan; and [4]Vivotecnia Research S.L, Madrid, Spain.* Sponsor: S. Ito

Propylene Glycol (PG) is commonly used as a main ingredient of e-liquids. Although PG is known to cause dehydration, the biological effects of PG are not entirely clear. To investigate such effects, we conducted a 28-day *in vivo* inhalation study using rats exposed to a PG aerosol, water mist, or their sequential combination (PG-Mist). An aerosol with a PG concentration of 1,500 µg aerosol corrected mass (ACM)/L was generated from a vaping device using a smoking machine, and water mists with water concentrations of 5,000 and 15,000 µg ACM/L were generated using a nebulizer. Nine-week-old male Sprague-Dawley (SD) rats were exposed to these conditions for 5 days/week for 1 hour, and then necropsies were performed following 28 days and 14 days of recovery. In addition to these exposure conditions, PG-Mist groups were exposed to alternating PG aerosol and water mist every 30 minutes for 2 hours over 28 days. All results were compared with a filtered air-exposed group. The composition and characteristics of test atmospheres were stable throughout the study period. No relevant effects of exposure to PG aerosol, water mist, or PG-Mist were observed on body weight, hematology, blood biochemistry, bronchoalveolar lavage fluid analysis, or respiratory parameters compared with the filtered air group. In the histopathological examination, some adaptive changes, such as basal cell hyperplasia and metaplasia (graded as low-medium severity) were found locally in the nasal cavity and larynx in not only PG aerosol and PG-Mist groups, but also water mist groups, suggesting that these changes were attributed to particle exposure. Therefore, adverse effects of PG and the effect of PG-induced dehydration were not obviously observed. In conclusion, these results indicate that there might be no clear biological effects of PG inhalation.

3174 The Differential Responses of Human Nasal Epithelial Cells (hNECs) from Nonsmokers and Smokers to "Vaped" Propylene Glycol and Glycerol

Y. H. Escobar, C. Morrison, C. Ehre, and I. Jaspers. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

In the United States, over 10 million adults are current e-cig users. Among 18-24 years old e-cig users, 40% are considered to be never smokers. It is not clear, whether and to what extend prior smoking status affects biological responses induced by e-cigs. There is ongoing research on the general effects of e-cig use, with additional focus on the toxicity of specific e-cig components, such as flavoring compounds and nicotine, yet less focus on the humectants, PG and GLY. The goal of this study is to compare the biological effects of the aerosol from the vaped humectants, PG and GLY, on airway epithelial cells from smokers and non-smokers. Differentiated human nasal epithelial cells (hNECs) from smokers and non-smokers were exposed at air liquid interface to the aerosol of the vaped humectants at PG:GLY ratios of 100:0 (PG), 0:100 (GLY), 55:45 (PG:GLY). Each 10 minute exposure consisted of 4 sec puffs every 30 seconds for a total of 20 puffs at a flow rate of 2.5 LPM. Cells were analyzed 24hrs post-exposure. Our data demonstrate that hNECs from non-smokers have elevated secreted MUC5AC and MUC5B in the apical wash in response to vaped GLY and PG:GLY as compared to air while no significant changes in mucin levels were detected in hNECs from smokers. However, pro-inflammatory cytokines, IL-6, IL-8, IL-1β, VEGF, and IP-10 are only elevated in the basolateral supernatants of hNECs from smokers in response to vaped GLY. These data indicate that different PG:GLY ratios induce differential pro-inflammatory cytokine and mucin secretion. In addition, there are also apparent differences in how hNECs from non-smokers and smokers respond to the aerosol of vaped humectants. Together, these data suggest that prior smoking status determines the biological responses induced by inhaling e-cig aerosols.

3175 E-cig Aerosol Induces Lung Dysregulated Repair Response and Extracellular Matrix Remodeling via α7 Nicotinic Acetylcholine Receptor

Q. Wang, J. H. Lucas, I. K. Sundar, and I. Rahman. *University of Rochester Medical Center, Rochester, NY.*

Electronic cigarettes (e-cigs) are considered as less harmful alternative to tobacco smoke. However, there is very little evidence on the toxicological and respiratory health effects of e-cig exposure, especially on lung dysregulated repair and extracellular matrix (ECM) remodeling mechanisms. We hypothesized that sub-chronic (one month) e-cig exposure affects the ECM remodeling/dysregulated repair possibly via α7 nicotinic acetylcholine receptor (α7nAChR) in a sex-dependent manner. Adult C57BL/6J mice (WT) and α7nAChR knock out (KO) mice were exposed to e-cig aerosol containing propylene glycol (PG) with or without nicotine (24 mg/mL) for 30 days (2 hrs/day, 5 days/week). Total RNA and protein were isolated from mouse lungs for NanoString and Western blot analysis. Sub-chronic e-cig aerosol exposure with or without nicotine caused dysregulation of several different matrix metalloproteinases such as MMP2, MMP8, and MMP9 in both male and female mice both at the level of protein abundance and gene expression. Further, MMP12 protein abundance was significantly increased in male mice only. Surprisingly, both MMP9 and MMP8 protein abundance were significantly decreased and MMP2 protein levels were increased in both male and female mice exposed to PG alone. Additionally, we found protein abundance of tissue inhibitor of metalloproteinases (TIMP3), a negative regulator of MMP activity, was significantly decreased in female exposed to e-cig with or without nicotine. Furthermore, e-cig aerosol exposure significantly increased the protein levels of COL1A2 but decreased COL1A1 and fibronectin in both male and female mice. The α7nAChR KO mice exposed to e-cig aerosol showed attenuation of COL1A2 and fibronectin in male, but not in female mice. Similarly, protein levels of MMP2 and MMP12 were modulated in male mice. Overall, this study demonstrates that mice exposed to sub-chronic e-cig aerosol containing PG alone can cause significant effects on both repair responses and ECM remodeling processes at the mRNA and protein levels possibly via α7nAChR in a sex-dependent manner. These findings support the long-term respiratory health effects of e-cig exposure leading to altered dysregulated repair responses and ECM remodeling of the lung in a sex-dependent manner. *This work was funded by the NIH 1R01HL135613.*

3176 Systemic Immune and Oxidative Stress Gene Expression Differs in Smokers and Nonsmokers in Response to Flu

A. M. Bailey, M. E. Rebuli, and I. Jaspers. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Epidemiological studies have found that smokers are more susceptible to respiratory infections, including influenza virus. Cigarette smoke weakens the immune system by suppressing host defense mechanisms necessary to fight off infections. To understand the mechanisms underlying this immune suppression, we previously analyzed immune responses in the respiratory tract of smokers following exposure to live attenuated influenza virus (LAIV), a cold adapted virus that limits replication to the nasal passageway. Analysis of nasal lavage fluid (NLF) from smokers following inoculation with LAIV showed both reduced expression and responsiveness of inflammatory markers. We propose that cigarette smoke-induced immune suppression is not limited to the respiratory tract and is indicative of broader systemic immune suppression. To test our hypothesis, we analyzed peripheral blood mononuclear cells (PBMCs) from nonsmokers (n=14) and cigarette smokers (n=11) pre- and post-inoculation with a LAIV for cytokines and markers of antioxidant responses. Participants self-reported smoking status, which was verified by tobacco use diaries and urine cotinine/creatinine ratios. We extracted RNA from PBMCs and assessed them for changes in expression of immune and antioxidant enzyme genes with known functions during antiviral host defense using qPCR. Targets included inflammatory genes *IL-6* and *CXCL10* and antioxidant enzymes *HO-1* and *NQO1*, all of which are important mediators in orchestrating influenza-induced antiviral host defense responses. We analyzed our data using a mixed-effect model followed by a Fisher's LSD post-hoc test. Our findings include baseline, pre-LAIV sex-differences in circulating immune gene expression and tobacco use-dependent responses to LAIV. Male smokers had lower *IL-6* expression than nonsmokers and female smokers had higher HO-1 levels than non-smokers pre-LAIV. In response to LAIV, *CXCL10* expression decreased in smokers at day 4 post-LAIV and increased in smokers by day 21 post-LAIV. In addition, *HO-1* levels decreased in smokers at day 4 post-LAIV, while *NQO1* levels increased in smokers at day 4 and returned to baseline by day 21. These results indicate that smoking is associated with alterations in systemic expression of *IL-6*, *CXCL10*, *HO-1*, and *NQO1*, which may be associated with the suppressed antiviral host defense responses seen in smokers.

3177 The Effects of Electronic Nicotine Delivery System (ENDS) on Immune Cell Effector Functions

E. Scott[1], S. Arimilli[2], and G. Prasad[1]. *[1]RAI Services Company, Winston-Salem, NC; and [2]Eurofins Professional Scientific Services, Winston-Salem, NC.*

Cigarette smoking is a major risk factor for lung cancer. Immune suppression, resulting from chronic inflammation, is suggested to increase the susceptibility of smokers to cancer. Electronic Nicotine Delivery Systems (ENDS) are non-combusted, inhaled tobacco products that are relatively new in the market place and whose long-term health effects are not completely understood. We have previously reported that exposure of human peripheral blood mononuclear cells (PBMCs) with aqueous extracts (whole-smoke condition media, WS-CM) from 3R4F reference cigarettes suppressed agonist-stimulated cytokine secretion and cytolytic killing. In this study, we evaluated the effect of exposure to two marketed ENDS aerosol extracts (aerosol-conditioned media, A-CM) on select immune functions. Natural Killer (NK) cells effector function, as measured by cytolytic killing, was equivalent in PBMCs exposed to either of the ENDS preparations compared to unexposed cells. In addition, the levels of cytokines secreted by PBMCs exposed to either ENDS preparation were comparable to unexposed PBMCs. Collectively, these data show that the tested ENDS aerosol preparations did not adversely impact cytolytic killing or cytokine secretion even at higher doses relative to combustible tobacco product preparations.

3178 Acute Electronic Vapor Product Aerosol Exposure of 3D Human Bronchial Tissue Results in Minimal Gene Expression Changes When Compared with Tobacco Smoke

G. Phillips[1], L. Czekala[1], H. Behrsing[2], J. Dendy-Budde[3], M. Stevenson[1], T. Walele[1], and L. Simms[1]. *[1]Imperial Brands, Bristol, United Kingdom; [2]Institute for In Vitro Sciences Inc., Gaithersburg, MD; and [3]Reemtsma Cigarettenfabriken GmbH, Hamburg, Germany.*

Amongst adult smokers, the use of electronic vaping products (EVPs) continues to increase worldwide. This is in parallel with accumulating evidence of the potential reduced toxicity of EVPs and their harm reduction potential compared to combustible cigarette. Advances in molecular biology and the computational sciences now allow for a deeper and more mechanistic understanding of the potential risks associated with cellular exposure to EVP aerosols. In this study, the transcriptomic, functional and cellular perturbations that occur in a fully differentiated 3D *in vitro* reconstituted upper airway human epithelium (MucilAir™) were investigated. We assessed acute exposure to whole EVP aerosol (*my*blu™ blueberry flavour, 2.4% nicotine) with 4-and 48-hours recovery. Results were compared to combustible reference cigarette (Kentucky Reference Cigarette 3R4F) smoke (3.5% whole smoke concentration with an equivalent nicotine dose). Exposure to cigarette smoke resulted in a significant impact on normal barrier integrity and cilia beat frequency at 4 hours compared to both air control and EVP exposure. Proinflammatory cytokine concentrations in culture medium following 48 hours recovery were also significantly increased. EVP aerosol had no observable impact on barrier integrity, cilia beat frequency or proinflammatory cytokines under the conditions of test. RNA sequence and gene set enrichment analysis demonstrated a minimal gene set response to EVP aerosol, whilst exposure to cigarette smoke triggered a clear response in several key disease pathways. In conclusion, an acute EVP aerosol exposure of a 3D *in vitro* reconstituted human lung cell culture had a minimal transcriptomic effect and no functional or inflammatory response when compared to cigarette smoke exposure in this study setup.

3179 Exposure to Pod-Based Electronic Cigarettes Flavors Causes Mitochondrial Dysfunction in Lung Epithelial Cells

T. Lamb, T. Muthumalage, K. Maremanda, and I. Rahman. *University of Rochester, Rochester, NY.*

The use of electronic cigarettes has been on the rise in western populations with the use of electronic cigarettes in middle- and high-schoolers being of particular concern. This increase in use and the emergence of vaping associated respiratory illnesses have resulted in certain states, to ban the sale of flavored e-cigarettes, with few exclusions such as tobacco flavors. The health effects of electronic cigarettes are not fully known and we hypothesize that the electronic cigarettes flavors will decrease mitochondrial function and induce mitochondrial superoxide production. Mitochondrial oxidation-phosphory-

lation was measured in lung epithelial cells (Beas2b) on seahorse plates and exposing the plates to air or pod-based e-cigarette aerosols for three 30 minute sessions. Immediately after and 24 hours after exposure, mitochondrial respiration was measured with the cell mito stress test kit using the Seahorse XFp analyzer. Mitochondrial superoxide production was measured in Beas2b cells and exposing the cells to air or pod based e-cigarette aerosols in three 30 minute sessions. Six hours after the last exposure the cells were measured by flow cytometry using Guava Millipore Easycyte-8 instrument. Immediately following the last exposure to JUUL Menthol aerosol resulted in a significant increase in non-mitochondrial oxygen consumption and proton leak compared to air control and also resulted in a decrease coupling efficiency compared to air control. Twenty-four hours following the last cell exposure to JUUL Menthol aerosol resulted in a significant increase in non-mitochondrial oxygen consumption along with a significant decrease in basal respiration, maximal respiration, and spare capacity of the mitochondria compared to air controls. Exposure to JUUL menthol aerosol resulted in an increase in MitoSox high and Annexin V low cell populations and a decrease in MitoSox low and Annexin V low cell populations compared to air. Our results indicate that exposure to pod-based e-cigarette flavors result in mitochondrial dysfunction and the potential to increase mitochondrial superoxide production. *Supported by T32 ES007026, NIH 1R01HL135613, and CTP NCI U54CA228110.*

PS 3180 Elemental Leaching from Electronic Cigarette Coils over Time

N. Singhrao, C. Li, M. E. Poindexter, and K. E. Pinkerton. *University of California Davis, Davis, CA.*

Electronic cigarettes (e-cigarettes) were first introduced to the US market in the mid-2000s. In 2018, e-cigarette sales were approximately $3.6 billion. This industry has greatly influenced nicotine use and possible addiction in adolescents. E-cigarette use in high school students has increased from 1.5% to 16% from 2011 to 2015, surpassing the prevalence of conventional cigarette use. While the majority of studies focus on flavorings and/or nicotine effects for e-cigarettes, the effect of elements leaching from the metal coils that heat e-cigarette solutions has been largely overlooked. Studies have shown exposure to metals contributes to breathing difficulty, kidney dysfunction and even cancer, depending on the element. A number of e-cigarettes use coils made from stainless steel containing silicon (Si), chromium (Cr), nickel (Ni) and molybdenum (Mo). Our objective was to determine the degree and type of elemental leaching that might occur from a heated e-cigarette coil into the aerosol. A third-generation e-cigarette device was used that heats the coil to 232°C, to produce an aerosol. The aerosol was generated using an equal ratio of propylene glycol (PG) and vegetable glycerin (VG) solvent solution (50:50 PG/VG). The aerosol created was introduced into a chamber. The vaping device was set at a puff time of 3 seconds twice a minute over a 3-hour period (3 seconds/puff, 2 puffs/minute) for a total of four consecutive days. Aerosol was collected on Teflon filters with characterization done by X-Ray Fluorescence (XRF). Two collection times were selected: after 720 puffs (day 2) and after 1440 puffs (day 4). XRF analysis detected the presence of Si and aluminum (Al) in the aerosol. Si is a metal normally present in stainless steel. The presence of aluminum in the aerosol might be due to suboptimal stainless-steel manufacturing practices. Thus, the presence of both metals would appear to be via leaching from the coil. A large amount of chlorine (Cl) was also detected by XRF. The origin of the chlorine is unclear, since it should not arise from the stainless-steel coil or come from the pure PG/VG solution. One possible source might be from the wick used in the vaping device. These findings demonstrate the composition of e-cigarette vaping is not simply the product of aerosolized PG/VG, but rather, other components arising from the device, including metals found in the coil and released by heating, thus leaching into the vaping/aerosol mixture.

PS 3181 Biological Effects of Progressive Exposure to Vapor from a Third-Generation E-cigarette Device

M. E. Poindexter, N. Singhrao, X. Li, and K. Pinkerton. *University of California Davis, Davis, CA.*

E-cigarettes are popular devices that deliver nicotine to users by heating e-liquid: a mixture of propylene glycol (PG), vegetable glycerin (VG), nicotine, and artificial flavors. Since these devices are relatively new, the long-term health effects of inhaling e-cigarette vapor are largely unknown. To investigate the pulmonary effects of these devices, a novel 3rd generation e-cigarette exposure system was created to expose mice to e-cigarette vapor. This system features precise control of temperature and power (wattage) settings on the device to ensure puff consistency. The system also controls the frequency and duration of each puff, as well as the concentration of e-cigarette aerosol generated. A total of 48 BALB/c mice were placed in the e-cigarette exposure chamber or a filtered-air control chamber for 3 hours per day, 5 days per week for 2 weeks. During the 3 hours, 3-second aerosol puffs were generated twice per minute. Daily aerosol and nicotine concentrations were measured using gravimetric filters and XAD-4 cartridges, respectively. Necropsies were performed immediately following exposure on days 1, 3, 5 and 10 (n = 6/time point). Serum was collected for nicotine and cotinine measurement, and bronchoalveolar lavage fluid (BALF) was collected to determine total cell number, viability and differentials. Right lung lobes were flash-frozen for qPCR and ELISA, and the left lung was inflation-fixed with 4% paraformaldehyde for histological analysis. Over the 10-day exposure, average e-cigarette aerosolized nicotine concentrations were 16 ± 1 mg/m^3, resulting in serum nicotine concentrations of 133 ± 46 ng/mL and serum cotinine levels of 712 ± 302 ng/mL. These serum values are consistent with published serum nicotine and cotinine levels found in active tobacco smokers. Interestingly, both serum nicotine and cotinine were highest on day 3, with values on day 5 and 10 decreasing to levels similar to day 1. This is despite exposure conditions being consistently maintained throughout the 10-day period. E-cigarette exposure significantly increased total cell numbers in BALF on day 1 (P= 0.028), but did not increase to a statistically significant degree on days 3, 5 or 10. Macrophages were significantly increased compared to control on day 5 (P=0.026) with a trend of increased macrophages at all other time-points. These data suggest that exposure to e-cigarette vapor may alter the cellular infiltrate of the lungs which could dysregulate the pulmonary immune system as a whole.

PS 3182 Zinc at Concentrations in the Electronic Cigarette Aerosols Induces Stress in Human Bronchial Epithelial Cells

R. Phandthong, P. Da Silva, T. Martinez, M. Rubin, and P. Talbot. *University of California Riverside, Riverside, CA.*

Several studies have reported elevated zinc concentrations in aerosols from electronic cigarettes (ECs); however, the effect of inhaled zinc in EC aerosols on the respiratory system has not been investigated. The components, including metals, in EC aerosols are of interest given the recent increase in hospitalizations and deaths due to VAPI (vaping-associated pulmonary illness). In this study, we investigated the effect of zinc on cultured human bronchial epithelial cells (BEAS-2B) using a range of concentrations of zinc found in EC aerosols. The highest concentration of zinc decreased mitochondrial reductase in the MTT assay. In addition, zinc produced a concentration dependent inhibition of cell proliferation in live cell imaging experiments. We then used Fluozin3™, a fluorescent zinc probe, to track the movement of zinc inside cells. Within 24 hours of treatment, numerous vesicles containing zinc were present in the cytoplasm. To determine if uptake was via endocytosis, cells were incubated for 24 hrs with Dextran- Alexa555™ and zinc, and then incubated in zinc probe for 30 minutes. The dextran and zinc vesicles were co-localized, supporting endocytotic uptake of zinc. Endocytosis was validated using Dyngo4A®, an endocytosis inhibitor. Zinc was tracked through the endocytotic pathway using markers for late endosomes (Rab7), multivesicular bodies (TSG101), and exosomes (CD63). Exosomes were isolated from culture medium using an ExoQuick kit and sized and quantified using a NanoSight 300. Exosomes were lysed in RIPA buffer and released zinc, which was quantified using the zinc probe. After 24 hrs of zinc treatment, there was a significant increase of IL6 in the culture medium as determined using an ELISA. In addition, after 48 hrs, an increase in oxidized glutathione was observed in the treated cells. Similar uptake of zinc was observed when cells were exposed at the air-liquid interface (ALI) to $ZnCl_2$ using a cloud chamber. Our data showed that human bronchial epithelial cells in submerged culture are stressed by concentrations of zinc found in EC aerosols. Cells rapidly internalized excess zinc and packaged it into exosomes, which were secreted, while at the same releasing an inflammatory cytokine and showing evidence of oxidative stress. Chronic stress induced by zinc exposure may damage the respiratory epithelium and could lead to disease and/or contribute to VAPI.

PS 3183 Analysis of Popular Disposable E-cigarette Liquids Using Gas Chromatography-Mass Spectrometry

C. C. Chiari, and C. L. McGinnis. *Quinnipiac University, Hamden, CT.*

For the past ten years, there has been a shift in the way people use nicotine, from cigarettes to electronic smoking devices (e-cigarettes). The recent surge of use also comes from teenagers and adolescents, with reports from the Food and Drug Administration (FDA) claiming that use of popular devices rose from 11.7% in 2017 to 20.8% in 2018 in high schools (FDA 2018). This in an alarming 78% increase that affects over 3.05 million American high school students. Not only is it effecting high school age students, the FDA claims that middle school age use has increased from 3.8% in 2017 to 4.9% in 2018. This

4.9% translates into about 570,000 middle school aged students (FDA 2018). The focus of this research is on four different brands of disposable e-cigarette devices and cartridges: STIG, EONSMOKE, FLAIR, and JUUL. The STIG device was the only one that was a disposable unit rather than a cartridge. It is known that these cartridges contain a highly concentrated solution of salt-based nicotine (5%), as well as other chemicals such as, propylene glycol, vegetable glycerin, benzoic acid, and come in a variety of flavorings. However, it is unclear if there are additional chemicals within the cartridges that may have a harmful impact on the user. To assess that we utilized solid-phase microextraction (SPME) gas chromatography-mass spectrometry (GC-MS) to analyze the solution in the cartridges. We analyzed each brand at full strength, 66% and 50% and then compared the spectra between the brands. There were trace amounts of many different chemicals in each solution, however, we focused on the conserved compounds found within the cartridges and absent from ingredient lists or warning labels. Those include: palmitic acid, myristic acid, acetophenone, stearic acid, bisphenol A, and 2,2-dimethoxy-2-phenylacetophenone. Bisphenol A has been shown to moderately decrease scores on two key lung functional measurements in children, FEV1/FVC method that measures airway obstruction and the FEF2575 method that measure small airway functions (Spanier, Adam J 2014). The FEF2575 is the forced expiratory flow at 25%-75% pulmonary volume method, while the FEV1/FVC is the forced expiratory volume in one breath (FEV1) divided the total amount of air exhaled during FEV1 (Thompson, Gregory 2018; Marseglia, Gian Luigi 2007). Stearic, myristic, and palmitic acids are respiratory and skin irritants that are also known benefactors in the development of acute respiratory distress syndrome (RDS) and pneumonia through the alteration of pulmonary surfactant (Schmidt, Reinhold 2001). The chemical 2,2-dimethoxy-2-phenylacetophenone is known to induce apoptosis in MRC-5 cells in the lungs as well as cytotoxicity in human embryonic fibroblasts (Kawasaki, Yoichi 2014). Acetophenone is another chemical that is a known skin and eye irritant that could also be a contributor to respiratory distress as well as irritation. *(McAuley, David B 1984.)*

3184 *In Vivo* Genotoxicity Testing of Aerosolized ENDS E-Liquids

A. Kumar[1], J. Zhang[1], U. Doshi[1], S. Jaligama[2], and K. Lee[1]. *[1]Altria Client Services LLC, Richmond, VA; and [2]Battelle Memorial Institute, West Jefferson, OH.*

The US Food and Drug Administration (FDA) guidance on premarket tobacco applications for e-vapor products recommends toxicity assessment including *in vitro* genotoxicity. As part of the hazard assessment, we tested three different e-liquids (Formulations-I, II, and III, with nicotine levels ~ 2.1%) according to standard OECD *in vitro* cytotoxicity (NRU TG129) and genotoxicity (Ames TG471 and micronucleus [MN TG487]) guidelines. None of e-liquids were mutagenic (in Ames assay) or cytotoxic (in NRU assay) under tested conditions, however they showed a weak but statistically significant dose-related increase in MN, resulting in positive findings in the MN assay. A follow-up *in vivo* genotoxicity inhalation study (a combined MN and Comet assay) was conducted according to ICH guidance S2(R1). Male Sprague Dawley (SD) rats were exposed to filtered air (negative control) or e-liquid aerosols via nose-only inhalation for up to 6 hr/day for 4 consecutive days. The capillary aerosol generator (CAG, 275°C) was used to generate the aerosols with total particulate matter (TPM) within the respirable size range for rodents (MMAD 1-1.7µm and GSD 1.5-2.0). The maximum exposure concentrations (up to 8 mg/L total particulate matter [TPM]) were tested based on their respective maximum tolerated dose in SD rats. The study included concurrent positive controls for MN (cyclophosphamide) and comet assay (ethyl methane sulfonate). Blood was collected immediately after the last exposure for analysis of nicotine and cotinine as biomarkers of exposure. At necropsy, bone marrow samples were collected for MN, and liver, lung, and nasal tissue samples were collected to evaluate DNA damage using the Comet assay. The plasma nicotine (575-5830 ng/mL) and cotinine (607-8210 ng/mL) levels increased with increasing aerosol exposure. There was no increase in the induction of micronuclei formation (% MN) in the bone marrow and DNA damage (% tail DNA) in the liver, lung or nasal tissue. In conclusion, under *in vivo* assay conditions, all tested e-liquids were negative for genotoxicity, implying no biological relevance of the *in vitro* genotoxicity signals for the three e-liquid formulations tested.

3185 Evaluation of the Cytotoxic and Genotoxic Potential of Select Flavor Additives Used in Cigarettes

E. Beier[1], Z. Tu[1], C. Leggett[1], S. Belinsky[2], H. Irshad[2], L. G. Valerio Jr[1], H. Rosenfeldt[1], and B. Yucesoy[1]. *[1]US FDA, Silver Spring, MD; and [2]Lovelace Respiratory Research Institute, Albuquerque, NM.*

Flavor additives are commonly used in tobacco products. However, their contribution to the inherent toxicity of cigarette smoke remains unclear. The present study was designed to investigate the potential cytotoxicity, genotoxicity, and mutagenicity associated with ten additives: benzaldehyde, black licorice extract (LE), ethyl vanillin (EV), glycerol, hot cocoa, 4-hydroxyphenylbutanone (HPB), L-menthol (LM), peppermint oil (PO), piperonal, and sucrose. Lung epithelial (HBEC4 or A549) and cardiac myoblast (H9c2) cells were exposed to these additives at defined dose ranges in their native form and in combinations as an aerosol (at the air-liquid interface) following addition to a Kentucky reference (3RF4) cigarette. The Canadian Intense (CI) and the International Organization for Standardization (ISO) smoking regimens were used to generate the aerosol. Cytotoxicity was assessed using the neutral red uptake [NRU], methylthiazol tetrazolium [MTT], and lactate dehydrogenase [LDH] assays. Genotoxicity was examined using the Comet and micronucleus [MN] assays while mutagenicity was assessed using the Ames assay. In their native form, six additives (benzaldehyde, EV, HPB, LM, PO, and piperonal) showed significant cytotoxicity in both cell lines with the NRU and MTT assays. Regarding aerosol exposure, cigarettes containing defined combinations of additives yielded IC50 values in cytotoxicity assays that were not different than reference cigarette with either smoking regimens. The H9c2 lines appeared more resistant to the cytotoxicity of the cigarette smoke than HBEC cells. In the Ames assay, significant mutagenicity was largely seen in the TA100 strain with and without S9 and the YG1024 strain with S9. The CI smoke regimen induced more mutagenicity than the ISO regimen. Only the custom cigarettes containing LM and LE with the YG1024 strain +S9 exposed using the CI regimen, and benzaldehyde with TA100, and EV with TA97a and TA98 showed a significantly elevated dose response from the Kentucky reference cigarette. The IC50 values in the MTT and LDH assays were much lower in cigarettes containing LM compared to the other additives or reference cigarette. Although all custom cigarettes caused a significant dose-dependent increase in the Comet assay, a dose response that differed significantly from the Kentucky reference cigarette was seen only for EV at the highest dose with the CI regimen in HBEC4 cells. Under the study conditions, the tested additives either alone or in combination demonstrated increased cytotoxicity and genotoxicity, thereby suggesting a contribution to the toxicity of cigarette smoke.

3186 A Structure-Based Grouping Approach for Predicting Biological Activity of Flavor Ingredients Contained in E-vapor Products

D. Sciuscio[1], K. D. Ehman[2], T. B. Langston[2], A. Kumar[2], K. M. Lee[2], D. Marescotti[1], F. Martin[1], and P. Vanscheeuwijck[1]. *[1]Philip Morris Products S.A., Neuchatel, Switzerland; and [2]Altria Client Services LLC, Richmond, VA.*

The use of flavors is important for development of e-vapor products. However, many flavors do not have safety or toxicity data, especially for inhalational administration. Considering the large number of available flavors and potential combinations, standard toxicological testing of individual ingredients is not always feasible, as it may require extensive animal testing. We developed a structure-based approach to select a total of 38 flavor group representatives (FGRs) from more than 200 commonly used neat flavors based on the concept that structurally-related compounds have comparable metabolic and biological activities (as outlined in the European Commission Regulation [EC] No. 1565/2000). We propose that the representative FGR mixtures could be tested in inhalation studies to support the toxicological assessment of all structurally-related individual flavors. Prior to FGR selection, the available toxicological data were reviewed for each flavor (e.g., NOAEL, LC50, and LD50). If no experimental data were available, toxicological predictions (p) were made for key endpoints by using the TOPKAT software (pIrritancy, pCarcinogenicity, pChronic LOAEL pDevToxicity, and pCramerClass). In addition, cytotoxicity potential of the flavors (XCelligence) was experimentally tested by real-time cellular analysis, and the biological impact of a subset of the most cytotoxic substances was evaluated by high-content screening (HCS). HCS data for the remaining flavors were obtained by using a predictive model based on pCramer, pIrritancy, pChronicLOAEL, pExpCarcinogenicity, and pXCelligence (pToxPiHCS). For objective selection of FGRs, flavors within each group were ranked based on pLD50, pDevToxicity, PToxPiHCS, pChronicLOAEL, and pIrritancy scores. The average rank for each flavor ingredient was then computed to generate the final ranking upon which the predicted "worst case" FGRs were selected for each structural group. The resulting FGRs could be tested alone or in combination as mixtures using *in vitro* and *in vivo* toxicity testing

and the results would help deriving acceptable levels for their use in e-vapor products. Once validated, this process will facilitate the read-across of new flavors according to structural groups.

3187 A Structure-Based Grouping Approach to Evaluate Toxicity of e-Vapor Flavor Ingredients: Five-Week Inhalation Study in A/J Mice

E. Wong[1], K. Luettich[2], D. Sciuscio[2], K. Ashutosh[3], P. Leroy[2], J. Hoeng[2], K. M. Lee[3], and P. Vanscheeuwijck[2]. *[1]Philip Morris International, Singapore, Singapore; [2]PMI R&D, Neuchatel, Switzerland; and [3]Altria Client Services LLC, Richmond, VA.*

Flavor ingredients are widely used in e-cigarette products. Most flavors are generally recognized as safe for use in foods. However, limited toxicological information is available to evaluate the potential hazard of flavors delivered via inhalation. Considering the number of available flavors and the numerous potential flavor combinations, toxicity testing of each individual compound or formulation is not always feasible. Therefore, we selected the Flavor Group Representatives (FGR) based on structural grouping: a total of 38 representatives were selected from ~200 common flavors, based on known and *in silico* predicted toxicological information. In this study, the selected FGRs were combined to create a potential "toolbox" flavor mixtures and subjected to *in vivo* inhalation testing using A/J mice. The study is a dose range finding study with emphasis on subacute toxicity and respiratory tract irritation and inflammation. The results from the study may be used to select the appropriate concentrations of flavor mixtures for future chronic inhalation study. A/J mice were whole-body exposed to fresh air (Sham), aerosol from base (propylene glycol (PG) and vegetable glycerin (VG) with 2% nicotine (N)), aerosol from flavor mixtures (PG, VG, 2% N with up to 18% of flavors (F)), or to mainstream smoke (MS) from the 3R4F reference cigarette for 6 hours per day, for 5 days per week, for 5 weeks. The aerosols was well tolerated by the mice, without signs of severe acute toxicity post-exposure. Exposures to the flavored aerosols, even at the highest flavor concentration, did not cause lung inflammation based on the lack of immune cell infiltrate in the bronchio-alveolar lavage fluid and histopathology evaluation. By contrast, exposure to MS resulted in lung inflammation and also moderate to severe adaptive changes in the nasal and laryngeal epithelia. Most of upper respiratory track changes were absent in mice exposed to flavored e-vapor or significantly less severe than in the MS-exposed mice. In summary, the tested flavor concentrations did not result in severe subacute toxicity or respiratory tract irritation/inflammation and were considered suitable for use in future chronic inhalation study in A/J mice.

3188 Comparison of Biological Effects between Reference Cigarettes 1R6F and 3R4F: A 28-Day *In Vivo* Inhalation Comparative Study

K. Oishi, T. Hirata, S. Onami, M. Matsuda, and H. Suzuki. *Japan Tobacco Inc., Yokohama, Japan.* Sponsor: S. Ito

Kentucky reference cigarettes have been widely used as comparative cigarettes for *in vitro* and *in vivo* toxicological research of tobacco-related products. The 1R6F Kentucky reference cigarette (1R6F) has been made available because of the depleting supply of the 3R4F Kentucky reference cigarette (3R4F). Recently, an *in vitro* comparative study of 1R6F and 3R4F was reported, but these is no *in vivo* toxicological research comparing those reference cigarettes. Therefore, to investigate differences in the *in vivo* biological effects of both reference cigarettes, we conducted a 28-day *in vivo* inhalation toxicity study with reference to the OECD Test Guideline 412 (OECD, 2018). In this study, male Sprague Dawley rats were exposed to mainstream cigarette smoke (MCS) from 1R6F or 3R4F (330 µg wet total particulate matter/L) by nose-only inhalation for 6 h/day, 5 days/week for 4 weeks. The control group was exposed to filtered air under the same exposure condition. In addition to the endpoints provided by the OECD TG412, we performed lung function measurements using the flexiVent® system and transcriptomic analysis of lung tissues. As a result, 1R6F and 3R4F groups were confirmed to show effects related to MCS exposure in any biological parameter listed in the OECD TG412 and in lung function measurements, compared with the control group. In addition, no significant differences were found in the effects of 1R6F and 3R4F groups. In transcriptomic analysis, the number of differentially expressed genes in the lungs almost corresponded between 1R6F and 3R4F groups after 4 weeks of exposure. Furthermore, the results of Gene Ontology enrichment analysis suggested that the gene expression profile of 1R6F group was similar to that of 3R4F group. On the basis of these results, we indicated that 1R6F can be used as a comparative cigarette as well as 3R4F for *in vivo* toxicological research.

3189 Effects of an Aqueous Extract of Aerosol from a Heated Tobacco Product on Reconstructed 3D Human Epithelial Tissues

K. Matsumura, and S. Ito. *Japan Tobacco Inc., Yokohama, Japan.*

Next generation tobacco products, including heated tobacco products (HTPs), are becoming increasingly available worldwide. HTPs heat a tobacco without combustion. Hence, the resulting aerosol theoretically contains reduced amounts of harmful and potentially harmful constituents resulted from combustion. However, the biological effects of aerosol from HTPs on the respiratory tract are not fully understood. In the current study, we investigated the biological effects of aerosol from one of our HTPs, prototype tobacco vapor product (PTVP), on reconstructed three-dimensional (3D) human airway epithelial tissue in comparison with that from the 1R6F reference cigarette. Each aqueous extract (AqE) of 1R6F and PTVP was prepared by bubbling the generated aerosol into medium. Then, the AqEs of 1R6F and PTVP were diluted to each concentration ranging from 50 to 200 puffs/L and 200 to 10000 puffs/L, respectively. After 24 h of exposing the tissues to each AqE, we analyzed the cytotoxic effect [adenylate kinase (AK) activity], ciliary function [ciliary beating area (CBA)], inflammatory response [interleukin (IL)-8 secretion], and global gene alteration [transcriptome]. The tissues exposed to AqE of 1R6F showed a significant increase in AK release at 200 puffs/L, while it was observed at a higher concentration (only at 10000 puffs/L) when AqE of PTVP was exposed to the tissues. A significant decrease in CBA was also observed in the tissues exposed to AqE of 1R6F at 200 puffs/L, whereas no significant change was observed in the tissues exposed to AqE of PTVP at any concentration. Furthermore, the AqE of 1R6F induced a dose-dependent and significant increase of IL-8 secretion, while no significant change was observed in the tissues exposed to AqE of PTVP at any concentration. In the transcriptomic analysis, fewer differentially expressed genes (DEGs) were detected in the tissues exposed to AqE of PTVP than 1R6F at comparable nicotine concentration. We identified 483 of DEGs at a sub-toxic concentration (10000 puffs/L) in AqE of PTVP exposure, and those DEGs were mostly related to oxidative stress response pathways (e.g., NRF2-mediated oxidative stress) which are well-known cigarette smoke-inducible pathways. Taken together, although the high amount of PTVP aerosol exposure may elicit similar biological processes as cigarette smoke exposure, our results suggest that the PTVP have weaker biological effects than cigarette smoke.

3190 Cigarette Smoke-Induced Autophagy Is Regulated by FOXO Transcription Factors

P. Bagam[1], D. Singh[2], G. Kaur[1], and S. Batra[1]. *[1]Southern University and A & M College, Baton Rouge, LA; and [2]Louisiana State University, Baton Rouge, LA.*

Chronic obstructive pulmonary disease (COPD) is a progressive and life-threatening disease with the major risk factor being exposure to cigarette smoke. Cigarette smoke (CS) contains more than 5000 chemicals which exposes lungs to high concentration of free radicals and bioactive chemicals. Oxidative stress results in DNA damage, degradation of proteins and cell death resulting in acute lung injury. The lung damage in COPD is irreversible with currently no available therapy helpful in regressing the damage. Therefore, further understanding about the disease pathogenesis in terms of molecular mechanisms associated with cellular damage during CS exposure is highly warranted. Earlier studies have demonstrated a functional role of autophagy in COPD. Autophagy is a lysosomal degradation process that clears off damaged organelles and misfolded or aggregated proteins as a critical cell survival mechanism in response to stress. Expression and activation of autophagy related proteins is regulated by Fork head box class O (FOXO) transcription factors. Our preliminary findings revealed CS-extract mediated induction of inflammatory responses and regulation of transcription factors FOXO3a and FOXO1 in human lung adenocarcinoma cells with type II characteristics (A549). We thus hypothesized that FOXO transcription factors play a vital role in regulating CS-induced inflammation and autophagy. To test our hypothesis, we challenged A549 with cigarette smoke extract (CSE) for 24 hr. Our findings revealed significantly reduced expression of FOXO3a at both transcriptional and translational level in CSE-exposed A549 cells as compared to control. To further elucidate the role of Foxo3a in CSE-induced autophagy we transfected A549 cells with SiRNA-scrambled or SiRNA-FOXO3a followed by challenge with CSE. We first determined the effect of FOXO3a knockdown on the production of cytokines/chemokines and observed that knockdown of transcription factor augments CSE-induced IL-6, CCL-2 and IL-8 production by A549 cells. Moreover, we also observed FOXO3a mediated transcriptional regulation of several autophagy (LC3B, ATG4, ATG16 and ATG12) and antioxidant (MnSOD and catalase) genes in CSE-challenged A549 cells. Next, we performed chromatin immunoprecipitation assay to determine interaction between FOXO3 and autophagy related genes. The qPCR analysis showed significant increase in the binding of FOXO3a transcription factor on the promoter regions of LC3B, ATG12, GABARAL1 and ATG4 in CSE-challenged cells.

Further experiments are in progress to define the role of FOXO3a and FOXO1 in CSE-induced inflammation and autophagy. Overall, our results will provide important information about the therapeutic targets for the management of CS-induced inflammation/pathologies.

3191 Cigarette Smoke Exposure Exacerbated Silica-Induced Pulmonary Toxicity

P. Joseph, C. Umbright, G. Mustafa, M. Kashon, T. Sager, and W. McKinney. *NIOSH, Morgantown, WV.*

Smoking, an avoidable life style factor, may modify the lung response to silica exposure including cancer and silicosis. Studies have shown that smoking induces oxidative stress and inflammation, etiological factors involved in the development and progression of cancer and silicosis. Nevertheless, the precise role of cigarette smoke (CS) exposure on the lung response to silica exposure and the underlying mechanisms are unclear. Therefore, the objectives of the present study were to determine the role of CS on lung response to silica exposure and the underlying mechanism. Male Fischer 344 rats were exposed by inhalation to air, crystalline silica (15 mg/m^3, 6 hrs/day, 5 days), CS (80 mg/m^3, 3 hrs/day, twice weekly, 6 months), or silica (15 mg/m^3, 6 hrs/day, 5 days) followed by CS (80 mg/m^3, 3 hrs/day, twice weekly, 6 months). The rats were euthanized 6 months following initiation of the exposures and lung response parameters including, lactate dehydrogenase (LDH) activity, oxidant production, cell counts, and cytokines in broncho-alveolar lavage (BAL) were assessed. Silica exposure resulted in significant lung toxicity as evidenced by lung histological changes, enhanced neutrophil infiltration, increased LDH levels, enhanced oxidant production, and increased cytokine levels. The CS exposure had only a minimal effect on the toxicity parameters. However, the combined exposure to silica and CS caused a significant increase in lung response, compared to silica or CS exposure alone. For example, CS or silica exposure alone resulted in neutrophil infiltration 5 and 150 times, respectively, compared to the air-exposed controls. The combined exposure to silica plus CS, on the other hand, caused a neutrophil infiltration that was 500 times higher compared to air controls suggesting a synergistic effect of silica and CS on lung toxicity. Global gene expression changes detected in the rat lungs correlated with the toxicity. Bioinformatic analysis of the gene expression data demonstrated significant enrichment in functions and pathways relevant to silica exposure which correlated with the lung toxicity. Unique pathways relevant to lung response to silica exposure, for example disruption of circadian rhythm signaling, were detected in the rat lungs exposed to silica and CS. Collectively our data demonstrated an exacerbation of silica-induced lung toxicity by CS exposure and the molecular mechanisms underlying the exacerbated toxicity.

3192 Bioinformatics Approach Unravels Toxic Effects of Waterpipe Tobacco Smoking

D. Mitic Potkrajac[1], K. Jankovic[1], T. Krsmanovic[1], G. Apic[1], and R. B. Russell[2]. *[1]Metisox Ltd., Cambridge, United Kingdom; and [2]Heidelberg University, CellNetworks, Heidelberg, Germany.*

Waterpipe tobacco smoking (WTS), in Middle East known as shisha or narghile, is becoming more popular in Western societies, particularly among young people as an alternative form of tobacco use other than traditional cigarettes. The health risk associated with WTS is highly underestimated, despite the fact that waterpipe tobacco use is associated with greater carbon monoxide, similar nicotine, dramatically more smoke exposure and some of the same toxicants as cigarette smoking. The aim of this study was to investigate toxicities induced by light-use WTS. We analysed gene expression data (Walters MS *et al*, 2017) from small airway epithelium of waterpipe tobacco smokers and WTS impact on pathological changes and affected pathways. 282 signature genes (<.05, >.5) were detected from the whole genome analysis, as significantly dysregulated after exposure to WTS., By manually annotating and processing molecular information from the publicly available data (PubMed articles and FDA reports), we created a computational model of biological pathways describing cellular processes in human respiratory tissues and made the information computable. WTS exposure induced genes involved in immune responses, G-protein coupled receptor signalling, oxidative stress and mRNA regulation of translation. In addition, we annotated data about WTS toxic components (such as the ones from Hoffmann's list, Hoffmann D *et al,* 1998) and generated a comprehensive database of known side effects and protein targets of these toxicants. By applying bioinformatics analysis tools to gene expression data and combining with toxicants data, we have identified several pathologies that affect respiratory and circulatory system. We generated mechanistic hypothesis for each of these pathologies, supported by current knowledge. Together, these data indicate that even light-use waterpipe tobacco smoking is as much harmful as traditional cigarettes smoking, and may damage respiratory system.

3193 Toxicological Evaluation of E-vapor Aerosols Using *In Vitro* Regulatory Cytotoxicity and Genotoxicity Assays under Air-Liquid and Air-Agar Interface Conditions

U. B. Doshi[1], J. Zhang[1], M. Scian[2], R. L. Wolz[2], P. Kosachevsky[2], B. Sukka G[2], S. Bharti[2], G. Gillman[2], and K. Lee[1]. *[1]Altria Client Services LLC, Richmond, VA; and [2]Enthalpy Analytical LLC, Richmond, VA.*

Users of electronic nicotine delivery systems (ENDS) inhale generated aerosols; therefore, it would be ideal to conduct *in vitro* toxicity testing using systems that mimic direct aerosol exposures to the apical surface of cells or bacteria, i.e., air-liquid interface (ALI) or air-agar interface (AAI). Here we evaluated a cig-a-like device with base formulation (containing humectants and 4% nicotine) and three commercially available cig-a-like ENDS (containing humectants, varying flavors and a range of nicotine concentrations (2.4%-4.8%)) using the Vitrocell®- 24/48 [ALI] and Ames 48 [AAI] exposure modules and regulatory cytotoxicity (neutral red uptake (NRU)) and genotoxicity (Ames) assays. The lung adenocarcinoma cell line, A549 was used for the cytotoxicity assay and was exposed to either air or to e-vapor aerosols at varying puff numbers (50-400 puffs). For the Ames assay, 5 *Salmonella* strains (TA98, TA100, TA102, TA1535 and TA1537) were used and exposed to either humidified air or to 400 puffs of aerosol from each test article. Aerosols were generated using a modified CORESTA CRM 81 puffing regimen (55ml puff volume, 5 sec puff with 30 sec interval). Concentration of the deposited nicotine in the insert was measured as marker of exposure. In the NRU assay, the base formulation was cytotoxic only at 400 puffs (39.1±30.1 % viability), while all three tested e-vapor products showed a concentration dependent cytotoxicity with the estimated IC50 ranging from 72-146 puffs. In the Ames assay, the base formulation and two of tested e-vapor products were found to be negative, however, one e-vapor product was positive in strain TA1535 (>18-fold increase above air control) following exposure to 400 puffs of e-vapor aerosol. The study was repeated with varying puff numbers (50-400) using strain TA1535, wherein a concentration dependent increase in response was observed in comparison to air treated group. In summary, the employed ALI and AAI *in vitro* testing conditions were able to detect varying degrees of cytotoxic and genotoxic hazard in e-vapor aerosols, demonstrating the potential use of direct aerosol testing as part of the toxicological evaluation of e-vapor products.

3194 Thirdhand Smoke Adhesion to and Removal from Indoor Fabrics: Factors Affecting Human Exposure and Remediation

G. L. Pozuelos[1], P. Jacob III[2], S. Schick[2], E. Omaiye[1], and P. Talbot[1]. *[1]University of California Riverside, Riverside, CA; and [2]University of California San Francisco, San Francisco, CA.*

Thirdhand smoke (THS) consists of residual tobacco smoke that settles and remains on indoor surfaces after smoking has ceased. Remediation of these chemicals is important in reducing exposure to THS. In this study, we investigated the affinity of THS chemicals to common household fabrics that are not washed frequently (e.g. draperies and upholstery) and could act as chemical reservoirs. Cotton, terry cloth, polyester, and wool carpet fabrics were washed four times before being placed in a chamber designed for THS exposure smoke exposure. They were then exposed for 1, 6, 12 or 18 months to 696, 1569, 1795, 3617mg of smoke, respectively. THS was extracted from each fabric at a concentration of 0.1g of fabric/mL of PBS, DMSO, or cell culture medium. Extraction media were examined using fluorescence spectroscopy at various wave lengths. Nicotine, nicotine alkaloid and tobacco specific nitrosamine (TSNA) concentrations in extracts were quantified using liquid chromatography-tandem mass spectrometry (LC-MS/MS). Affinity of nicotine to terry cloth and polyester was compared by exposing each fabric to 10 mg/ml of nicotine, and quantifying the amount of nicotine recovered after extraction using high performance liquid chromatography (HPLC). Our results showed that THS chemicals in fabric extracts autofluorescence, and fluorescence was proportional to the time and amount of THS exposure received by the fabrics. THS autofluorescence was not detected in extracts from polyester and wool carpet at any of the excitations tested. Nicotine, nicotine alkaloid, and TSNA concentrations were higher in THS extracts from cotton and terry cloth than in polyester and wool carpet. Using fabrics spiked with 10 mg of nicotine, we showed that extraction efficiency was much higher from terry cloth (7mg) than from to polyester (0.11mg). The absorption into and release of THS from fabrics varied with the type of fabric. Human exposure to THS could be influenced by fabric type, and remediation techniques may need to vary depending on the fabrics reservoirs being treated.

3195 Transcriptome Analysis Reveals Lung-Specific miRNAs Associated with Aberrant Mucociliary Clearance Induced by Cigarette Smoke in an *In Vitro* Human Airway Tissue Model

R. Xiong[1], L. Wu[1], Y. Wu[1], Y. Chen[1], T. Chen[1], L. Muskhelishvili[2], K. Davis[2], H. Rosenfeldt[3], S. M. Healy[3], and X. Cao[1]. *[1]US FDA/NCTR, Jefferson, AR; [2]TPA Inc., Jefferson, AR; and [3]US FDA/CTP, Silver Spring, MD.*

Exposure to cigarette smoke (CS) is strongly associated with aberrant mucociliary clearance, which may increase risk for developing CS-related diseases, such as chronic obstructive pulmonary diseases and lung cancer. In this study, we employed miRNA-mRNA network analysis and identified miRNAs that may modulate tissue responses to CS in an *in vitro* human air-liquid-interface (ALI) airway tissue model. Cultures were exposed to CS (diluted in 0.5 L/min, 1.0 L/min, and 4.0 L/min clean air) from smoking five 3R4F University of Kentucky reference cigarettes under the International Organization for Standardization machine smoking regimen, every other day for 1 week (3 days, 40 min/day). Transcriptome analyses of CS-exposed ALI cultures identified 5090 differentially expressed genes and 617 differentially expressed miRNAs. A subset of cilia-associated mRNAs and miRNAs was further enriched by gene ontology and miRNA-mRNA network analysis. These findings are consistent with the reduction in cilia beating frequency and ciliary protein expression caused by CS exposure in the ALI cultures. In particular, a time-dependent decrease in the expression of miR-34/449, a conserved miRNA family highly enriched in multiciliated airway epithelia and implicated in motile ciliogenesis, was observed in CS-exposed cultures. Network analysis further revealed that the down-regulation of miR-34/449 by CS may derepress the cell-cycle proteins, which, in turn, can interfere with cilia biogenesis. Similar alterations have been observed in smokers with COPD. Investigating the effects of CS on miRNA expression in ALI tissue models, therefore, may provide not only mechanistic insights, but potential non-invasive biomarkers for respiratory diseases caused by cigarette smoking.

3196 Natural and Synthetic Antioxidants against Cigarette Smoke Extract-Induced Human Bronchial Epithelial Cell Toxicity

R. Reis, D. Orak, H. Çimen, and H. Sipahi. *Yeditepe University, Istanbul, Turkey.* Sponsor: H. Orhan

Cigarette smoke (CS) is an aerosol containing thousands of chemical substances which are not identified completely and suggested that there might be more than 5600 components in CS. From a toxicological perspective, the content of CS which is rich in many fat-soluble toxins, mutagens, and carcinogens which provide a basis for fatal outcomes. Over the last decade, researchers are concerned about the mechanisms of CS induced diseases due to its highly toxic content. Also, preventive strategies against CS is a trend research topic as a part of inhalation toxicology and environmental risk assessment. Alternative therapy methods, particularly natural compounds, are still under investigation due to their antioxidant capacity. In the present study, preventive effects of eucalyptol (EUC), curcumin (CUR) and their combination on CS induced toxicity and oxidative stress (OS) on human bronchial epithelium cells (BEAS-2B) have been investigated *in vitro*. Cigarette smoke extract (CSE) was prepared by 3R4F reference cigarette by bubbling smoke into cell culture medium and 20% CSE (v/v) was used for studies. For each experiment, 2 h pre-treatment with EUC (50 μM), CUR (5 μM) and EUC+CUR was followed by 4 h CSE exposure. 1 mM N-acetylcysteine (NAC) was used as positive control. Cell viability was assessed by MTT assay. Intracellular ROS was determined with using DCFDA in flow cytometry. Also, an important marker in cellular defense against OS, Nrf2 level was measured by western blotting. According to results, cell viability is increased with treatments compared to CSE group (70.13% ±7.65). Intracellular ROS induced by CSE was significantly decreased with NAC and EUC pre-treatments. Also, all pre-treatments lead to a decrase in CSE induced MDA level. CAT activity and GSH level increases with all pre-treatments compared to CSE alone. Nuclear Nrf2 level was significantly increased in CSE group as a response to cellular OS. Pre-treatment with NAC and EUC diminish CSE induced nuclear Nrf2 level while CUR itself act as a Nrf2 activator. According to present results, both EUC and CUR have shown protective effects against CSE induced oxidative bronchial epithelial damage and might be a potential remedy against CS related diseases.

3197 Effects of Exposure to Environmental Tobacco Smoke during Perinatal Development on Susceptibility to Infection and Mortality

C. Wu, M. Wesselkamper, A. N. Spediacci, J. A. Claude, L. Wang, and K. E. Pinkerton. *University of California Davis, Davis, CA.*

The purpose of this study was to examine the effect of perinatal exposure to environmental tobacco smoke (ETS) on primary influenza and secondary bacterial infection in young mice. Perinatal BALB/c mice were exposed to filtered air (FA) or ETS and then randomly assigned into groups. Three FA groups and three ETS groups were challenged with 1) murine-adapted influenza A virus, 2) the human bacterial pathogen *Staphylococcus aureus*, or 3) both virus + bacteria to determine if ETS impacts resistance to viral or bacterial infection. Bronchoalveolar lavage fluid (BALF) was collected 1, 3 or 10 days post-infection to determine cell numbers and types. Total cell number in the BALF of neonates exposed to influenza A or influenza A + S. aureus was significantly increased, compared to FA and ETS control and bacteria only groups. Clinical symptoms and lung tissue inflammation were scored. Neonates exposed to ETS had similar physical signs of infection compared to animals exposed to FA. FA neonatal groups exposed to influenza A or to both influenza A and S. aureus had 50% mortality. In contrast, neonates exposed to ETS and infection experienced 100% mortality by post-exposure day 10. FA and bacteria only groups had no mortality. Neonates exposed to FA or ETS in combination with virus or virus + bacteria demonstrated significantly higher inflammatory responses compared to groups exposed to only FA, ETS, or bacteria. Using immunohistochemistry, lung sections were stained for Club cell secretory protein (CCSP) and analyzed morphometrically to determine the volume of CCSP per surface area of basal lamina. Club cells are non-ciliated epithelial cells lining the airways which produce crucial proteins and immune factors that aid in the protection of the bronchioles of the lungs. Analysis of terminal bronchioles demonstrated a significant decrease in CCSP in mice exposed to either FA or ETS in combination with exposure to virus or virus + bacteria. There were no statistically significant differences in CCSP expression between the FA and ETS treatment groups. We conclude CCSP expression is significantly reduced in response to influenza A infection. A possible correlation between decreased CCSP levels and viral infection may explain the 100% mortality found in ETS-virus and ETS-virus + bacteria exposed groups in contrast to FA-virus and FA-virus + bacteria demonstrating a return of CCSP levels by day 10, similar to those in groups with no mortality.

3198 Telomere Protection Protein 1 (TPP1) Deletion in Lung Epithelial Cells Augments Environmental Tobacco Smoke-Induced Lung Inflammation

T. M. Muthumalage, I. K. Sundar, and I. Rahman. *University of Rochester, Rochester, NY.*

Telomere attrition is considered a hallmark of aging lung in chronic obstructive pulmonary disease (COPD). We have previously shown that telomere protection protein 1 (TPP1) involved in cigarette smoke (CS)-induced telomeric DNA damage and cellular senescence. TPP1 is one among the key players (shelterin complex: POT1, TRF1, TRF2, Tin2, Rap1, and POT1), that contributes to the maintenance of telomere length and integrity. However, the exact mechanism by which TPP1 mediates protection of shelterin complex against environmental tobacco smoke (ETS) induces lung inflammation, and injury remains unclear. We hypothesized that TPP1 protects against ETS induced telomere DNA damage via the shelterin complex. TPP1-flox and TPP1-CreCC10 (Clara cell-specific TPP1 deletion) mice were exposed to ETS (sub-chronic: 35 days, 100 mg/m^3 total particulate matter). Differential cell counts in the bronchoalveolar lavage (BAL) fluid and inflammatory cytokines were analyzed by flow cytometry and ELISA/Luminex assay, respectively. Additionally, we measured protein abundance of DNA damage, shelterin complex, and cellular senescence markers in the lungs by immunoblotting and histological analysis. Sub-chronic ETS exposure showed increased total cell counts in TPP1-CreCC10 compared to TPP1-flox mice. Neutrophil counts were altered in both TPP1-flox and TPP1-CreCC10 ETS exposed mice compared to air-exposed controls. T-lymphocyte counts were significantly increased in TPP1-CreCC10 compare to air-exposed control. ETS exposure affected inflammatory cytokines (increased: TNFα, IFNγ, IL-5, IL-6, MIP-1β, MCP-1, and eotaxin; significantly increased: IL-4, IL-9, G-CSF, KC, and IL-12p70) in the BAL fluid of TPP1-CreCC10 compared to TPP1 flox air and ETS exposed mice. ETS exposed TPP1-flox and TPP1-CreCC10 mice showed altered expression of DNA damage (γH2AX), shelterin complex (TPP1 and TIN2), and cellular senescence (p21 and p16) markers in the lungs. These data suggest an increased lung inflammation caused by ETS exposure resulted in altered differentiation of naïve T cells and regulation of Th1/Th2 response in TPP1-CreCC10. We conclude that

TPP1 plays a protective role against ETS-induced inflammation and cellular senescence processes that drive COPD pathogenesis. *Supported by the NIH R01 HL135613, R01 ES029177, R21 ES028006, R01 HL133404, and R01 HL137738.*

3199 Exosomal microRNAs Are Novel Circulating Biomarkers among E-cigarette Users, Cigarette, and Waterpipe Smokers

K. P. Singh, D. Li, and I. Rahman. *University of Rochester Medical Center, Rochester, NY.*

Electronic cigarettes (E-cigs) recently introduced and gained popularity in US and throughout world. There are severe pulmonary illnesses have been reported in users who used nicotine or cannabis extract in E-cigs. Cigarette and Waterpipe tobacco smoking causes various acute and chronic health effects including cardiovascular disease, chronic bronchitis and cancer. Exosomes are extracellular vesicles of lipid carrying various types of biological materials including RNA in various bodily fluids. MicroRNAs are present in higher concentration in whole RNAs, play a role in various physiological functions and diseases. No study has been done to identify and characterize the plasma-derived microRNAs in E-cig users, waterpipe smokers, and compared with cigarette smokers. The comprehensive analysis of exosomal microRNA expression profiles and their biological functions were performed in plasma samples from normal, E-cig users, waterpipe, and cigarette smokers groups. Our results show upregulation of 17 and downregulation of 5 microRNAs in E-cig users in comparison with non-smokers. Upregulated hsa-miR-30c-5p, hsa-miR-125b-5p, hsa-miR-423-3p, hsa-miR-21-5p, hsa-7f-5p are involved in inflammation, cell proliferation, and epithelial-mesenchymal transition. Downregulated hsa-miR 451a, hsa-miR-10b-5p, hsa-miR-30e-5p are associated with proliferation and inhibition of apoptosis. The altered expression of microRNAs in E-cig users affects several physiological functions, such as biological pathways (erbB receptor signaling network, trail signaling pathway, integrin family cell surface interactions, endothelins pathway) and molecular functions (transcription factor activity, extracellular matrix structure constituent, metallopeptidase activity). Further, significant changes in transcription factors (EGR1, SP1, SP4, ZFP161, POU2F1, NFIC) were also observed. The comparative analysis of microRNA expression and functional characterization of all smoking groups will be presented. Thus, E-cig users and all smoking groups have alteration in plasma exosomes microRNAs expression that may be useful as biomarkers, which are involved in pathophysiology of cardiopulmonary system. *Support by NIH 1R01HL135613 and NIH FDA CTP U54CA228110.*

3200 Menthol Induces Oxidative Stress and an Inflammatory Response in Human Lung Cells Exposed in Both Submerged Culture and at the Air-Liquid Interface

M. Tran, V. Nair, S. Zhai, X. Cui, R. Phandthong, Y. Wang, D. Volz, and P. Talbot. *University of California Riverside, Riverside, CA.*

Menthol is a commonly used flavor chemical that is found in many tobacco products, including electronic cigarettes (ECs). In spite of its widespread use, relatively little is known about how menthol affects the respiratory epithelium when inhaled during smoking or vaping. The purpose of this study was to characterize the effects of menthol on bronchial epithelium using three *in vitro* platforms: submerged culture, VITROCELL cloud chamber that provides air liquid interface (ALI) exposure without solvents nor heating, and a Cultex ALI exposure system the delivers aerosol equivalent to that inhaled by an EC user. The latter platform was used in conjunction with 3D human bronchial epithelium. A cytotoxic concentration of menthol was determined using the MTT assay in submerged culture. Menthol exposure significantly increased calcium influx and mitochondrial ROS via the TRPM8 receptor. These responses were inhibited by BCTC, a TRPM8 antagonist. VITROCELL cloud chamber exposure of BEAS-2B cell monolayers produced an increase in oxidation of mitochondrial proteins, increased expression of mitochondrial specific antioxidant enzyme SOD2, activation of NFκ-B, and secretion of inflammatory cytokines IL-6 and IL-8. Proteomics data collected following ALI exposure of EpiAirway tissue in the Cultex exposure system was analyzed using Ingenuity Pathway Analysis (IPA) and DAVID software. Menthol exposure of EpiAirway showed upregulation of NRF-2 mediated oxidative stress (z-score = 2.236), oxidative phosphorylation (z-score = 2.828), and IL-8 signaling (z-score = 2.714) as well as a downregulation of cell cycle regulation (z-score = -2.236), PTEN Signaling (z-score = -2.333), and HIPPO Signaling (z-score = -2.449). Our data are in good agreement across the three platforms and show that menthol causes adverse effects on respiratory epithelium via oxidative stress and inflammation, changes that could lead to disease with chronic exposure.

3201 Activation of Sensory Irritant Receptors by Pulegone, a Flavoring Monoterpene in Mint- or Menthol-Flavored Electronic Cigarettes

S. V. Jabba, and S. Jordt. *Duke University, Durham, NC.*

Pulegone is a naturally occurring organic monoterpene that is widely present in mint plants, including peppermint, spearmint and pennyroyal. As an ingredient of mint oils derived from these plants, pulegone is often found in food flavorings. Pulegone was recently detected in menthol/mint-flavored e-cigarettes and smokeless tobacco products in amounts that exceeded safety margins, raising health concerns. Pulegone is a group 2B carcinogen with clear evidence for promoting respiratory metaplasia and other neoplasms in rodent oral toxicity studies. Pulegone is also a respiratory irritant, producing strong sensory and epithelial irritation in the nose and lower airways upon inhalation. TRP ion-channels such as TRPA1, TRPV1 and TRPM8 serve as irritant and thermoreceptors in the sensory nerves innervating the airways. They are activated by aldehydes, acids and diverse flavor chemicals and initiate sensory irritant effects or chemesthetic effects such as cool or hot sensations. It is unclear which of these receptors are targeted by pulegone to elicit irritation. Using calcium microfluorimetry of 293T cells transiently expressing human and rodent orthologs TRPA1, TRPM8 & TRPV1 we demonstrate that pulegone has differential and species-specific pharmacological effects on irritant receptors. Pulegone robustly activated human TRPA1 but had very limited effects on rodent TRPA1 orthologs. Pulegone acted as a partial agonist of TRPM8 and TRPV1 for all species tested. Pulegone also inhibited menthol-induced TRPM8 activity, observed for both human and rodent TRPM8. Taken together, the data suggests that pulegone is a strong agonist of human TRPA1 irritant receptors and inhibits the TRPM8 cold/menthol receptor, potentially increasing irritant effects further. These mechanisms may underlie pulegone's strong irritant effects in the nose and lower airways.

3202 Transgenerational Effects of *In Utero* Secondhand Smoke Exposures on Asthma Development in Mice

A. Zaman. *Harvard College, Cambridge, MA.*

While the significant contribution of maternal smoking to the rise of asthma worldwide is well documented, recently, childhood asthma has also been associated with grand-mother smoking, indicating a potential trans-generational heritable effect. However, the mechanisms by which cigarette smoke (CS) or even second-hand smoke (SHS) exposures cause these trans-generational effects on lung disease development are currently unknown. It was previously demonstrated that CS induces a persistent activation of macrophages in the lungs, which produce matrix metalloproteinase-12 (Mmp12). This elastolytic enzyme is involvement in airway inflammation and remodeling. This study aimed to investigate the trans-generational effects of *in utero* SHS exposures on asthmatic responses in wild-type (WT) and Mmp12 knockout (KO) mice offspring. The parental WT and MMP12KO dams were exposed to 10 mg/m^{3}of SHS for 4 hr/day from gestational days 6 to 19. Respective control mice were exposed to filtered-air. Sub-groups of male F1 and F2 generation controls and SHS-exposed offspring were exposed to house dust mite (HDM) via intranasal instillation, to induce asthma-like symptoms; respective controls were treated with saline. The F1 and F2 offspring generations were sacrificed during adulthood. Biological endpoints included broncho-alveolar lavage fluid (BALF) analysis, lung histopathology, and gene expression. BALF analysis showed inflammatory responses to SHS plus HDM exposures. We evaluated the expression of 16 genes involved in chronic respiratory illness and we found that in both generations, 10 genes were up-regulated, including Ccl8, Ccl24, Ear11, Il13, and Muc5ac, and 4 genes were down-regulated, including Ahrr, Igf1, Lmo2, and Nfkb. Overall, these results suggest that *in utero* exposures to SHS may affect the susceptibility to develop asthma later in life and this effect may persist over generations.

3203 A Comparative Analysis of Salivary and Nasal Inflammation Biomarkers in Users of E-cigarettes, Hookah, and Cigarettes

J. Hess[1], E. Karey[1], J. Shearston[1], J. Eazor[1], T. Reed[1], L. Lee[1], I. Jaspers[2], M. Weitzman[1], T. Gordon[1], and T. Gordon[1]. *[1]New York University, New York, NY; and [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

The effects of cigarette smoking on human health have been extensively investigated, but the impacts of other tobacco derived products, hookah and e-cigarettes, are less known. Saliva collection is the prevailing non-invasive method to detect a range of biomarkers in clinical and research settings. Recent advances in biological sample collection and subsequent analysis

techniques have led to a non-invasive sampling method of the epithelial lining fluid (ELF) from the nasal passage. The ELF method collects a consistent volume, allowing quantification of low-abundance soluble biomarkers such as IL-2, IL-4, IL-6, IL-8, IL-10, IL-12p70, IL-13, IL-1ß, INF-y, and TNF-a. These inflammatory biomarkers can indicate the presence of chronic inflammation caused by cigarette, e-cigarette, and hookah use. Several studies have quantified inflammation marker levels in individuals utilizing either saliva or ELF, but no data have been published comparing saliva and ELF samples from the same individual for smokers or vapers. In this study, baseline samples of saliva and ELF were collected from 13 cigarette smokers, 17 e-cigarette vapers, 7 hookah smokers, and 16 non-smokers. Ten inflammation-related cytokines were quantified using the Meso Scale system. Seven of the biomarkers from the ELF of vapers showed significant differences from smokers and non-smokers, while no significant differences were seen in the salivary biomarkers.

3204 An Integrated *In Vitro* Mechanism of Action Assessment Approach for Evaluating E-cigarette Flavoring Compound Toxicity

D. Marescotti[1], D. McHugh[1], S. Acali[1], E. Nallet[1], A. Huber[1], F. Helbling[1], K. Kabalan[1], P. Leroy[1], M. Biasoli[1], F. Frauendorfer[1], D. Sciuscio[1], D. Utkarsh[2], K. Lee[2], M. Peitsch[1], P. Vanscheeuwijck[1], and J. Hoeng[1]. *[1]Philip Morris International, Neuchatel, Switzerland; and [2]Altria Client Services LLC, Richmond, VA.*

The use of flavors is important in the development of electronic nicotine delivery systems (ENDS). However, many flavors do not have safety or toxicity data. In this study, we structurally grouped over 200 common flavors into 38 groups and identified the Flavor Group Representatives (FGR) for each group. We evaluated the biological activity of each FGR and flavor mixture (with and without nicotine) by using a mechanistic *in vitro* screening assays of the real-time cellular analysis (RTCA) and the ToxTracker™ assay. RTCA with primary human bronchial epithelial cells helped identify the most cytotoxic flavors among individual FGRs, including (E,Z)-2,6-nonadienal, alpha-damascone, ambrox, alpha-pinene, 2-methoxy-4-methylphenol, benzyl alcohol, and delta-nonalactone. A parallel *in vitro* test was performed by using the mouse stem cell reporter assay (the ToxTracker® assay) to decipher the potential mechanism of action of each of the FGRs and flavor mixtures in terms of genotoxicity. Flavors and flavor mixtures with a positive signal in the initial ToxTracker® assay were further assessed in human TK6 cells by the *in vitro* FACS-based micronucleus assay, paired with the Multiflow™ assay (DNA-damage signature analysis as well as reactive oxygen species scavenger assay). This study demonstrates that *in vitro* screening assays such as RTCA and DNA-damage signature assays allow mechanistic investigation of the potential contribution of individual flavors to the cytotoxicity and genotoxicity of flavor mixtures.

3205 A Six-Month Inhalation Toxicology Study in ApoE$^{-/-}$ Mice Demonstrates Substantially Reduced Effects of E-vapor Aerosols on Cardiorespiratory Diseases

J. Szostak[1], E. Wong[2], B. Titz[1], T. Tom Lee[2], S. Wong[2], T. Low[2], K. M. Lee[3], J. Zhang[3], A. Kumar[3], W. K. Schlage[4], E. Guedj[1], B. Phillips[2], P. Leroy[1], A. Buettner[5], F. Martin[1], A. Sewer[1], A. Kuczaj[1], N. Ivanov[1], K. Luettich[1], P. Vanscheeuwijck[1], M. Peitsch[1], and J. Hoeng[1]. *[1]PMI R&D, Neuchatel, Switzerland; [2]PMI R&D, Singapore, Singapore; [3]Altria Client Services LLC, Richmond, VA; [4]Biology Consultant, Bergisch Gladbach, Germany; and [5]Histovia GmbH, Overath, Germany.*

Chronic cigarette smoke (CS) exposure causes cardiorespiratory diseases in smokers. Considerable attention has been given to the reduced harm potential of e-vapor products. ApoE$^{-/-}$ mice were used to evaluate lung inflammation, emphysema, atherosclerosis, and cardiovascular function upon chronic (6-month) exposure to fresh air, CS, or e-vapor aerosols. Mice were exposed to CS from 3R4F cigarettes or e-vapor aerosols (generated by using capillary aerosol generators) from various e-liquids (CARRIER: humectants [propylene glycol and glycerin]; BASE: humectants and nicotine; and TEST: humectants, nicotine, and flavors) via the whole-body inhalation system. Exposure to CS (35 µg nicotine/L) caused adverse effects on the lungs (including increased lung volume and inflammation), accelerated atherosclerotic plaque formation, and altered the cardiorespiratory transcriptome. CS exposure caused impairment of systolic and diastolic cardiac function, as assessed by ejection fraction, fractional shortening, isovolumic relaxation time, and E/A ratio. In contrast to CS, e-vapor aerosol exposure did not accelerate atherosclerotic plaque formation, was associated with limited to absent inflammatory cells in the lung tissue, and induced substantially fewer molecular changes in the cardiorespiratory transcriptome. Ultrasound analysis revealed that cardiac dysfunction and aortic stiffness were less prominent in the nicotine-containing e-vapor aerosol-exposure groups than in the CS-exposed group. In conclusion, these results suggest that, relative to CS, e-vapor aerosols induce substantially lower biological responses associated with smoking-related cardiovascular and pulmonary diseases.

3206 Novel Uses of Analytical Platforms for Efficacy/Safety Biomarker Selection to Improve De-Risking of Therapeutics

J. McDuffie. *Janssen Research & Development, San Diego, CA.*

Monitoring for drug-induced organ toxicities remains a challenge. A critical gap is the availability of tools to specifically and sensitively detect changes in the emerging variety of biomarkers. The Critical Path Institute's Predictive Safety Testing Consortium, industry, and academic researchers have performed prospective preclinical and clinical studies that reveal the unique challenges and benefits of novel biomarker detection technologies. Best practices were established to ensure reproducible approaches for identifying gene and protein expression profile changes in biopsies, single cells, blood, and/or urine samples that define and reveal cross-species concordances. The most robust platform for analyte measurement depends on the biological matrix and anticipated biomarker context of use. Next-generation multiplex instruments and assays have been developed to support microRNA, gene transcript, and protein quantitation. These tools provide a variety of species-directed high-throughput ribonucleic acid sequencing (RNA-seq) assays and antibodies to discover and validate biomarkers that distinguish injury to specific organs. The aim of this session is to provide an overview of analytical platforms, assays, and translational, drug-induced organ-specific biomarkers to support risk assessment.

3207 Next-Generation Toxicologist Training through Innovative Summer Internships

L. Aleksunes. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Establishing a pipeline for the next generation of scientists is critical for the advancement and expansion of toxicology. Only a limited number of students are exposed to toxicology through curricula in typical undergraduate science majors. As a result, immersion experiences, including fellowships and internships, provide intensive training of undergraduates in toxicology. Typically, summer programs include full-time mentored research in toxicology for up to three months. These experiences cover responsible conduct of research, experimental design, literature evaluation, data interpretation, and scientific communication. Cohort experiences that engage multiple undergraduate students provide the opportunity for networking and other career-directed activities. This session aims to provide five-minute talks by successful summer program directors and principal investigators from academia, government, and industry that highlight innovations in undergraduate student engagement in toxicology research. A "blitz" of short talks will provide tangible examples that individual scientists and programs can apply to designing and developing their own summer research experiences. This session will be particularly valuable to research advisers, program directors, and near-peer mentors (including graduate students and postdocs). Topics that will be highlighted include innovation in recruitment, resources, weekly programming, peer-peer networking, faculty training, diversity and inclusion, field trips, internships in pharmaceutical companies, and social enrichment. Initiatives include pipelines between liberal arts colleges and research universities, as well as long-term sustainability of programs using sound financial models. Opportunities for funding summer internships from federal sources, such as the National Institutes of Health, and organizations, including the SOT internship program, will be reviewed. The second half of the session will include a moderated panel discussion of various approaches to recruitment, mentoring, team-building, networking, presentation, assessment, matriculation into PhD programs, and long-term tracking. During the panel discussion, attendees are encouraged to ask questions of successful program directors with deep experience in developing and maintaining successful summer internships.

3208 Human Stem Cell-Derived Test Systems as Alternative Approaches for Developmental Neurotoxicity (DNT) Evaluation: Research and Regulatory Perspectives

A. Price. *European Commission Joint Research Centre, Ispra, Italy.*

There is consensus between scientific stakeholders from regulatory agencies, academia, and industry calling for a new framework for regulatory developmental neurotoxicity (DNT) testing based on implementation of alternative approaches relevant to human brain development. A variety of methods have been developed over the past decade to assess neurotoxicity, developmental toxicity, and developmental neurotoxicity, based on human biology instead of animals. Stem cell-based methodologies have taken centerplace here. Although these methods are widely used in research, their implementation within a regulatory context has been slow. This Symposium will give an overview of the human stem cell-based methods for (developmental) neurotoxicity evaluation, and it will highlight their status of regulatory implementation, hurdles encountered on the way there, and strategies to promote their increased use. A pivotal step for regulatory implementation is confidence building, with respect to the reproducibility, reliability, and relevance of the methods. To facilitate this process, methods will be regarded as to their position on a quantitative readiness scale developed two years ago in an international collaboration of regulators and scientists. Requirements for readiness differ for various applications (e.g., for initial screens to prioritize compounds for further testing versus risk assessment of a final product), and this determines the panels of methods currently available for the respective regulatory applications. New developments of stem cell-based neuronal/glial *in vitro* methods will be discussed in light of their use as alternative *in vitro* test systems for (D)NT evaluation for different regulatory purposes (screening and prioritization, hazard identification/characterization, and risk assessment). The ongoing international DNT project under the umbrella of the OECD and in close collaboration with the European Food Safety Authority, US Environmental Protection Agency and US Food and Drug Administration, Health Canada, and Japan that aims to develop the OECD Guidance Document on an *in vitro* battery of DNT assays' regulatory application and data interpretation will be presented. Scientists with relevant expertise in basic stem cell research and regulatory toxicology will present the potentials and limitations of human stem cell-derived neuronal/glial cultures for evaluation of peripheral and central nervous system (D)NT. Two dimensional (2D) models will be characterized against three dimensional (3D) culture systems, discussing the implementation of the *in vitro* battery of assays that permits evaluation of key neurodevelopmental processes. Furthermore, recent studies in which assembly of organotypic vascular and brain tissues has been explored will be presented, with emphasis on reproducibility and data transferability. The difference in response of neuronal culture derived from human pluripotent stem cells to a single chemical and in mixture will be evaluated using *in vitro* assays anchored to key events identified in the adverse outcome pathways network relevant to DNT (AOP-Wiki). The session attendees will have a better understanding of the benefits, challenges, and applications of stem cell-derived *in vitro* models for disease modeling and neurotoxicological studies, with emphasis on DNT evaluation for regulatory purposes. They will be informed on current international efforts that should soon result in the development of the first OECD Guidance Document on an *in vitro* approach to DNT testing.

3209 Differentiation of Human Pluripotent Stem Cells to Specific Neuronal Lineages to Study Windows of Susceptibility and Lineage-Specific Effects of Toxicants: Perfluoralkyl Substances and Methylmercury

A. Bowman. *Purdue University, West Lafayette, IN.*

Human induced pluripotent stem cells (hiPSCs) can be differentiated down specific neuronal lineages in a manner that models typical developmental ontogeny. Such ontogeny-recapitulating methods yield the temporal expression patterns of neural lineage specific markers in sequence to their expression seen during embryonic development. Thus, by timing *in vitro* exposures during hiPSC differentiation, it may be possible to model windows of developmental exposure susceptibility in a lineage specific manner. Further, experimental approaches can be established to determine whether exposures tied to a specific developmental time point will impact subsequent developmental markers and function. We have established methods to differentiate hiPSCs along a cortical glutamatergic lineage and a floorplate dopaminergic lineage. Exposure of both lineages during two key developmental stages: (1) early neuroprogenitor stage, and (2) at the post-mitotic neural specification stage—corresponding to *in vitro* differentiation time points of days 4-10 and 14-20. Continued differentiation and maturation to early premature neurons day 60 and beyond permits assessment of mature neuronal markers and functional characterizations. Exposures to three known or suspected neurodevelopmental toxicants are being examined: methylmercury (MeHg) and two perfluoralkyl substances, perfluorooctanesulfonic acid (PFOS) and perfluorooctanic acid (PFOA). Continuous exposure over one or both developmental windows at concentration curves spanning environmentally relevant exposures (MeHg: 0.1-10 μM; PFOS and PFOA: 4-4,000 ppb) is being performed and comparative toxicological and developmental outcomes measures assessed at early and late developmental time points. These data will be used to highlight the strengths and weaknesses of this approach to understand developmental neurotoxicity.

3210 Robust and Scalable Assembly of Human Neurovascular Tissues for Disease Modeling and Discovery

W. L. Murphy. *Forward BIO Institute and University of Wisconsin–Madison, Madison, WI.* Sponsor: A. Price

The need for human organotypic culture models coupled with the requirements of contemporary drug discovery and toxin screening (i.e., reproducibility, high-throughput, transferability of data, clear mechanisms of action) frame an opportunity for a paradigm shift. The next generation of high-throughput assay formats will require a broadly applicable set of tools for human tissue assembly and analysis. Toward that end, we have recently focused on (1) generating iPS-derived cells that properly represent the diverse phenotypic characteristics of developing or mature human somatic cells; (2) assembling organotypic cell culture systems that are robust and reproducible; (3) translating organotypic cell culture models to microscale systems for high-throughput screening; and (4) combining genomic analyses with bioinformatics to gain insights into organotypic model assembly and the pathways influenced by drugs and toxins. This talk will emphasize assembly of organotypic vascular and brain tissues. These tissues mimic aspects of human organ structure and can be used for reproducible identification of drug candidates and toxicants by both academic and industry scientists. We particularly emphasize reproducibility and data transferability, which are important for the widespread use of organotypic human models in toxicity testing, including in emerging industry applications. The talk will also describe assembled human tissues as models of rare neurodevelopmental disorders of the brain.

3211 Mechanistic Studies of Developmental Neurotoxicity Induced by Exposure to Mixture of Chemicals Using Human *In Vitro* Model for Regulatory Purposes

A. Price. *European Commission Joint Research Centre, Ispra, Italy.*

Key neurodevelopmental processes are vulnerable to perturbations by exposure to environmental chemicals that induce toxicity through multiple mechanisms. We have confirmed in hiPSCs-derived mixed cultures of neuronal and glial cells the physiological response of Nrf2 (nuclear factor erythroid 2-related factor 2) and CREB (cAMP responsive element binding protein) signaling pathway upon specific stimulation and inhibition. In the presence of oxidative stress, Nrf2 nuclear translocation and the upregulation of Nrf2-target enzymes (NQO1, SRXN1, and HMOX1) was observed. The inhibition of the CREB pathway decreased neurite outgrowth and synaptogenesis, presumably through decreased BDNF production. In the follow-up studies, using the same hiPSCs-derived mixed neuronal/glial cultures, the effects induced by mixtures of heterogeneous classes of chemicals (industrial chemicals, drugs, pesticides, endocrine disruptors, and cosmetics) acting through similar and dissimilar modes of action have been evaluated in comparison with a single chemical exposure. The applied assays were anchored to common key events (including oxidative stress and alternations in BDNF levels) of adverse outcome pathways (AOPs in AOP-Wiki), resulting in learning and memory impairment in children. The readiness of these assays for regulatory use was evaluated following semi-quantitative criteria. Based on the obtained results, a battery of *in vitro* DNT assays is proposed for the potential identification of chemicals associated with learning and memory impairment in children, discussing how observed *in vitro* cellular alternations could facilitate mechanistic understanding of behavioral changes. These assays could be included in an Integrated Approaches to Testing and Assessment for different regulatory purposes since learning and memory evaluation is required for DNT regulatory testing.

3212 Stem Cell-Based Developmental Toxicity Testing of the Peripheral Nervous System in Various Regulatory Contexts

M. Leist. *EU-ToxRisk, Konstanz, Germany.*

In the past years, pluripotent human stem cells and their progeny have been used increasingly to establish assays for neurotoxicity testing. Many examples on the measurement of positive controls and underlying mechanisms of toxicity are available, but regulatory uptake has been slow. We present steps to overcome this for tests addressing toxicity to the peripheral nervous system. Three different assays are described here: UKN1 measures early neural differentiation (up to the neuroepithelial stem cell stage), the cMINC measures the capacity of peripheral nervous system precursors (neural crest cells) to migrate, and the PeriTox test measures formation and function of peripheral nervous neurites. Tests were used for regulatory mock submission dossiers to obtain feedback from regulators on the sufficiency of test documentation, validation state, and data relevance. The tests also were used to establish QSAR for potential neurotoxicity of novel cancer drugs and to support read-across hazard evaluation of valproic acid derivatives. The data suggest that the stem cell-based tests for peripheral neurotoxicity are robust and sensitive for questions in a regulatory context. The three tests together detected 48% of a large panel of developmental neurotoxicants. However, many of these toxicants have modes of actions not covered by the test we focused on. Therefore, they will have to be integrated into a larger test battery, which is then expected to have higher sensitivity. A pilot study on this is ongoing, and the outcome is likely to be available by the end of 2019, and to be presented in the session.

3213 2D and 3D Stem Cell-Based *In Vitro* Methods for Assessing DNT: From Basics toward Regulatory Application

E. Fritsche. *IUF—Leibniz Research Institute for Environmental Medicine, Düsseldorf, Germany.*

Testing for DNT according to the OECD/US Environmental Protection Agency guidelines is performed in rats. This rodent bioassay does not allow the evaluation of large numbers of chemicals because it is too resource intensive. In addition, species differences between rodents and humans might impede extrapolation of testing results to humans. Due to these obstacles, a DNT *in vitro* testing battery has been assembled that is currently challenged with more than 100 chemicals. Under the umbrella of the OECD and in a collaborative effort with several regulatory agencies as well as academia and industrial partners, a DNT *in vitro* guidance is being developed, taking the future results of the testing battery into consideration. Besides guiding how to perform DNT *in vitro* assays, this OECD guidance will advise on data interpretation, considering metabolism, biological barriers, and temporal aspects of brain development. Also, limitations of the battery (e.g., concerning spatial complexity of brain development) will be pointed out. Results of the testing battery of the test methods neural progenitor cell (NPC)1-5 (i.e., NPC proliferation, migration, differentiation into neurons and glia) will be presented. These methods are thought to predict human DNT; however, due to the lack of human data, only few examples of *in vivo* to *in vitro* extrapolation with regard to toxicodynamics will be given. Toxicokinetics will be covered by *in silico in vitro in vivo* extrapolation (IVIVE). In addition, as the test methods of the battery will be subject to change as science moves on, data on hiPSC-derived 2D and 3D neural differentiation will be shown as examples of test development at an earlier stage. Here, the focus will be on standardization and reproducibility of endpoint measurements. Advantages of fluorescence-labeled target cells will be presented. Results of this current work in progress will reveal suitability of NPC test methods for DNT *in vitro* testing as part of a testing battery. This DNT *in vitro* battery aims to be implemented in regulatory frameworks by the OECD guidance and may finally be included into the OECD DNT TG426 as a basis for more targeted *in vivo* testing. In the long run, it is anticipated to fully replace the *in vivo* TG 426 with a combination of *in silico* and *in vitro* assays. This battery not only will reduce the number of animals used but also will provide a new business opportunity for CROs.

3214 Improving Our Understanding of Toxicant Metabolism and Cytochrome P450s Using Novel Knockout Models and High-Throughput Methods

D. Carlin. *NIEHS, Research Triangle Park, NC.*

The relationship between exposure to environmental chemicals/pharmaceuticals, tissue dose, and toxic mechanism cannot be properly understood without a thorough understanding of compound metabolism, whether it is bioactivation or detoxification, or somewhere in between. Specifically, a thorough understanding of the role that the major metabolic enzyme family, the cytochrome P450s (CYPs), plays in metabolism is needed, as these enzymes are of critical importance in the detoxification of harmful environmental chemicals and drugs. CYP enzymes are particularly challenging to study because they may vary in their metabolism of chemicals, they exhibit significant overlap in substrate specificity between isoforms, and they have large differences in complement and function across species. To add to these challenges, toxicology is moving toward high-throughput assays in toxicity testing due to the expanding number of chemicals found in commerce and the environment. In this session, we will examine the state-of-the-science of CYP in metabolism, novel *in vitro* and *in vivo* high-throughput assays, the challenges to implementation of these assays, and the development of various novel knockout and humanized models to support extrapolation of data from these systems. This session also will highlight future directions for the application of these systems in intervention and prevention of exposure to harmful environmental chemicals and to accelerate the prediction of toxicity of novel pharmaceuticals.

3215 The Future of P450 Research: Basic Questions and Practical Applications

F. Guengerich. *Vanderbilt University Medical Center, Nashville, TN.*

Our collective knowledge about the application of cytochrome P450 (P450, CYP) research to problems in toxicology has grown considerably since the enzyme system was discovered 57 years ago by Omura and Sato. These enzymes are the major catalysts in the biotransformation of drugs, environmental pollutants, and chemical carcinogens, and fundamental knowledge about them has led to important advances in toxicology and pharmacology, as well as fields as diverse as endocrinology, environmental remediation, and biotechnology. As the field has matured, more detailed investigations are in order. Major ones include the molecular basis of the broad specificity of P450s and the nature of the conformational changes that permit P450s to catalyze oxidations of so many molecules. An important deficit is the effects of binding of accessory proteins to P450s on their structures, regarding their functions. Another structural biology deficit involves the genetic variants of human P450s, as related to abnormal function and, in some cases, phenotypic deficiencies related to disease susceptibility. This laboratory has been interested in several of these questions, as well as the continuing issue of how to annotate P450s in regard to their functions (i.e., classifying "orphan" P450s in terms of catalytic function). In addition to these fundamental science problems with P450s, there are many applied issues to address as well. Major questions involve applications to using our knowledge of human variants to avoid drug toxicity and increase efficacy, as well as to better understand roles of these variations in responses to environmental exposures. There also are issues related to genetic variations on an international scale. We have identified oxidative damage in human P450s (sulfenylation, including the heme thiolate) but need to address the significance of this and other oxidative damage under physiological conditions. There are many facets of P450 research that still remain to be addressed.

3216 High-Throughput Screening for Zebrafish Cytochrome P450 Substrates Provides Insight into Enzyme Function

J. Wilson. *McMaster University, Hamilton, ON, Canada.*

The functions of many mammalian cytochrome P450 (CYP) enzymes are well understood, and there are specific and selective probe substrates to assess enzyme expression and function. Yet, there are significant numbers of orphan CYP enzymes, and functional characterization of these proteins is very challenging. These challenges are due to complex evolution and gene duplications in the families responsible for chemical detoxification and co-expression of CYP enzymes in detoxification organs. While heterologous expression of individual CYP enzymes proffers the assessment of individual CYP *in vitro*, deploying individual assays for compound metabolism is a slow and arduous process to characterize function. High-throughput screening offers an exciting opportunity to more quickly provide data on CYP-mediated com-

pound metabolism. This talk will outline the major issues with assessing CYP-mediated compound metabolism, based on evolutionary differences in gene complement and the overlapping capacities of zebrafish enzymes for fluorogenic probe substrates, using CYP1 and CYP3 enzymes as primary examples. To address these issues, we have developed a high-throughput screening approach based on the consumption of the co-factor nicotinamide adenine dinucleotide phosphate (NADPH) as an endpoint to indirectly measure catalytic activity. Using heterologously expressed enzymes and a compound library of pharmacologically active, natural or off-patent small molecule compounds, we have screened zebrafish CYP1 and CYP3 enzymes. The screen and follow-up provide key data to assess the important role of CYPs in xenobiotic metabolism and a direct assessment of the potential for neo- or sub-functionalization of CYP enzymes.

W 3217 Cytochrome P450 Knockout Zebrafish in Toxicology

J. Goldstone. *Woods Hole Oceanographic Institution, Woods Hole, MA.*

Zebrafish are important test organisms for mechanistic toxicological research and for the safety assessment of manufactured and environmental chemicals, yet aspects of metabolism critical to the use of this model are not fully understood. Zebrafish are used in a regulatory context for environmental toxicology in Europe and have become an important toxicology model in the US. However, while cytochrome P450 gene regulation is an important bioindicator in zebrafish, the functioning of the cytochrome P450 systems in xenobiotic metabolism is not well described. Gene-engineered model organisms offer potent systems for studying metabolism and disposition. We have produced and partially characterized transgenic knockout zebrafish for five CYP1 genes, as well as for the orphan CYP20A1 gene. Knockout strains exhibit generally normal development, suggesting that endogenous substrates of these P450s may be generated by other P450s (substrate overlap) or may not be essential for laboratory reared zebrafish. Xenobiotic and indicator substrate metabolism also is altered in these knockout strains. In particular, CYP1A-null zebrafish larvae exhibit strongly decreased whole body ethoxy- and methoxyresorufin (EROD and MROD) metabolism when treated with beta-naphthaflavone for 24 hours, although the EROD/MROD ratio is nearly the same. In addition, the "orphan" CYP20A1-null zebrafish exhibits altered behavior in different behavioral paradigms, particularly those correlating with hyperactivity. Zebrafish increasingly are being used as predictive models of toxicity in various organs, with predictivity in the range of 70%-91%. This research provides a mechanistic understanding of CYP function in a powerful *in vivo* model.

W 3218 Transgenic *Caenorhabditis elegans* Models for Studying P450-Mediated Drug- and Toxicant-Induced Toxicity

J. Hartman. *Duke University, Durham, NC.*

Cytochrome (CYP) P450 enzymes (P450s) metabolize hydrophobic drugs, pollutants, and endogenous chemicals by a monooxygenase reaction that can result in detoxification or, paradoxically, bioactivation to reactive metabolites. Although the metabolism of many chemicals by P450s has been studied in-depth through *in vitro* and *in vivo* experiments, many more chemicals' toxicity and, importantly, mechanism of toxicity are not well understood. As a new tool to study the consequences of P450 metabolism, we developed transgenic *Caenorhabditis elegans* nematodes that express human cytochrome P450 enzymes or orthologs. *C. elegans* have 84 cytochrome P450 genes in their genome; however, total P450 expression levels and activity for common P450 marker substrates are very low relative to high-expression vertebrate tissues such as liver, giving a minimal background in these transgenic animals. The animals are also short-lived (with median life span about 17 days), allowing toxicity outcomes to be measured throughout their lifetime. Other benefits of *C. elegans* include a fully sequenced and well-annotated genome, access to genetic mutants and/or RNAi knockdown of most genes in the genome, ease of generating transgenic mutants through various methods including CRISPR/Cas9, and availability of many fluorescent reporters that allow for medium-throughput analysis of gene expression, redox status, and other measures. So far, we have successfully generated nematodes expressing zebrafish CYP1a and human CYP2E1. We have measured expression of these enzymes at the mRNA and protein level, and enzymatic activity using EROD and 4-nitrophenol assays, respectively. We cannot detect either enzyme expression or activity in wild-type animals but are able to measure robust expression and activity *in trans*genic animals. Compared with wild-type, transgenic CYP1a-expressing nematodes are dramatically protected from PAH toxicity, while CYP2E1-expressing animals are more sensitive to toxicity from the drug acetaminophen. In ongoing and future studies, we are further utilizing CYP1a- and CYP2E1-expressing animals, creating a CYP1B1-expressing nematode, as well as targeting expression of these P450 enzymes specifically in cells of interest, such as dopaminergic neurons. This model holds promise for mechanistic toxicological studies of compounds that are metabolized through cytochrome P450 enzymes.

W 3219 Novel Knockout Animal Models for Studying P450-Mediated Toxicity

W. Baldwin. *Clemson University, Clemson, SC.*

Our laboratory is investigating the roles of CYPs in the regulation of lipid metabolism, obesity, and liver disease in mouse models, and the mechanisms by which toxicants disrupt lipid homeostasis. We recently developed a novel Cyp2b-null mouse model using Crispr/Cas9 that lacks the hepatic Cyp2b members, Cyp2b9, Cyp2b10, and Cyp2b13, found in tandem repeat to test whether loss or inhibition of CYPs increases non-alcoholic fatty liver disease (NAFLD) and obesity. Cyp2b-null male mice develop NAFLD and are diet-induced obese (60% fat; HFD) in comparison with wild-type mice. Interestingly, Cyp2b-null male mice develop steatosis regardless of diet. Thus, normal diet (18% fat)-fed Cyp2b-null male mice show a similar RNA-seq-generated transcriptomic profile as HFD-fed wild-type mice with significant changes in lipid metabolism pathways, including PUFA metabolism and fatty acid elongation. Because of the increase in NAFLD in Cyp2b-null mice, we investigated the effects of a methionine-choline deficient diet on HFD-induced fatty liver disease. This research confirmed that Cyp2b-null male mice are more susceptible to NAFLD and non-alcoholic steatohepatitis (NASH) than wild-type mice. In contrast, female Cyp2b-null mice are less susceptible to NASH than wild-type mice. We also just finished producing a transgenic humanized CYP2B6 (hCYP2B6-Tg) mouse model on the Cyp2b-null background, and CYP2B6 reversed the diet-induced obesity found in Cyp2b-null mice. Targeted lipidomics suggests that changes in linolenic acid metabolism may be responsible for these effects. Lastly, the presentation also will briefly discuss the phenotype of Cyp3a-null mice as in contrast to Cyp2b-null mice, the females are somewhat resistant to diet-induced obesity. Overall, the purpose of this project is to test whether alterations in Cyp2b and Cyp3a activity (such as chemical inhibition) can alter lipid metabolism and in turn cause NAFLD and obesity.

W 3220 New Frontiers in Dynamic Toxicology

J. Wambaugh. *US EPA, Research Triangle Park, NC.*

The evolution of toxicity over time has often been characterized with serial observations and models based upon differential equations. New techniques are becoming available that allow additional insight into the dynamics of toxicology from various perspectives. In addition to addressing when, the speakers in this session describe tools for understanding who, what, where, how, and/or why chemical toxicity and exposure may occur to specific, susceptible populations. Depending upon the mechanism of action, windows of susceptibility exist as part of biological development and aging during which the effect of toxic perturbations may be greatly increased. The timing and magnitude of chemical exposures add a layer of complexity on top of biology, as exposures are subject to human activities and whims. Passive samplers can provide a record of exposure to a variety of chemicals over a time interval of activity. Alternatively, exposomics projects can provide snapshots of diverse biometric and chemical exposure information. Mathematical modeling and dynamic machine learning can allow inferences to be drawn from both time-integrated and instantaneous information. Affect modeling can help address the why of human behavior—what drives patterns of product use and chemical co-exposure? Meanwhile, machine-learning methods for time-series data can draw powerful inferences about what goes on between the sampling intervals. All the new approach methodologies (NAMs) presented can inform modern toxicological assessment of the chemical effects on public health. The Workshop will conclude with a moderated panel discussion where speakers will address audience questions on how to apply the methods presented to toxicology. In this session, each speaker will (1) provide example systems, made relevant to toxicologists, in which important aspects change over time; (2) describe the key challenges in understanding the example systems; (3) characterize which aspects change over time and which are constant; (4) describe publicly available tools or methods for analysis of their examples; and (5) consider how better characterization of dynamics can inform toxicology and chemical risk assessment.

3221 Windows of Susceptibility

A. Lumen. *US FDA/NCTR, Jefferson, AR.*

Several physiological changes occur during gestation to meet the needs of both the mother and the developing fetus. Such increased physiological demands and strained compensatory functions leave pregnant women and the fetus more vulnerable to toxicological perturbations. In this talk, the speaker will introduce the audience to the concept of "windows of susceptibility," specifically focusing on the gestational period. Often, it is implausible to obtain rich toxicodynamic data in these sensitive life stages. Therefore, the need and utility of computational tools such as physiologically based pharmacokinetic (PBPK) and biologically based dose-response (BBDR) modeling to make appropriate toxicological evaluations will be discussed. The talk also will feature a case study demonstrating the application of modeling techniques to evaluate perturbations due to environmental contaminant exposure in sensitive gestational life stages (pregnant women and developing fetus). References for published and publicly available algorithms for such computational tools for independent evaluation by the audience will be provided.

3222 Time-Integrated Exposures to Identify Chemical Profiles between Healthy and Dysphagic Foals

B. Rivera. *Oregon State University, Corvallis, OR.*

Passive samplers serve as a sensitive tool to capture time-integrated exposure of an individual. Sequential sampling can be done to determine if exposure profiles vary over time, based on other environmental factors (seasonal variability, location, etc.). In this study, foals born at a location in proximity to unconventional drilling had a higher incidence of dysphagia compared with foals, bred by the same owner, in an area without active drilling. Consecutive sampling was conducted over the entire gestational period of these foals to investigate if an association between exposure profiles and health outcome exists. Halter samplers, capturing individual exposure, and stationary well water and air samplers were used to identify potential routes of exposure associated with unconventional drilling. Analysis of well water samplers identified differences in polycyclic aromatic hydrocarbon (PAH) profiles between the two locations. PAHs with three or more rings were higher in the area with active drilling, and two-ring PAHs were higher in the area not active in drilling. After the installation of a water treatment system at the active drilling location, a decrease in concentration of PAHs with three or more rings was reported. Additionally, during this time, a decrease in incidence of dysphagia also occurred.

3223 Air Force Surgeon General's Total Exposure Health Initiative: At the Intersection of Toxicology and Exposomics

H. Pangburn[1], D. Yamamoto[2], Y. Chushak[3], R. Pitsch[3], J. Martin[3], M. McCarthy[3], C. Davidson[3], E. Pitts[3], D. Ott[3], J. Wambaugh[4], M. Linakis[3], T. Covington[3], L. Sweeney[3], and J. Gearhart[3]. *[1]US Air Force Research Laboratory, Wright-Patterson AFB, OH; [2]Air Force Research Laboratory, Wright-Patterson AFB, ND; [3]Air Force Research Laboratory, Wright-Patterson AFB, OH; and [4]US EPA, Research Triangle Park, NC.*

Health care in the 21st century has been transformed with the availability of a reference human genome sequence accompanied by intensive efforts to understand the genetic basis of disease and treatment on an individualized level as exemplified by President Obama's Precision Medicine Initiative. A strategic vision of the Air Force Medical Service is to craft the "healthiest and highest performing segment of the US by 2025." In a step toward realizing this strategic vision, the Air Force Surgeon General launched the Total Exposure Health (TEH) initiative. TEH envisions transforming health care from a reactive stance to a proactive stance by harnessing informatics to integrate all available data (genomic, lifestyle, occupational, environmental exposures, etc.) to inform the warfighter and commanders of their health risks, fostering health-engendering behaviors and actions. This presentation will address how the Air Force is leveraging and advancing exposure science coupled with employing a systems biology approach that uses toxicological new approach methodologies (NAMs) to include computational modeling and cell biology with proteomics, genomics, metabolomics, epigenetics, and bioinformatics to address TEH requirements in hopes of elucidating underlying mechanisms of effects based on given sets of exposures from a molecular- to human-level perspective. A case study on research in the area of characterizing physiological and environmental effects in the very dynamic environment of high-performance aircraft (almost all parameters change over time: exposure, breathing rate, chemical profile, altitude, humidity, physiological support, etc.) pertaining to in-flight physiological stressors will be discussed, as well as how the Air Force routinely leverages public databases and software to include ECHA, nite, httk, OECD QSAR Toolbox, and ochem.eu to deliver rapid responses to our operational community. Using a systems biology approach to address TEH requirements has great potential to determine/deliver personalized safe exposure levels and knowledge supporting the development of individualized treatment and mitigation strategies.

3224 The Habits and Practices of Beauty: The Technical Truth Underlying Consumer Perception

K. Krishan. *Procter & Gamble, Singapore, Singapore.* Sponsor: J. Wambaugh

Product innovation for fast-moving consumer goods is designed around consumer behavior and linking consumer perception to product performance. The challenge is to deliver delighting experiences across a spectrum of end-use conditions. Physical, biological, social, and environmental conditions lead to usage habits and practices impacting product performance that are hard to reproduce in the laboratory. The forefront of innovation in the beauty industry relies on deeper behavioral insights that determine the short- and long-term benefits of products. This will be illustrated with examples from across this industry. The characterizations here place the context under which toxicological impact factors need to be assessed.

3225 Modeling, Machine Learning, and Time-Series Data

A. Pitruzzello. *Northrop Grumman Corporation, Morrisville, NC.* Sponsor: J. Wambaugh

Wristbands can give us a time-integrated measure of chemical exposure, while exposomics can give us a snapshot of instantaneous exposure and health metrics. How can we bridge the gap? Given a mathematical model characterizing the dynamics of a system, time-series machine learning can allow classification and anomaly detection. These techniques have been applied in systems ranging from medical (ECG signals) to interpreting data from diverse sensor arrays. The speaker will provide commentary on how these technologies can inform inference of cellular dynamics. Brief examples will be given to introduce toxicologists to these powerful, open-source algorithms and tools.

3226 Parental Cannabis Exposure and Long-Term Neurobehavioral Deficits in Offspring

K. Ryan. *NIEHS/NTP, Research Triangle Park, NC.*

Recreational and medical marijuana are not recommended for use during pregnancy. However, cannabis use by pregnant women in the US has increased as much as 62% (2002-2014) with an overall prevalence of use between 3-16%. Current human and experimental evidence suggest that maternal cannabis use during pregnancy is associated with a spectrum of adverse neurological deficits in children or offspring. Similarly, paternal cannabis use causes abnormal epigenetic imprinting on sperm which could impact development of the next generation. However, some discrepancies exist in the available data which could contribute to some confusion among consumers or a lack of concern related to cannabis use during times of fetal development. In addition, many consumers may not be aware of the harmful consequences of cannabis use, by either parent, on fetal development as well as long-term effects on neurocognition and behavior. The firs presentation will highlight the increasing use of cannabis among women during pregnancy and nursing for pain and nausea as well as among men prior to conception. Some misconceptions regarding cannabis use and risk among consumers will also be presented. As a result of increased use, longitudinal studies are linking fetal cannabis exposure to decreased growth, cognitive impairment, and behavior deficits in children. The second presentation will provide evidence suggesting that studies performed in rodents mirror clinical findings and allow more in-depth assessments of neurobehavior and associated molecular phenotypes. Results of various human and animal studies will also be discussed in the context of generating education strategies or interventions to improve the mental health outcomes of children subjected to cannabis exposure *in utero*. In addition to maternal exposure, the third presentation will highlight new evidence suggesting that paternal exposure to cannabis prior to conception can also impact neurobehavior using preclinical rodent models. A goal of this talk is to link cannabis exposure, changes in DNA methylation, and subsequent cognitive impairment as well as bring awareness to this understudied

area of research. The fourth presentation strengthens the weight of evidence by linking parental cannabis exposure and adverse effects on neurodevelopment in a third species (i.e. zebrafish). Use of this complementary model system allows for the assessment of cannabis or its hundreds of components on development, behavior, and reproduction across multiple generations; which is often a resource intensive task in rodent models or human studies. The final presentation will provide insight from the public health perspective. This presentation focuses on the real-world application and utilization of preclinical and clinical research which is critical to the development of public health recommendations and communication of risks related to prenatal cannabis use and potential adverse childhood health outcomes. The workshop will end with an informal deliberation among panel speakers and audience to 1) review the current weight of evidence for neurological deficits in children as a result of parental cannabis use during pregnancy, 2) propose strategies for research data gaps, and 3) discuss communication strategies to highlight risks for consumers. This session brings together experts across clinical and preclinical research settings, including several non-SOT members with expertise specifically identified to highlight the state of research regarding parental cannabis exposure and adverse consequences to the developing nervous system. Importantly, adverse effects on neurobehavior are supported by results across multiple species including humans, rodent models, and zebrafish which emphasizes the need for more toxicological research during critical stages of development. Furthermore, the toxicological science of drugs of abuse has been greatly under-represented at SOT relative to its societal importance and progress in the field. In 2019, SOT had one workshop about the toxicology of drug abuse. That workshop focused on how many types of drug abuse affect adolescence. In 2020, we have a chance to continue our efforts promoting research into the socially important areas of the toxicology of drug abuse, this time with a focused discussion of cannabis exposure during early development and its persisting neurotoxic effects.

W 3227 Marijuana Use in Pregnancy: Sorting through Hazy Evidence

T. Metz. *University of Utah Health, Salt Lake City, UT.* Sponsor: K. Ryan

The prevalence and perceived safety of marijuana use in pregnancy are increasing with expanding legalization in the United States. Marijuana crosses the placenta and passes into breast milk. Some women cite reasons for marijuana use in pregnancy and while breastfeeding, such as nausea, pain, and anxiety. The existing literature is heterogeneous with regard to the impact of marijuana use on pregnancy and early childhood outcomes. A National Academies of Sciences report on the health effects of cannabis concluded that marijuana use is associated with poor fetal growth but that evidence for the association between marijuana use and other perinatal outcomes is inconclusive. There are limitations of the existing literature that preclude firm conclusions as to the effects of prenatal marijuana use. These limitations include a high reliance on self-report for ascertainment of use and incomplete adjustment for confounding factors such as tobacco use. Two recent systematic reviews and meta-analyses found an association between marijuana use and adverse perinatal outcomes, especially with heavy marijuana use. In addition, there are three longitudinal studies examining the relationship between prenatal marijuana exposure and childhood neurodevelopment. While early childhood neurodevelopmental outcomes are similar, investigation later in life demonstrates decreased attention, verbal reasoning, and cognitive function. With the high prevalence of marijuana use among reproductive-age women, it is critical for health care providers to query women regarding use and provide information regarding the potential harms. Given the available evidence, women should be advised to refrain from marijuana use during pregnancy and while breastfeeding.

W 3228 Developmental Consequences of Early-Life Cannabis Exposure

Y. Hurd. *Icahn School of Medicine at Mount Sinai, New York, NY.* Sponsor: K. Ryan

The expanding legalization of recreational and medical cannabis as well as the changing attitudes regarding the harm of cannabis have contributed to a significant increase in women using cannabis while pregnant. Additionally, there is increased prevalence of cannabis consumption among breastfeeding women and of children with secondhand cannabis exposure. Delta-9-tetrahydrocannabinol (THC), the psychoactive component of cannabis, readily crosses the placenta barrier and also is transferred through breast milk, which raises significant concern about the impact of early-life cannabis exposure during these critical periods of development. The goal of our project is to examine the trajectory of behavioral and neurobiological disturbances associated with early-life cannabis/THC exposure. Preclinical rodent models, postmortem human fetal brain specimens, and longitudinal human investigations were investigated in relation to early-life cannabis/THC exposure. Biochemical, molecular, epigenetic, and behavioral studies were carried out at different developmental periods. Findings from our human studies and animal models, in combination with results from the field, emphasize neurobehavioral, socioemotional, physiological, molecular, and epigenetic consequences of developmental cannabinoid exposure that extends from the neonatal period through adolescence and into adulthood. For example, daily maternal exposure to THC (resulting in 10 ng/mL plasma concentration; ~1 joint/day) during pregnancy alters molecular mechanisms related to synaptic plasticity well into adulthood of their offspring, linked to disturbances of histone methylation epigenetic marks and depression-like behavior. The stress system appears to be a particularly critical biological substrate affected by the developmental effects of cannabis/THC. The accumulating data emphasize long-term impact on specific neural systems and phenotypes predictive of psychiatric and addiction vulnerability that altogether provide scientific evidence to help guide interventions and education strategies to improve the mental health outcomes of children and adults.

W 3229 Pre-conception Paternal THC Exposure of Male Rats Causes Long-Term Neurobehavioral Effects in the Next Generation

E. Levin. *Duke University, Durham, NC.*

Maternal exposure during gestation to a wide variety of toxicants has been widely shown to cause neurobehavioral toxicity in the next generation. However, the impacts of paternal toxicant exposure pre-conception on offspring neurobehavioral function have been much less studied. We have found that pre-conception delta-9-tetrohydrocannabinol (THC) exposure in male rats significantly alters sperm DNA methylation and that cannabis smoking in human males is significantly associated with altered sperm DNA methylation in similar pathways (Murphy et al., *Epigenetics*, 13:1208-1221, 2018). The functional impact of THC-induced altered sperm DNA methylation on the next generation is still largely unknown. In the current studies, we investigated the effects of pre-conception THC exposure of young adult male rats (0 or 2 mg/kg/day for 12 days or 0, 2, or 4 mg/kg/day for 28 days) on the neurobehavioral development of their offspring. These dose regimens of paternal THC exposure were not found to significantly impact the clinical health of the fathers or offspring. However, they did cause a long-lasting, significant effects on locomotor activity and cognitive function in the offspring relative to controls when they were tested in adolescence and adulthood. The shorter paternal THC exposure caused a significant increase in habituation of locomotor activity and attentional impairment in the adult offspring of the males exposed to THC prior to mating. The longer paternal THC exposure caused significant locomotor hyperactivity in the adolescent offspring, significantly quicker habituation in novel object exploration, and significantly delayed acquisition of the radial-arm maze in adult offspring. These studies demonstrate that pre-conception paternal THC exposure, even at a modest dose, can cause deleterious neurobehavioral effects in their offspring, including cognitive impairment. Additional research is needed to determine the degree to which this type of neurotoxic risk in offspring is seen in humans, to investigate the mechanisms underlying these effects, and to develop therapeutic treatments to ameliorate these long-term adverse behavioral consequences of paternal pre-conception THC exposure.

W 3230 Assessing Effects in Zebrafish of Parental Exposure to Delta-9-Tetrahydrocannabinol on Long-Term Neurobehavior and Aging Phenotypes

K. Willett. *University of Mississippi, University, MS.*

Countries are relaxing laws regarding the use of cannabinoids such as delta-9-tetrahydrocannabinol (THC). As a consequence of their increased consumption, understanding potential adverse outcomes following exposure to cannabinoids during critical developmental periods such as pregnancy is important. Zebrafish (*Danio rerio*) as a research organism provide a relatively high-throughput model by which both the efficacy and potential toxicity of THC can be assessed. Furthermore, they can be used to determine molecular/cellular mechanisms of the developmental neurotoxicity of cannabis and to more quickly vet the hundreds of different compounds in cannabis products. To assess the acute developmental consequences of THC, zebrafish were exposed through the larval stage to 0.08 to 1.25 μM THC. Developmental deformities, behavioral analysis, and RNA-seq analysis of the transcriptome are being used to identify potential target organ and toxicity pathways. This study investigated developmental origins of health and disease (DOHaD) via multigenerational gene expression patterns, 96 hpf behavior of larval offspring (F1 and F2), locomotive and anxiolytic behavior of adult fish assessed

through open field testing at 12 months, and reproductive fitness of a subsequent F1 following the F0 developmental exposure of zebrafish. Three years following the initial larval exposure, aged F0 fish were assessed to determine if early-life exposure to cannabinoids alters aged fish behavior or offspring survival, as well as aging phenotypes such as brain and liver expression of genes involved in: neurodevelopment (bdnf), proliferation (p53), cell cycle arrest (p16, p21), and immune markers (tnfa, Il-6, Il-1b). Results from this work highlight that zebrafish (1) offer a good tool to measure multigenerational impact of THC exposure, (2) demonstrate that THC effects on neurobehavior mirror effects in rodent models with the advantage of greater throughput, and (3) can inform policy considerations related to THC expanded use.

3231 The Public Health Perspective on Prenatal Cannabis Use: What Do the Data Tell Us, and What Are the Data Gaps?

E. Contreras. *Colorado Department of Public Health and Environment, Denver, CO.* Sponsor: K. Ryan

From the public health perspective, more data are needed to better understand and communicate risks regarding the impact of marijuana use on pregnancy and childhood outcomes such as neurodevelopmental disorders. At the Colorado Department of Public Health and Environment, the Marijuana Health Monitoring and Research program (MHMRP) has an obligation to "monitor changes in drug use patterns and the emerging science and medical information relevant to the health effects associated with marijuana use." This goal is achieved through a panel of health care professionals with expertise in varying aspects of cannabis. Experts are tasked with collecting and reviewing relevant data in the peer-reviewed literature to develop and approve public health recommendations related to cannabis use in Colorado. As a first step, a broad search (e.g., Medline) of current peer-reviewed publications is conducted quarterly, and these are rated as a high-, medium-, or low-quality finding based on the strengths and limitations of the methods via the GRADE system. Next, draft evidence statements for population, exposure, and outcome (health effect) are summarized based on the quantity and quality of evidence. This information is then used to draft public health recommendations (e.g., for education or monitoring) as well as data gaps that are reviewed and approved by the expert panel. Our work has led to the development of 26 evidence statements on marijuana use and pregnancy and breastfeeding. Areas with moderate evidence of concern for maternal use of marijuana during pregnancy include reduced cognitive function, lower IQ, and attention problems in exposed offspring. Unfortunately, most of the evidence for health outcomes such as birth defects, motor deficits, and mental health issues is still limited or mixed. Due to the Schedule I status of marijuana, federally, it is extremely difficult to study any health outcomes related to marijuana. As such, the marijuana industry is outpacing public health regulations due to lags in high-quality research on the health impacts of marijuana use. Overall, it remains imperative that research continue on marijuana use and health impacts, including childhood neurodevelopmental disorders. More research is needed in vulnerable populations like prenatal exposures, second- and third-hand exposures in children, youth use, medical use among immunocompromised populations, and use in populations with mental illness. Additionally, research is needed on how different modes of marijuana use affect health or how potency may or may not exacerbate a health condition. Until all these areas are well described in literature, we will not know the true impacts of marijuana legalization on the health of populations.

3232 Differentiating Respirable Sensitizer and Irritants Using *In Vitro* Models: Analysis of Cell-Based Monolayers versus Co-cultures

M. J. Gibb, and C. M. Sayes. *Baylor University, Waco, TX.*

In an effort to decrease the use of animals used in toxicological research testing, investigations that lead to verifiable *in vitro* testing methods are desperately needed. Unlike that of the skin, the lungs lack validated and universally-accepted *in vitro* testing methods that differentiate between irritating and sensitizing aerosols. To complicate the issue further, these toxicity-inducing aerosols could exist as either liquid droplets or solid particulates. Therefore, validating an *in vitro* model requires both comprehensive aerosol and cell characterization. Previously, we have developed and tested an *in situ* real-time model system that collects both physical, chemical, and biological data before, during, and after aerosol exposure to lung cell cultures at the air-liquid interface. In this study, further investigate *in vitro* based testing systems by utilizing the liquid-liquid interface to compare the irritation versus sensitization effects to cell monolayers and co-cultures of pulmonary cells. The monolayer includes human lung epithelial cells, only; while the co-culture consists of epithelial cells plus human monocytes transformed into macrophage-like phenotype and dendritic cells that function as antigen presenting cells. Results show that after exposure to the known solid particulate irritant crystalline silica nanoparticles, the co-culture model produced significantly more TNF-alpha as compared to the monolayer, suggesting the importance of using multiple cell-types when validating *in vitro* models. Similar results were found when exposing the known sensitizer nickel oxide and subsequently measuring endpoint IL-13. Interestingly, particle silver colloids did not induce a measurable increase in either biomarker (when compared to untreated control cell populations). These results show that *in vitro* co-culture models may be suitable for initial screening assessments of new materials suspected as either irritants or sensitizers. Implementation of this model would aid in the acceleration of bringing newly developed products (and formulations) in the laboratory to the commercial market.

3233 How Sex-Specific Arsenic Immunomodulation Influences Infectious Disease and Cancer Risk

F. C. Sille, S. E. Attreed, K. A. Rychlik, E. J. Illingworth, C. M. Kashiwagi, J. Liao, H. Zhang, T. Howard, I. F. Sanchez, A. Fink, S. L. Klein, and C. D. Heaney. *Johns Hopkins University, Baltimore, MD.*

Inorganic arsenic (iAs) is a potent carcinogen and immunotoxicant, posing a risk to more than 200 million people worldwide through the consumption of contaminated water and food. iAs exposure has been correlated with, often sex-dependent, increases in risks of cancer and respiratory tract infections, including tuberculosis (TB) and influenza. However, it is unclear what the causal mechanisms are. We hypothesize that iAs causes a sex-specific immune imbalance leading to on the one hand increased infectious disease risk, while on the other hand contributing to a tumor-promoting microenvironment. We focused on the effects of iAs (sodium meta-arsenite) on macrophages, innate immune cells known to influence both cancer and TB pathogenesis. We observed sex- and dose-specific suppression of nitric oxide (NO) and cytokine production, phagocytosis and differences in cell surface expression as assessed by flow cytometry in activated bone marrow-derived macrophages (BMDMs) *in vitro* treated with iAs (0.0001 - 1 μM) either during or after macrophage differentiation. Moreover, signaling lipid analysis revealed a skewing towards a tumor-promoting phenotype. We observed similar findings in activated lung macrophages from mice either *in utero* or chronically exposed to 100 ppb and 1000 ppb iAs. We are currently investigating how these macrophage alterations influence TB and cancer risk. Using an influenza A virus (IAV) mouse model, we also studied the sex-specific effects of iAs exposure on the immune responses against primary infection. We observed exacerbated disease severity, proinflammatory cytokine responses and mortality in iAs-exposed females compared to males upon primary IAV infection. Despite an increased early cytokine storm, influenza viral titers remained high in iAs-exposed females compared to controls and males over the course of infection. We are currently investigating how observed differences in immune cell infiltration and function may contribute to the arsenic-induced disease phenotype. Overall, our data elucidate the different ways that iAs influences both cancer and infectious disease risk in exposed populations through immunomodulation. *NIEHS R00ES024808 (FS), T32ES07141 (KR, EI) and 5T32HL007534-37 (SA)*

3234 Development of a T Cell-Specific Nrf2-Null Mouse Model to Determine the Role of Nrf2 in Impaired T Cell Response to Influenza by tBHQ

R. A. Freeborn[1], A. P. Boss[1], S. Liu[1], Y. Jin[1], S. Brocke[1], A. E. Turley[1], J. W. Zagorski[1], R. C. Kennedy[1], S. S. Biswal[2], E. M. Gardner[1], and C. E. Rockwell[1]. *[1]Michigan State University, East Lansing, MI; and [2]Johns Hopkins University, Baltimore, MD.*

Influenza infections cause hundreds of thousands of hospitalizations in the United States each year. Despite increased vaccination compliance, the number and severity of infections have not improved, suggesting there is a disconnect between vaccination and disease protection. Accordingly, there has been considerable interest in identifying factors that contribute to susceptibility to influenza virus infections and/or reduce vaccine efficacy. $CD8^+$ T cells play an indispensable role in clearing virus-infected cells during infection and controlling viral replication by secreting antiviral cytokines. Early work from our lab identified an immunosuppressive effect of the Nrf2-activating food additive *tert*-butylhydroquinone (tBHQ) on murine $CD8^+$ T cell activation *ex vivo*. Accordingly, we hypothesized that tBHQ would suppress the $CD8^+$ T cell response to influenza infection. To test this, wildtype mice were fed diets with or without 0.0014% tBHQ - a dose that correlates well with estimated human exposure and is also the concentration in common rodent chows. Two weeks after acclimation to the diets, mice were challenged with a sublethal titer of influenza A/PR/8/34 (H1N1). At the peak of the T cell response, the $CD8^+$ T cell response to infection was assessed through RNA, ELISA, and FACS analyses.

Mice on the tBHQ-supplemented diet had a reduced number of $CD8^+$ T cells in the lungs and a reduced number of influenza-specific $CD8^+$ T cells in draining lymph nodes compared to their control-diet counterparts. Furthermore, tBHQ reduced $CD8^+$ T cell activation as evidenced by a decrease in the number of $CD25^+$ $CD69^+$ $CD8^+$ T cells and effector function as determined by reduced expression of FasL and CD107a. Moreover, mice on the tBHQ diet had a trend towards increased viral burden in the lungs. To investigate the role of Nrf2 in these effects, Nrf2-floxed mice were crossed with mice expressing Cre under the CD4 promoter to generate mice lacking Nrf2 in both $CD4^+$ and $CD8^+$ T cells. *Ex vivo* analysis of the T cells from these mice demonstrated that Nrf2 expression is ablated and Nrf2 target gene expression substantially decreased, indicating this will be a useful model to assess the role of Nrf2 in T cells during influenza infection. *This work was supported by NIH grants ES024966 and GM092715.*

PL 3235 Cannabidiol-Regulated microRNAs Promote Mast Cell Signaling via Peroxisome Proliferator-Activated Receptor-γ to Protect against Staphylococcal Enterotoxin B-Induced Liver Injury

C. D. Culpepper, W. Becker, K. Miranda, B. Holloman, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

Recreational use of cannabis and its components, such as tetrahydrocannabinol (THC) and cannabidiol (CBD), is now legal in several states. Despite the increased popularity of these products, there is a gap in knowledge surrounding the effects of their daily usage. Our previous studies demonstrate that CBD treatment of naïve mice causes significant expansion of $CD11b^+Gr\text{-}1^+$ myeloid derived suppressor cells (MDSC), as a result of increased peroxisome proliferator-activated receptor gamma (PPARγ) signaling. Using a staphylococcal enterotoxin B (SEB)-induced liver injury model, we examined CBD regulation of mast cells during acute inflammation. Herein we report that CBD treatment before SEB exposure prevents immune cell-mediated liver damage. Briefly, mice were intraperitoneal (I.P.) injected with 20mg/kg or 50mg/kg of CBD for 4 days (d), followed by SEB challenge on d 3. Flow cytometry analysis of the peritoneal and liver contents revealed a significant reduction in inflammatory cell types, including T helper, T cytotoxic, and $CD19^+$ B cells. Additionally, we show that despite decreased numbers of $CD11b^+$ $F4/80^+$ macrophages, there was an increase in the total number of $CD11b^+$ myeloid cells. Further analysis revealed that the expanded population of myeloid cells was comprised of $Ly6C^{HI}MHCII^{LO}$ MDSC. Employing microarray analysis, we examined differences in microRNA (miRNA) expression of liver mononuclear cells to identify possible gene targets of CBD. Compared to leukocytes isolated from disease mice, SEB mice treated with CBD displayed enrichment of miRNAs targeting mast cell growth factor, KIT ligand (KITLG). Furthermore, miR-217-5p, which is predicted to interact with the co-activator of PPARγ (PPARγC1A), was significantly downregulated in these mice. Downregulation of miR-217-5p tightly correlated with increases in PPARγ mRNA expression. These findings and our previous data taken together suggest that CBD dynamically regulates miRNAs targeting KITLG and PPARγC1A to enhance mast cell signaling via PPARγ during acute inflammation. Enhanced PPARγ signaling likely induced proliferation of $Ly6C^{HI}MHCII^{LO}$ MDSCs, as it has been shown to result in the secretion of myeloid colony-stimulating factors. *Supported by NIH grants P01AT003961, P20GM103641, R01ES030144, R01AI129788, and R01AI123947.*

PL 3236 Mechanisms of Cannabidiol-Induced Immunosuppression Mediated by Myeloid-Derived Suppressor Cells

K. Miranda, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

Myeloid-derived suppressor cells (MDSC) are heterogeneous immune cells that are immunosuppressive against other leukocytes such as T cells. While the immunosuppressive functions of MDSC can contribute to amelioration of inflammatory and autoimmune diseases, high MDSC accumulation in cancer can promote malignancy progression by inhibiting anti-tumor immune responses and interfering with immunotherapy. Cannabidiol (CBD) is a major nonpsychoactive phytocannabinoid derived from cannabis, which has anti-inflammatory properties, and whose use is becoming widespread worldwide. Research from our laboratory has shown that CBD is a potent inducer of MDSCs with robust immunosuppressive activity. In this study, we investigated the immunosuppressive phenotype of CBD-induced MDSCs. Naïve C57BL6 mice were administered CBD (20mg/kg, i.p.) or Vehicle (Veh) and euthanized after 24h. Gr1+ cells were then isolated from bone marrow and peritoneal cavities and subjected to transcriptome expression analysis. Consistent with previous reports from our lab, CBD induced massive expansion of Gr1+ cells in the peritonea, but not in the bone marrow of mice. Identification of the top significantly altered genes revealed that bone marrow compared to peritoneal Gr1+ cells had elevated expression of neutrophil-specific genes such as *Ngp (Neutrophil granulocyte protein), Camp (Cathelicidin antimicrobial peptide),* and *Elane (Elastase, neutrophil-expressed),* confirming that bone marrow Gr1+ cells were predominantly neutrophils, while peritoneal Gr1+ cells were predominantly MDSCs. Subsequent comparison of peritoneal Gr1+ MDSCs between Veh- and CBD-treated mice showed that CBD-induced MDSCs had dramatically elevated expression of *Crip1* (Fold change: +20.77, p=0.0016) and *Arg1* (Fold change: +6.24, p<0.0001), which encode Cysteine-rich intestinal protein 1 and Arginase-1, respectively. Cysteine and arginine are well-known to be necessary for T cell activation. Therefore, our results demonstrate that the potent immunosuppressive functions of CBD-induced MDSCs likely involve sequestration of cysteine and arginine due to upregulation of these genes. These results suggest that CBD-induced MDSCs may have pleiotropic effects on cancer models by dampening anti-tumor immunity or attenuating inflammation-induced cancer. *Supported by NIH grants P01AT003961, P20GM103641, R01ES030144, R01AI129788 and R01AI123947.*

PL 3237 The Herbicide Glyphosate Directly Affects Human T Cell Responses

A. Maddalon, V. Galbiati, M. Marinovich, and E. Corsini. *Università degli Studi di Milano, Milan, Italy.*

Glyphosate [N-(phosphonomethyl)glycine] is an active ingredient of one of the most used herbicides. Glyphosate targets the 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS); a key enzyme of the shikimate pathway which plays a pivotal role in the biosynthesis of aromatic amino acids (AAs). This pathway is present in several organisms, like plants, algae, fungi and bacteria, but neither in animals nor humans. The use of glyphosate is currently a very debated topic as several studies indicating its hazard and toxicity are emerging. There are few human epidemiology studies investigating the correlation with glyphosate exposure and human diseases. But there are several evidences of adverse effects in laboratory animals (i.e. liver, cardiovascular and reproductive toxicity, genotoxicity). In addition, studies conducted on animals suggested that glyphosate could also act as an immunomodulator. In a mouse model, glyphosate was able to promote Th2 type cytokines. This result has been partially confirmed in a previous study we conducted on 26 farmers of Northern Italy professionally exposed to glyphosate. Serum samples presented higher level of IL-4, IL-5, IFN-γ and lower levels of IL-8 and IL-33 upon glyphosate exposure. Lymphocyte subpopulation analysis revealed a higher count of Th1 and Th2 cells and a lower count of Th17, suggesting an immunomodulatory effect of glyphosate characterized by an impairment of the Th1-Th2 profile. Based on these data, the aim of this work was to investigate if glyphosate could directly affect T cells. *In vitro* studies were conducted using peripheral blood mononuclear cells obtained from buffy coats of male donors (n=5). Lympho-monocytes were treated with increasing concentration of glyphosate (0.01-0.1-1-10 μg/ml) in the presence or absence of T cell mitogens, namely PHA and PMA+ionomycin for different times (24-72 h). In agreement with what was observed *in vivo*, *in vitro* treatment resulted in an enhancement in IL-4 as well as IFN-γ levels. Furthermore, miRNA production contained in exosomes was also analyzed as possible mediator of the observed effects. Following *in vitro* exposure to glyphosate an up-regulation of several miRNAs involved in the immune system has been found (i.e. miR-10b and let-7f), consistent with the *in vivo* findings. These results indicate a direct action of glyphosate on immune cells. Further studies are underway to better understand the mechanism of action underlying the direct effects of glyphosate on T cells, while prospective studies will be necessary to understand the prognostic significance of the observed effects.

PL 3238 Aryl Hydrocarbon Receptor Regulation of T Follicular Helper Cells

C. L. Houser, A. M. Franchini, and B. P. Lawrence. *University of Rochester, Rochester, NY.*

Environmental factors influence the function of the immune system in ways that enhance or limit disease. One means by which environmental signals regulate immune responses is via a ligand-activated transcription factor called the aryl hydrocarbon receptor (AhR). The AhR binds structurally diverse molecules, including certain pollutants, dietary factors, and chemicals from microorganisms. AhR activation modulates adaptive immunity, but the cellular mechanisms are not fully defined. Changes in T cells and T cell dependent immune responses are among the most consistently observed effects of AhR activation. For instance, AhR ligands alter the differentiation and function of Th1, Th2, Th17 and Treg CD4+ T cell subsets. AhR activation also affects antibody responses to immune challenges; a process for which another CD4+ T cell subset, called T follicular helper cells (Tfh cells) are critical. Thus, we

hypothesize that the AhR regulates Tfh cell differentiation and function. We show that AhR activation with the prototype AhR agonist, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) reduces the percentage and number of Tfh cells in mice infected with influenza A virus (IAV); changes that correlate with diminished levels of virus-specific, isotype switched antibodies. Generating Tfh cells is a multistep process that involves signaling within CD4+ T cells and from accessory cells. Using mice that lack *AhR* in the hematopoietic compartment, we show that changes to Tfh cells requires AhR expression in immune cells. AhR activation also skews Tfh cell differentiation *in vitro* further supporting that it controls cell autonomous pathways in CD4+ T cells. The AhR regulates gene expression and cellular function directly, by interacting with DNA via its DNA-binding domain (DBD), and indirectly via interactions with other signaling molecules. To delineate which pathways the AhR invokes to modulate Tfh cells, we used mice with a mutated DBD and demonstrate that the AhR requires its cognate DBD to modulate Tfh cells during IAV infection. All together, these findings provide new information about how the AhR transduces environmental signals to influence the generation of humoral immunity. Given that exposure to AhR-binding pollutants correlates with greater severity of infections and reduced antibody responses to common vaccines, better understanding of the mechanisms that control Tfh cell differentiation and function has broad reaching impact on immune defenses and immune-mediated diseases.

PL 3239 Treatment with AhR Ligands Modulates Concanavalin-Induced T Cell-Mediated Liver Injury by miRNA Dysregulation

A. Cannon, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

It has been established that immune cells play an important role in the development of many liver diseases, which is a major health problem. A mouse model of immune cell-mediated liver injury that can be compared with Autoimmune Hepatitis in humans by administration of Concanavalin A (ConA) was used to study the effects of aryl hydrocarbon receptor (AhR) ligands. The environmental toxin, 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD), an AhR ligand has been shown to promote the differentiation of FoxP3+ regulatory T cells (Tregs), whereas yet another endogenous AhR ligand, 6-formylindolo[3,2-b] carbazole (FICZ) has been shown to exert contrasting effects and promotes proinflammatory Th17 cells. In this study, we tested the hypothesis that AhR ligands are capable of modulating Autoimmune Hepatitis severity by differentially regulating miRNAs to promote or limit these T cell subsets. Mice were injected intravenously with 12.5 mg/kg ConA and then treated with vehicle, 10 µg/kg TCDD, or 50 µg/kg FICZ intraperitoneally, one hour after ConA challenge. Histopathological analysis revealed liver damage in vehicle- and FICZ-treated ConA administered mice but not in TCDD-treated group. Additionally, TCDD-treated mice showed a trend of having lower levels of liver injury enzymes, Alanine Aminotransferase (ALT) and Aspartate Aminotransferase (AST) as compared to vehicle-treated ConA exposed mice. Furthermore, flow cytometric analysis of liver-infiltrating mononuclear cells demonstrated that following treatment with TCDD, there was an increase in the percentage and absolute number of FoxP3+CD4+ Tregs as well as a decrease in proinflammatory T bet+ Th1 and RORγt+ Th17 T helper cell subtypes after induction of the disease. In contrast, FICZ did not promote Treg induction. In order to assess the epigenetic mechanisms underlying this T cell dysregulation, total RNA was isolated from liver mononuclear cells and a microRNA microarray was performed. Further, the miRNA expression profile revealed differentially regulated miRNAs such as miR374 associated with T helper transcription factors and cytokines (IL-17). In summary, our data suggests that AhR ligands are capable of dysregulating miRNAs in autoimmune hepatitis, which in turn modulate T cell differentiation to affect the progression of this disease. *Supported by NIH grants P01AT003961, P20GM103641, R01ES030144, R01AI129788 and R01AI123947.*

S 3240 Application of RISK21 Framework in Regulatory-Based Decision-Making: From Business Decisions to Prioritization to Risk Assessment

M. Embry. *HESI, Washington, DC.*

A risk-based approach should be the basic operating principle for decision-making for chemical prioritization and evaluation. An exposure-driven assessment for chemicals proposes a paradigm shift in support of a harmonized risk assessment-based regulatory decision-making. The application of best available science, via integration of new and traditional data streams, will create a risk-based prioritization scheme and tailored exposure-driven risk assessments. A common framework of an integrated approach that enhances efficiency and informs business and risk management decisions that is scientific, transparent, and efficient is available and easy to incorporate into any chemical decision process. The Health and Environmental Sciences Institute (HESI) Risk Assessment in the 21st Century (RISK21; www.RISK21.org) project was initiated to develop a scientific, transparent, and efficient approach to the evolving world of risk assessment. The RISK21 team developed a framework that reconsiders the way chemical risk assessment information is obtained and used. It is a problem formulation-based, exposure driven, tiered data acquisition approach that allows an informed decision on human and environmental safety to be made when sufficient evidence is available and maximizes the ability to inform decisions and optimize resource usage. To achieve innovative solutions in risk evaluation one needs to apply a systematic approach to formulate consistent, technically robust and scientifically credible problems that need to be solved. A structured problem formulation approach enables one to keep focused on describing and evaluating the breadth and depth of the specific problem to be solved, instead of rapidly trying to create solutions. The application of the framework enables the evaluator to identify key issues and possible approaches to address the value of available information and make decisions about what, if any, additional information is needed to inform a decision. This problem formulation-based, exposure-driven, tiered data acquisition approach allows a decision on the sufficiency of available evidence of safety, business risk, or prioritization across a large group of chemicals to be made. The framework enables the assessment of the value of available information and deciding what, if any, additional evidence is needed to reach a decision.

S 3241 High-Throughput Risk-Based Prioritization for Ecological Risk Assessment

J. Arnot. *ARC Arnot Research & Consulting, Toronto, ON, Canada.*

A common approach used in regulatory programs to evaluate chemicals for their potential effects on the environment is to categorize chemicals using various criteria for Persistence, Bioaccumulation, and Toxicity (PBT). Alternative methods screen and prioritize chemicals based on estimates of exposure and potential risk. Recent amendments to the Toxic Substances Control Act (TSCA) have led the US Environmental Protection Agency (US EPA) to consider new approach methodologies (NAMs) in many aspects of TSCA implementation, including prioritization. Much focus has been directed toward *in vitro* toxicity testing. As highlighted in the National Academy of Sciences, Engineering, and Medicine report "Using 21st Century Science to Improve Risk-Related Evaluations," there is a need to develop and evaluate exposure models to compare against existing and emerging data streams of toxicity information to guide risk-based decision-making. The Risk Assessment IDentification And Ranking (RAIDAR) model combines chemical fate and transport at a regional scale with bioaccumulation in aquatic, terrestrial, and agricultural food webs using toxicokinetic models to estimate exposures to a wide range of representative ecological receptors. User-defined toxicity data can then be compared with exposure estimates to quantify risk. To demonstrate high-throughput risk-based prioritization for ecological health, the RAIDAR model was applied as a case example to 11,000 organic chemicals and the results were evaluated using the RISK21 matrix tool. The risk-based estimates span more than 10 orders of magnitude, demonstrating the capacity to screen and prioritize large numbers of chemicals for ecological risk. Uncertainty analysis further demonstrates the greatest overall source of uncertainty in the prioritization is the emission rate estimate used as input into the model. The results of the RAIDAR calculated risk estimates and ranking for chemical prioritization are compared against traditional "PBT" categorization results, highlighting the need for considering NAMs in regulatory decision-making.

S 3242 Exposure- and Hazard-Driven Prioritization for Evaluation of Chemicals in Canadian Drinking Water

I. Moffat. *Health Canada, Ottawa, ON, Canada.* Sponsor: M. Embry

Health Canada, in collaboration with the Federal-Provincial-Territorial Committee on Drinking Water, develops and publishes the *Guidelines for Canadian Drinking Water Quality* for chemical and microbiological parameters. For chemicals, the guidelines specify the maximum acceptable concentrations of a chemical(s) in drinking water. As part of our cyclical five-year prioritization process, a list of 421 chemicals was identified for potential evaluation (based on new science, existing priorities, emerging concerns, monitoring, sales/use, and reviews by other agencies). Our goal was to identify which of these 421 chemicals have the highest priority for evaluation. Health Canada used the RISK21 framework (HESI, US), including problem formulation, which integrates tiered exposure and hazard information into a risk plots for iterative rounds of decision-making, ultimately using the appropriate tier to decide on a chemical's priority. Exposure information relied on national and global exposure databases. Tier 1 exposure information included physi-

cochemical properties, and Tier 2/3 information was from biomonitoring and monitoring databases (examples will be provided in the presentation). For hazard characterization, Tier 1 information was from published reference values, while the later tiers used predictor information (e.g., extrapolation/activity models, apical endpoints, and mode-of-action analysis). Iterative rounds of exposure and hazard information from appropriate tiers were used to generate risk plots (exposure versus toxicity) until a decision (high, low, wait) could be made on all chemicals. We prioritized 62 high, 290 low, and 69 wait priority chemicals for further evaluation. Using this tiered system, we efficiently used resources and precision to make a decision to rank the priority of all chemicals. This prioritization process provides a science-based, methodologically robust, and transparent way to identify and prioritize chemicals/groups requiring the development of a drinking water risk assessment.

3243 Using the RISK21 Framework as a Tiered Approach for Chemical Risk Assessment: A Proof of Concept

S. Deglin. *HESI, Washington, DC.* Sponsor: M. Embry

This presentation will ground-truth the RISK21 approach through the systematic and tiered risk assessment of a large number of chemicals. The purpose of this example is to illustrate the advantages of a tiered approach by comparing risk-based estimates of lower-tier, less resource-intensive methods with the higher-tier, more traditional information sources. This work builds upon initial evaluations performed by Wetmore et al. (2015) and Patlewicz et al. (2018), where numerous chemicals were evaluated using high-throughput exposure (HTE) predictions combined with either oral equivalent doses (OEDs) derived from dosimetry-adjusted *in vitro* bioactivity data from ToxCast (Wetmore) or the Threshold of Toxicological Concern (TTC) approach (Patlewicz). In this case study, the RISK21 approach is applied to over 7,000 chemicals from the previous studies to verify that the framework is valid, and protective, of human health. First, the TTC approach and HTE values were applied as a Tier 0, and most conservative assessment. The Cramer class of each chemical was determined using Toxtree, and the corresponding toxicity values and HTE estimates from previous studies were plotted on the RISK21 matrix. OED values from ToxCast data were then combined with the HTE estimates to evaluate the relative conservativism between the two approaches (TTC + HTE versus OED + HTE). As a third step, *in vivo* hazard data from traditional animal studies were used in concert with the HTE estimates to further evaluate the tiered approach. The most conservative No-Observed-Adverse-Effect Level (NOAEL) values were used in this last phase. This case study showed that the RISK21 framework is a valid approach to evaluate risk at various levels of refinement. Although both the TTC and ToxCast approaches present some limitations that need to be accounted for upfront when dealing with certain chemistries such as bioaccumulative chemicals, metals, and inorganic substances for TTC, and volatiles, some surfactants, and non-DMSO soluble substances for ToxCast.

3244 Use of RISK21 for Communication of Absolute and Comparative Risks: The Case of Glyphosate Use in Different Countries

A. Moretto. *Università degli Studi di Milano, Milan, Italy.*

The RISK21 framework was used to evaluate glyphosate risk to the general population in Italy (and the broader European Union), Argentina, and Brazil. Exposure estimates were based on available water and food monitoring data, and an estimate of farmworker exposure was performed using European exposure models. Monitoring data have been collected for water and food over the years, and glyphosate intakes have been estimated both deterministically and probabilistically, based on national food consumption data and the default assumption on drinking water intakes. Acceptable daily intakes (ADI) as set by the Joint FAO/WHO Meeting on Pesticide Residues, the European Food Safety Authority (EFSA), and the US Environmental Protection Agency using the standard safety factor of 100 (i.e., a margin of exposure [MoE] from the critical NOAEL) have been used. For the European scenario, the Acceptable Operator Exposure Level was compared with the estimated exposure based on the EFSA models. Exposures of both the general population and the farmer applying glyphosate were well below the health-based limits. This information was graphically visualized in the RISK21 matrix and contrasted with similar assessments performed for other herbicides, possible substitutes of glyphosate, which proved to pose a higher risk. The use of the RISK21 matrix helps to clearly present the conclusion to the stakeholders, including the less technically prepared general population.

3245 Application of the RISK21 Framework as a Decision and Communication Support Tool to Inform Project Risk and Business Decisions in Crop Protection Active Substance Development

D. Cowie. *Syngenta, Bracknell, United Kingdom.* Sponsor: M. Embry

A modern approach to informing agrochemical product development decision-making applies the RISK21 framework to incorporate new approach methods and predictive tools to determine data needs to deliver registerable products and inform re-registration decisions. Using problem formulation directs the process for determining what exposure and hazard data are necessary to develop in order to adequately inform each step of the new product development or respond to issues that arise during re-registration discussions. The presentation will provide examples of problem formulation focused on risk management decisions that drive studies to assess relevant exposure and hazard concerns to enable risk-based decisions for safe use.

3246 Chemical Probes in Toxicology: From Defining Exposures to Identifying Novel Toxicity and Druggable Targets

J. Smith. *Pacific Northwest National Laboratory, Richland, WA.*

As an emerging scientific discipline, chemical biology utilizes synthetic chemical probes to functionally identify and measure reactive biological molecules such as proteins and nucleic acids. Researchers design and synthesize small molecule chemical probes to functionally target and covalently label enzymes, receptors, and nucleic acids based on catalytic activities and selective affinities. Combined with fluorescence gel electrophoresis, liquid chromatography-mass spectrometry-based proteomics, and bioinformatics, chemical probe platforms facilitate rapid and quantitative screening of cells, tissues, and biological fluids from microbes, animal models, and humans. Compared with conventional transcriptomics and proteomics, chemical probes provide measurements of functional activity rather than total abundance of transcripts, proteins, or nucleic acids. Thus, chemical probes have recently gained popularity among research toxicologists and drug developers as tools to measure enzymatic activity important in metabolism and identify novel molecular binding targets of toxicants and drugs. The session will highlight innovative methods using chemical probes in the field of toxicology. The first speaker will present how chemical probes can measure and predict metabolism and internal dosimetry. This will be followed by a demonstration on how chemical probes can be used to identify novel targets of organophosphates beyond acetylcholinesterase inhibition. The next presentations will discuss how chemical probes can reveal chemically induced damage to DNA and resulting mutations and how chemical probes can be used to reveal novel druggable targets and possible toxicity targets. The final speaker will demonstrate how chemical probe techniques can identify off-target proteins and mechanisms of a fatal experimental drug.

3247 Applying Activity-Based Protein Profiling to Better Measure and Predict Metabolism and Internal Dosimetry

J. Smith. *Pacific Northwest National Laboratory, Richland, WA.*

As one of the primary processes controlling internal dosimetry, metabolism plays a key role in (1) bioactivating xenobiotics to form an ultimate toxicant or (2) clearing and detoxifying toxicants post-exposure. Conventional methods measuring xenobiotic metabolism rely on descriptive experiments measuring parent disappearance or product formation in cell culture systems, subcellular fractions, or isolated enzyme systems. *In vitro* to *in vivo* methods translate metabolism measurements to applicable test systems (e.g., cell culture, zebrafish, animal model, humans) for internal dosimetry congruence, improving hazard identification and dose-response analysis. This talk will present novel approaches using activity-based protein profiling to better measure and predict metabolism and internal dosimetry across test systems using polycyclic aromatic hydrocarbons (PAHs). As classical procarcinogens, many PAHs require metabolic bioactivation to form the ultimate toxicant and metabolic detoxification for compound clearance. Our group has developed and applied activity-based probes of cytochrome P450s and glutathione S-transferases to identify enzymes involved with metabolism of PAHs, quantify enzyme induction from PAH exposures, measure implications of enzyme induction on PAH metabolism, and measure enzyme ontology in humans. Combining activity-based protein profiling methods with classical metabolism assays and physiologically based pharmacokinetic (PBPK) models allow for novel

approaches for *in vitro* to *in vivo* extrapolation of metabolism across systems and predictions of metabolism rates across human life stages and population variability. *Funded by NIEHS Grant No. P42 ES016465.*

3248 Structure-Dependent Determination of Organophosphate Targets in Mammalian Tissues Using Activity-Based Protein Profiling

V. Lin. *Pacific Northwest National Laboratory, Richland, WA.* Sponsor: J. Smith

Acute and chronic exposure to organophosphates (OPs), including agricultural pesticides, industrial chemicals, and chemical warfare agents, has significant short-term and long-term impacts on human health. The mechanisms by which OPs alter development and cognition in exposed individuals remain poorly understand, in part due to the large number of structurally diverse OPs that are used worldwide and the wide range of affected proteins and signaling pathways. To investigate the influence of structure on OP targets in mammalian systems, we developed a series of OP probes for activity-based protein profiling (ABPP) featuring two different reactive groups for mimicking OP chemical reactivity. ABPP using these new probes in mouse liver and brain revealed divergent protein profiles, demonstrating that probe structure influences identified protein targets. Competition experiments using paraoxon and chlorpyrifos oxon also showed that the probes can be used to detect differences in sensitivity toward OPs among protein targets in a complex mixture. Additionally, these probes can be used to assess reactivation of acetylcholinesterase by pralidoxime (2-PAM) and may serve as diagnostic tools for screening of therapeutic candidates in a panel of protein targets. These applications will help clarify the effects of OP toxicity beyond acetylcholinesterase inhibition, investigate potential points of convergence for broad spectrum therapeutic development, and support future efforts to screen candidate molecules for efficacy in various model systems.

3249 Chemical Probes to Uncover Genome-Wide Patterns of Chemically Induced DNA Damage and Mutagenesis

S. Sturla. *ETH, Zurich, Switzerland.*

Exposures to an increasing variety and amount of chemicals from the environment, diet, and drugs, together with defects or deficiencies in DNA damage tolerance pathways, contribute to carcinogenesis risk. Current understanding of how DNA oxidation and alkylation drive mutagenesis is advanced, but our ability to predict the mutagenicity of chemicals or disease risks related to these processes remains limited, in part because there exists a mismatch between our low-resolution understanding of how DNA adducts are distributed and dynamically altered on a genome-wide level versus our sophisticated knowledge of mutational landscapes of human cancers. Systems toxicology models linking chemical exposures with mutational signatures are fundamentally limited by this lack of information and methods to map DNA damage. The objectives of this work are to map oxidation and alkylation damage in mammalian cells, understand how damage maps are governed by chemical sources and repair, and relate chemical exposures with *in vitro* mutation signatures. To address these goals, we have developed chemical probe-based strategies for mapping damage regions in the human genome. Results include development and application of a method for single nucleotide mapping of damage in whole genomes and *in vitro* strategies to determine the impact of enzymatic deficiencies on mutation signatures. We found that the specificity of DNA repair enzymes could be coupled with efficient click DNA ligation reactions to insert a biocompatible nucleoside probe with a locator oligonucleotide code sequence. This approach enabled high-throughput, nucleotide-resolution sequencing of DNA damage. We mapped thousands of damage sites with distinct patterns related to transcription, chromatin architecture, and chemical oxidation potential. Furthermore, we found that loss of the capacity to extend DNA synthesis from methylnitrosourea-induced damage sites produced altered DNA mutation signatures. These sequence-specific chemical probe-based strategies for tracking chemically induced DNA damage overcome previous limitations to sequencing of DNA damage, provide information concerning the relationship between DNA repair enzyme function and mutation signatures, and could lead to new approaches for quantifying risk on the basis of early biomarkers and characterization of causative factors of individual cancers.

3250 Utilizing Chemoproteomic Platforms to Elucidate Toxicological Mechanisms

B. Ford. *US EPA, Research Triangle Park, NC.* Sponsor: J. Smith

A large number of pharmaceuticals, endogenous metabolites, and environmental chemicals act through covalent mechanisms with protein targets, yet the specific interactions with the proteome remain poorly defined for many of these reactive chemicals. Deciphering direct protein targets of reactive small-molecules is critical in understanding their biological action, off-target effects, and potential toxicological liabilities, as well as for the development of safer and more selective chemical agents. Chemoproteomic technologies have arisen as a powerful strategy that enables the assessment of proteome-wide interactions of these irreversible agents directly in complex biological systems. This talk will focus on the utilization of the powerful chemoproteomic approach termed Isotopic tandem orthogonal proteolysis-enabled activity-based protein profiling (isoTOP-ABPP) in identifying the direct protein binding, possible targets, mechanism of toxicity and target selectivity of environmental chemicals. The research discussed was all performed as within an academic setting and will demonstrate the potential of chemoproteomic platforms for understanding the mechanism of toxicity, off-targets, selectivity and potential of the platform as part of the covalent compound discovery and development process towards assessing and developing safer chemicals.

3251 Activity-Based Protein Profiling Reveals Off-Target Proteins of Fatal Experimental Drug BIA 10-2474

M. van der Stelt. *Universiteit Leiden, Leiden, Netherlands.* Sponsor: J. Smith

A recent phase 1 clinical trial of the fatty acid amide hydrolase (FAAH) inhibitor BIA 10-2474 led to the death of one volunteer and produced mild-to-severe neurological symptoms in four others. Although the cause of the clinical neurotoxicity is unknown, it has been postulated, given the clinical safety profile of other tested FAAH inhibitors, that off-target activities of BIA 10-2474 may have played a role. Here, we use activity-based proteomic methods[1] to determine the protein interaction landscape of BIA 10-2474 in human cells and tissues. This analysis revealed that the drug inhibits several lipases that are not targeted by PF04457845, a highly selective and clinically tested FAAH inhibitor. BIA 10-2474, but not PF04457845, produced substantial alterations in lipid networks in human cortical neurons, suggesting that promiscuous lipase inhibitors have the potential to cause metabolic dysregulation in the nervous system.[2] *References: 1. Van Rooden et al.,* Nature Prot*. 2018, 13, 752. 2. Van Esbroeck et al.,* Science*, 2017, 356, 1084.*

3252 Express Yourself (or Not . . .): the Nonclinical Safety of Oligonucleotide Therapeutics

J. Sutherland. *Alnylam Pharmaceuticals, Cambridge, MA.*

Oligonucleotide-based therapeutics that utilize nucleic acids to treat a variety of local and systemic diseases are very novel and relatively unknown to the public. This unique class of agents includes antisense oligonucleotides (ASOs), small interfering RNAs (siRNAs), aptamers, microRNA (miRNA) inhibitors and mimics, and modified messenger RNA (mRNA), which usually require special systems for delivery to patients and specific safety considerations. In the last 20 years, several ASOs have been approved for the treatment of serious diseases, including fomivirsen for cytomegalovirus retinitis; mipomersen for homozygous familial hypercholesterolemia; nusinersen for spinal muscular atrophy; and inotersen for polyneuropathy caused by hereditary transthyretin-mediated (hATTR) amyloidosis. In 2018, patisiran, the first siRNA therapeutic, was approved for the treatment of polyneuropathy of hATTR amyloidosis. A robust nonclinical and clinical pipeline features other ASOs, siRNAs, and modified mRNAs designed to treat a variety of systemic and local diseases. The goals of this Symposium are to provide an update on the current status of the ASO, siRNA, and modified mRNA platforms; their respective mechanisms of action; their chemistry; and some of the challenges each modality must overcome to enable effective systemic and localized delivery to target tissues, with an acceptable benefit-to-risk profile. Pharmaceutical development of these agents constitutes a prime example of bridging cutting-edge research with the established regulatory requirements allowing for clinical testing. Effective nonclinical safety assessment and the regulatory requirements for evaluating the risks and benefits of these molecules, including appropriate species selection and determination of safety margins, are of paramount importance in bringing them to the clinic as novel therapy options to patients. After this session, attendees will have a better understanding of the nonclinical safety characteristics and development strategies of this important emerging class of oligonucleotide-based therapeutics.

3253 What Do I Do with All This Data? Mining the Database of 2′-MOE ASO Monkey Toxicology Studies

S. P. Henry. *Ionis Pharmaceuticals, Carlsbad, CA.*

The development of ASOs has been a journey of optimizing chemistry, sequence, and screening methods to obtain the best drug candidates. The 30 years of ASO development experience have produced an unprecedented amount of data on a specific drug platform documenting the behavior in animals that broadly informs safety monitoring in clinical trials. Individual animal and time point data from toxicology studies have been collected into databases that represent >2,000 monkeys treated with 2′-MOE ASOs and >600 monkeys treated with GalNAc-conjugated 2′-MOE ASOS. This collective experience is particularly useful as the diversity of antisense applications expands with different routes of administration, chemical modifications, and tissue-targeting strategies. This database has proven to be useful in a number of ways, including better characterizing the dose-response for severe thrombocytopenia. The large datasets also have facilitated the overall safety evaluation of hepatic tolerability of GalNAc-conjugated 2′-MOE ASOs, compared with their unconjugated parent molecules. The ability to draw from data that represent multiple closely related compounds facilitates the interpretation of the relevance of findings to humans and safety margins. This is particularly important in the case of low incidence findings in toxicology studies that are limited to a relatively small number of animals. Thus, these databases help inform the appropriate safety monitoring in clinical trials within the context of the disease background. There also is an opportunity to use these data to tailor the nonclinical safety program to minimize animal use while efficiently supporting the investigation of rare diseases.

3254 Nonclinical Safety Assessment of siRNA Therapeutics

J. A. Dybowski. *Alnylam Pharmaceuticals Inc., Cambridge, MA.*

Short interfering RNA (siRNA) molecules are a new class of human therapeutics that selectively target the endogenous RNA interference mechanism controlling the translation of RNA to protein. Through this mechanism, siRNA therapeutics can be designed to specifically target mRNA and silence the production of disease-associated proteins. siRNA therapeutics are synthetic double-stranded RNA molecules that have been chemically modified (e.g., alterations to sugar moiety, phosphate backbone, nucleobase, termini, and conjugation groups) to enhance stability and specificity. Intracellular drug delivery of these highly polar compounds requires the use of encapsulating formulations (e.g., lipid nanoparticles) or the conjugation to ligands (e.g., N-acetylgalactosamine [GalNAc]) for receptor-mediated endocytosis. There is a lack of specific regulatory guidance for the safety assessment of oligonucleotides. The unique physical, chemical, and pharmacological properties of siRNA present challenges to the design of a nonclinical safety testing strategy that requires the leveraging of guidance for both large and small molecule therapeutics. This presentation will provide an overview with examples of the factors that need to be taken into consideration when designing a nonclinical toxicology testing strategy, including species selection, appropriate use of surrogate compounds, and impact of ADME properties. Additionally, an overview summarizing the toxicological properties of siRNA therapeutics commonly observed in nonclinical species will be provided along with a discussion of the relevance of these findings to patient safety.

3255 Delivering on the Promise of mRNA Therapeutics Safely and without Complement

J. J. Senn. *Moderna Inc., Cambridge, MA.* Sponsor: J. Sutherland

mRNA-based therapies have enormous potential. Nonetheless, how to combat mRNA's inherent biological lability, how to direct therapeutic mRNAs to desired cell types, and how to enable repeat dosing without eliciting adverse immune reactions remain significant challenges for the field. Lipid nanoparticles (LNPs), consisting of an ionizable lipid, a phospholipid, cholesterol, and a PEGylated lipid, are our current method of choice for packaging and *in vivo* delivery of therapeutic mRNAs. First-generation mRNA-LNPs enabled both proof of concept preclinical studies and early clinical trials demonstrating mRNA-based vaccine efficacy. Other uses of mRNA-LNPs have been hampered, however, by dose-limited toxicities and an inability to repeat dose upon IV administration. Like other PEGylated particles, PEGylated LNPs are known to induce complement activation upon bolus dosing, which can result in systemic inflammation and liver injury in rodents and systemic inflammation and anaphylactoid responses in swine and nonhuman primates. Although these effects can be ameliorated by long duration (> 60 min) infusions, an alternate means of administration is highly desirable. PEGylated mRNA-LNPs also are recognized by the immune system via IgM and IgG-mediated responses that both activate complement (causing toxicity) and redistribute them to the Reticuloendothelial System (RES), diminishing protein production by accelerated blood clearance. Over the past several years, we have invested significant effort into developing next-generation mRNA-LNPs with improved characteristics, such as better biodistribution to desired tissues and improved tolerability. Here, we describe new PEGylated lipids that substantially reduce both complement activation and accelerated blood clearance. Our propriety mRNA-LNPs containing these new PEGylated lipids allow for repeat IV bolus dosing with significantly increased therapeutic index compared with industry standards.

3256 Oligonucleotide Therapeutics: US FDA Experience and Regulatory Consideration

X. Chi. *US FDA/CDER, Silver Spring, MD.* Sponsor: J. Sutherland

This presentation will provide an overview of the oligonucleotide (ONT) regulatory landscape in terms of current guidance applicability and some special considerations based on US Food and Drug Administration (US FDA) experience with various classes of ONT submissions. ONT submissions to the Center for Drug Evaluation and Research (CDER) at the US FDA have increased substantially over the years. Over 300 ONT Investigative New Drug (IND) submissions and 16 New Drug Applications (NDAs) have been received by the center in the past 27 years, and the submissions span a wide variety of ONT classes, routes of administration (ROAs), and therapeutic areas. The changing trend in ONT classes and ROAs reflect the need for targeted organ delivery and strategies to reduce systemic toxicities. ONTs lie at the interface between small molecules and biologics in terms of physiochemical and toxicological properties. The nonclinical support required for clinical development tends to be determined case by case, and a hybrid of ICH M3(R2) and ICH S6 is generally applied. The requirement also is adapting to evolving knowledge and accumulating data in the field. For general toxicology evaluation, the two species rule applies and at least one species should be pharmacologically relevant. The CDER Pharmacology/Toxicology Coordinating Committee—ONT Subcommittee is developing an ONT Nonclinical Database on data submitted to the center, with a focus on dose-limiting toxicities stratified by ONT classes and translatability of nonclinical findings. Once clear patterns are identified, they can be used to help further inform regulatory decisions or contribute to the development of future position papers or guidance documents.

3257 Identifying and Modeling Gene-Environment Interactions in Neurological Diseases Associated with Metal Exposure: Challenges and Recent Advances

O. Adebambo. *Duke University, Durham, NC.*

Epidemiological studies have revealed that the interplay between genetic background and the environment can contribute to disease onset and severity. Even disorders that are recognized as straightforward Mendelian diseases have been shown to display substantial phenotypic variability attributable to multifactorial interactions, such as those between genes or the gene and the environment. With more etiologically heterogeneous disorders such as neurological diseases, these interactions are even more complex and accurately investigating them in a laboratory setting has proven challenging. To address these problems, the goal of this session is to examine experimental methodologies that are currently being used in the field to model and investigate the link between genetics and environmental exposures in neurologic diseases. In this context, environmental metal exposure is of particular interest because excessive metal levels can accumulate in the brain, thereby leading to detrimental intracellular events that can alter neurotransmission and lead to neurodegeneration. Thus, we will bring together experts to discuss the influence of exposure to metals and particulate matter on known nonpenetrant genetic mutations in Alzheimer's disease (AD), amyotrophic lateral sclerosis (ALS), Huntington's disease (HD), and Parkinson's disease (PD) using *in vitro*, mammalian, and nonmammalian experimental models. Additionally, the panel of presenters were selected based on their utilization of distinct modeling strategies so as to enrich the discussion with a diversity of perspectives. We will answer questions such as: How do external environmental factors gain access to the nervous system, alter its elements, and interact with the genome to generate disease? What experimental mammalian and nonmammalian animal models are available for interaction modeling? How can we use novel genetic engineering techniques such as CRISPR/Cas9 to generate humanized animal models to better investigate genetic-environment interactions that can be extrapolated to humans? What constitutes an actual gene exposure interaction versus additivity of stressors, and can we distinguish between them? Are there phenotypic or disease severity differences based

on timing of exposure? Does aging modulate the effect of metal exposure on neurodegenerative disease onset? After the session, attendees will have a better understanding of experimental models and tools available for modeling gene-environment interactions in neurologic diseases and how to circumvent the underlying challenges in implementing these studies. Furthermore, they will gain perspective on factors for consideration during experimental design, such as timing of exposure and determining susceptibility windows and aspects of data rigor and reproducibility.

S 3258 Age- and Manganese-Dependent Modulation of Dopaminergic Phenotypes in a *C. elegans* DJ-1 Genetic Model of Parkinson's Disease

M. Aschner. *Albert Einstein College of Medicine, Bronx, NY.*

Parkinson's disease (PD) is the second most common neurodegenerative disease, yet its etiology and pathogenesis are poorly understood. PD is characterized by selective dopaminergic (DAergic) degeneration and progressive hypokinetic motor impairment. Mutations in protein deglycase (DJ-1) cause autosomal recessive early-onset PD. DJ-1 is thought to protect DAergic neurons via an antioxidant mechanism, but the precise basis of this protection has not yet been resolved. Aging and manganese (Mn) exposure are significant nongenetic risk factors for PD. Modeling aging (A) and its interaction with genetic susceptibility (G) and environmental exposure (E) can be challenging in animals, but *Caenorhabditis elegans* (*C. elegans*) is an optimal model for PD (AXGXE) studies because of its simple nervous system, conserved DAergic machinery, and short 20-day life span. Here, we tested the hypothesis that *C. elegans* DJ-1 homologues were protective against Mn-induced DAergic toxicity in an age-dependent manner. We showed that the deletion of *C. elegans* DJ-1 related (djr) genes—djr-1.2 that is expressed in DAergic neurons—decreased survival, life span, and dopamine (DA)-dependent dauer movement after Mn exposure. We also tested the role of DAF-16 as a regulator of dj-1.2 interaction with Mn toxicity. Lifespan defects resulting from djr-1.2 deletion could be restored to normal by overexpression of either DJR-1.2 or DAF-16. Furthermore, dauer movement alterations after djr-1.2 deletion were abolished by constitutive activation of DAF-16 through mutation of its inhibitor, DAF-2 insulin receptor. Taken together, our results reveal PD-relevant interactions between aging, the PD environmental risk factor manganese, and homologues of the established PD genetic risk factor DJ-1. Additionally, our data demonstrate a novel role for the DJ-1 homologue, djr-1.2, in mitigating Mn-dependent life span reduction and DA signaling alterations, involving DAF-2/DAF-16 signaling. In this context, the experimental modeling strategies to account for interspecies differences and extrapolation to human PD pathogenesis will be discussed. Furthermore, the incorporation of rigor to ensure robust and unbiased experimental design that has resulted in reproducibility of our findings in *C. elegans* and other mammalian systems also will be examined.

S 3259 Utilizing a Knock-In Mouse Model of Disease to Evaluate the Effect of Gene-Environment Interactions on Cognitive Impairment Associated with Alzheimer's Disease

Z. Xia. *University of Washington, Seattle, WA.*

Environmental factors and gene-environment interactions (GXE) may increase Alzheimer's disease (AD) risk and accelerate cognitive decline. However, there is a paucity of information directly supporting this hypothesis. The goal of our study is to test this hypothesis in an animal model. Knock-in mouse models are particularly advantageous in this context because they enable us to create humanized mouse models in which the endogenous mouse gene is replaced by the human gene. Apoliprotein E4 (ApoE4) is the strongest genetic risk factor for late-onset AD, while ApoE3 is the most common allele of apolipoprotein in humans. The presence of the ApoE2 allele reduces AD risks. We assessed for a GXE between ApoE and environmental exposure to heavy metals (lead, cadmium) or diesel exhaust on cognitive behavior using transgenic knock-in (KI) mice that express the human ApoE4, ApoE3, or ApoE2 under the control of the endogenous mouse ApoE promoter. Lead and cadmium are heavy metals and ubiquitous environmental contaminants that pose significant public health concern globally. Young adult animals were exposed to lead or cadmium that yielded blood concentrations that are relevant to current human exposure. Separate cohorts of animals also were exposed to diesel exhaust-generated $PM_{2.5}$ at levels relevant to human exposure. Sample sizes of n=10-12 animals were used for each genotype and treatment group. We performed behavior tests to monitor learning and memory, and to elucidate underlying mechanisms, we also examined the effect on hippocampal adult neurogenesis. Statistical analysis was performed to examine the presence of GxE interaction. Our data suggest that GXE between ApoE4 and environmental exposure contribute to cognitive impairment, while ApoE2 may be protective. Furthermore, impaired adult hippocampal neurogenesis may contribute to the observed deficits in cognitive behavior.

S 3260 Manganese-Induced AKT Signaling Occurs via Direct Effects on Insulin Growth Factor Receptor Signaling and is Impaired in Huntington's Disease

A. B. Bowman. *Purdue University, West Lafayette, IN.*

Manganese (Mn) is an essential metal that is neurotoxic in excess. In this study, we assessed the effects of Mn exposure, and the altered Mn handling in Huntington's disease (HD) models, on insulin/insulin-like growth factor (IGF) signaling. Mn has been linked to insulin homeostasis and signaling, but the mechanism is unresolved. In this talk, we report that even at saturating concentrations of IGF1 (10 nM), high intracellular Mn levels (50 μM-500 μM exposures for 24 hrs) potentiates IGF-induced p-AKT in STHdh, PC12, and hiPSC-derived neuroprogenitor cell (NPCs) culture models, suggesting that elevated Mn levels can increase maximal insulin/IGF receptor activity and phosphorylation. Furthermore, chronic seven-day exposures of cells at environmentally relevant levels (1 μM-10 μM Mn) also activated AKT signaling, which is downstream of insulin/IGF receptors. Both the chronic and 24-hour Mn-dependent signaling effects are suppressed in the HD genotype, consistent with reports of an HD by Mn interaction effect. Given the synergy between Mn and insulin/IGF-receptors (IR/IGFR), we further hypothesized that Mn-induced p-AKT may be directly IR/IGFR dependent. Consistent with this hypothesis, >70% of Mn-induced p-AKT can be blocked with IR/IGFR inhibitors (BMS-536924, BMS-754807, Linsitinib [OSI-906], NVP-AEW541), demonstrating that Mn-induced p-AKT is almost entirely dependent on these receptors and that intracellular Mn, not extracellular Mn, is exerting these effects. To assess if Mn-induced IGF signaling facilitates relevant functional responses, we examined glucose uptake and found HD reductions in glucose uptake were selectively increased by Mn exposure. Collectively, our data suggest that (1) the majority of the known Mn-induced p-AKT response is IR/IGFR dependent versus other signaling pathways upstream of AKT activation, (2) Mn acts intracellularly to modify function of the insulin/IGF receptors, and (3) HD-associated changes in Mn homeostasis may underlie known HD reductions in IR/IGFR signaling. This work provides evidence that deviations in cellular Mn homeostasis by exposure or HD genotype effects may exert their pathophysiological effects via altered function of Mn-dependent cell signaling.

S 3261 Modeling Genuine Gene-Environment Interaction and Not Additivity in Amyotrophic Lateral Sclerosis (ALS): The Dilemma between "Real-World" Exposure/Genetic Makeup and Mouse-to-Human Translation

D. Re. *Columbia University, New York, NY.*

ALS is the most common adult-onset paralytic disorder, usually fatal within one to five years after symptom onset. Most previous ALS GXE studies have used animal models with a full-blown phenotype and environmental exposures already significantly neurotoxic by themselves, questioning whether GXE or G+E were actually studied. ALS patients do not usually report any signs of neurotoxicity before developing the paralytic disease, suggesting that genuine GXE interaction in ALS most likely results from the interaction between silent exposures and silent genetic susceptibilities. Therefore, a knock-in mouse model (on a C57BL/6J background) of an incompletely penetrant variant of TDP-43 "G298S" was used to model this hypothesis. The heterozygous (het-G298S) knock-in mice are "ALS-silent" over their life span, but the homozygous knock-in show mild neuromuscular junction denervation at an advanced age (2.5 years), confirming the validity of these models. Primary spinal cord cultures from het-G298S mice were generated to screen for possible GXE interaction with various neurotoxic metals previously proposed to have a role in ALS. This pilot *in vitro* study identified that G298S increased the vulnerability of motor neurons to manganese (Mn) exposure. Subsequently, wild-type (WT) and het-G298S mice were chronically exposed via drinking water to 200 ppm Mn (a level of exposure rarely met in human exposure but comparatively lower than used in previous mouse studies) for six months starting in young adulthood (P90). To control for sex effect, this study included 50% females and 50% males, and it was powered based on our past ALS mouse studies. Mn-exposed and control mice were tested weekly by treatment/genotype-blinded investigators for grip strength (loaded grid) or general locomotor activity (rotarod) over the six months of the study. At the end of the study, mice also were tested with CatWalk for gait and quantitative assessment of footfalls. Some mild motor deficits were observed in het-G298S mice, but no phenoconversion to an ALS phenotype was observed in relation

to Mn treatment. However, these are in contrast to data currently being obtained from a separate cohort of het-G298S and WT mice exposed to higher concentrations (400 ppm) of Mn, for which the installation of a GXE and progressive ALS-relevant motor deficits are observed.

3262 Modeling Gene-Environment Interactions in Manganese Overexposure Using Dopaminergic Cell Culture and MitoPark Model of Parkinson's Disease

A. Kanthasamy. *Iowa State University, Ames, IA.*

The preferential accumulation of manganese (Mn) in the basal ganglia induces death of pyramidal neurons, with processes paralleling that of dopaminergic cell death in Parkinson's disease (PD). However, it is not clear if Mn contributes to PD etiology. Mounting data have pointed to mitochondrial dysfunction as a major contributor to neurodegeneration. Coincidentally, exposure to heavy metals such as Mn could impair mitochondrial bioenergetics via accumulation in the mitochondria. Thus, genes important for mitochondrial bioenergetics and biogenesis found to be dysregulated in PD postmortem brains and PD animal models, namely mitochondrial transcription factor A (TFAM) and prokineticin 2 (PK2), have since come under scrutiny. To investigate the link between downregulation of these prosurvival genes involved in PD and susceptibility to Mn exposure, PK2 and TFAM knockout (KO) dopaminergic cell lines were generated using CRISPR/Cas9. The goal was to investigate the mechanism by which these prosurvival genes act during Mn neurotoxicity and to examine whether Mn exposure augments mitochondrial dysfunction. Both PK2-KO and TFAM-KO dopaminergic neuronal cells were more vulnerable to Mn toxicity than control cells at 300 μM Mn, as shown by increased cell death after 24 h of treatment, and exhibited statistically significant decrease in mitochondrial basal and ATP-linked respiration. To further validate these results *in vivo*, we utilized a newly available transgenic mouse model, the MitoPark mouse, which exhibits mitochondrially defective dopaminergic neurons via Cre-LoxP conditional KO of TFAM. Male and female MitoPark mice were randomly selected for Mn treatment. We found that exposure to a physiologically relevant dose of Mn (10 mg/kg for 30 days) caused a statistically significant increase in nigral dopaminergic neuronal loss and accelerated disease progression in MitoPark mice, with further exacerbation of oxidative damage in the striatum and substantia nigra. Our results collectively indicate the ability of heavy metals such as Mn to augment PD disease state in a rodent model of PD while demonstrating that CRISPR/Cas9 gene editing can be used as an excellent method to model gene-environment interactions associated with mitochondrial defects in dopaminergic neurons.

3263 Protecting the Force: Examining the Hazards of Military Service from the Bench and the Battlefield

M. Johnson. *Army Public Health Center, Aberdeen Proving Ground, MD.*

It is estimated that more than 20 million US citizens either have served or are currently serving in the military. Therefore, in addition to preparing a force that is ready to meet future challenges and threats to ensure national security, protecting the health of the service members and veterans is and must continue to be a national priority. Military service involves a vast and unique set of toxicological considerations when compared with most occupational settings, which varies for each individual. These include, but are not limited to, exposures related to the use of military-specific materials, hazards that are characteristic of the duties and/or locations of service (e.g., deployments), and the physical consequences of combat. A thorough understanding of the potential impacts of these experiences on health (both short- and long-term) is required. This information also is vital in preparing for future missions and ensuring the safety of service members and quality of life of veterans. As representative examples, the speakers in this session will discuss (1) the systemic and local effects of embedded metal fragments from blast injuries, (2) the identification of subtle respiratory dysfunction related to exposure to airborne hazards during deployment, and (3) evaluations of toxicity and long-term health implications due to jet fuel exposure. These topics will highlight some hazards and exposure pathways specific to military personnel, a large population with a unique and complex occupational environment, carrying out operations to sustain national security, and the challenges involved in maintaining their health during and after their service.

3264 Tungsten Alloys in Tissue, Biocorrosion, and Tumor Outcome

L. Roszell[1], D. I. Bannon[1], and B. Schuster[2]. [1]*Army Public Health Center, Aberdeen Proving Ground, MD; and* [2]*Army Research Laboratory, Aberdeen Proving Ground, MD.*

Military and civilian personnel in areas of conflict can be exposed to metal fragments from bullets or explosions. Depending on the size, body location, and risks associated with surgical removal, these fragments can remain in tissue for years, or even a lifetime. The potential toxicity and health effects of long-term exposure are therefore of concern. Tungsten alloys, which are used in munitions, are composed of tungsten microparticles embedded in a solid matrix of transition metals that can include nickel, cobalt, and iron. Intramuscular implants in rodents with different pellet compositions have been carried out by various groups, resulting in a range of sarcoma incidences. Our work has shown that alloy composition and biocorrosion of component metals are important determinants of health outcomes, while the species of rodent used also is a factor in tumor response to metal alloys. This presentation will summarize the field to date regarding studies on potential toxicity of tungsten alloys and identify future research needs.

3265 Metal Exposure in Veterans with Embedded Fragments from War-Related Injuries: Exposure Assessment and Surveillance Outcomes

J. M. Gaitens, and M. A. McDiarmid. *University of Maryland School of Medicine, Baltimore, MD.*

Injuries from blasts and explosions pose the "signature" health threat to service members deployed in recent military conflicts. Beyond acute traumatic injury, they can result in chronic sequela arising from significant wound contamination with foreign debris. Embedded metal fragments may cause local foreign-body tissue effects or, with fragment oxidation *in situ*, increased systemic metal concentrations. These raised systemic metal burdens permit insult to target organs far from the site of traumatic injury. Consequently, the US Department of Veterans Affairs established the Toxic Embedded Fragment Surveillance Center, which conducts the only national program that evaluates such war-injured veterans on a population level, after the first Gulf War in 1991. Several findings from this program will be presented, such as urine metal concentrations and surveillance outcomes, which include both routine clinical measures of metal target organ function and novel early effect biomarkers, in VA cohorts exposed either to depleted uranium or to improvised explosive device (IED) injury during combat deployments.

3266 Small Particles and Small Airways: Large Problems for Deployed Military?

M. J. Falvo, and A. M. Sotolongo. *US Department of Veterans Affairs War Related Illness and Injury Study Centers, East Orange, NJ.* Sponsor: M. Johnson

Particulate air pollution from both natural (e.g., sand and dust) and anthropogenic (e.g., burn pit smoke, industrial pollution) sources is ubiquitous in the deployment environments in Iraq and Afghanistan. This includes fine particulates with an aerodynamic diameter less than 2.5 microns ($PM_{2.5}$), which may penetrate deep within the distal or smaller airways. During and after deployment, military personnel exhibit respiratory symptoms and exertional dyspnea that may be associated with their deployment-related exposures, but to date, this has not been confirmed. Post-deployment lung function testing, such as spirometry, has been performed, though it is generally found to be within normal limits, even among symptomatic personnel. Our research and that of others suggests that traditional lung function testing is insensitive for evaluating the smaller airways, and alternative modalities, such as the forced oscillation technique (FOT), may be more sensitive. Work from our national referral clinic has found considerable small airway dysfunction, as detected by FOT, among symptomatic deployed veterans with otherwise normal lung function. Implications of these findings extend beyond the military and are broadly applicable to those with environmental/occupational and inhalational exposures.

3267 Breaking the Code: Identifying the Long-Term Health Implications of Occupational Jet Fuel Exposure in Air Force Personnel Using Military Occupation Codes

T. D. Vincent[1], W. J. Culpepper[1], J. Leon[2], J. Escobar[2], and A. Schneiderman[1]. *[1]US Department of Veterans Affairs, Washington, DC; and [2]US Air Force School of Aerospace Medicine, Wright-Patterson AFB, OH.*

The US Department of Veterans Affairs (VA) and the US Department of Defense (DoD) work together to address the concerns of service members and veterans regarding the health implications of their military service. While historical exposure concerns have focused on those that are characteristic of deployed environments, more frequently, both DoD and VA are receiving inquiries regarding the potential dangers of routine military duties. Exposure to jet fuels is one of the most commonly experienced, regardless of branch. The purpose of this study was to evaluate the sensitivity of military occupation codes as a surrogate for occupational exposure to jet fuels and to investigate the long-term health effects of such an exposure in veterans who served in the Air Force. Occupation codes were used to define levels of exposure, and associations between occupational exposure to fuels and health outcomes were assessed, especially those representing dysfunction in the respiratory and nervous systems. The health data from VA and DoD databases were linked to ascertain these outcomes. This study (1) demonstrates that occupation codes can be used to estimate relative jet fuel exposure in AF personnel, and (2) precedes a more comprehensive, joint VA-DoD, multidisciplinary investigation into the consequences of occupational exposure to jet fuels during service in all branches of the US military, which may have future implications in the development of policy, preventive measures, and health care guidance.

3268 Review of Inhalation Studies of Alternative Jet Fuels in Rodents for Occupational Exposure Limits

D. R. Mattie[1], K. L. Mumy[2], T. R. Sterner[3], and B. A. Wong[2]. *[1]Air Force Research Laboratory, Wright-Patterson AFB, OH; [2]Naval Medical Research Unit-Dayton, Wright-Patterson AFB, OH; and [3]Henry M. Jackson Foundation for the Advancement of Military Medicine, Wright-Patterson AFB, OH.*

The DoD has put forth significant effort in evaluating alternatively sourced fuels, including those derived from synthetic, plant- or animal-based, or genetically modified organisms, with the ultimate goal of reducing the use of petroleum-derived fuels. Candidate alternative fuels undergo tests of their physical and chemical properties, as well as operational testing, to ensure that they meet performance specifications. In addition to assuring that new fuels are operationally suitable, it is important to ensure that the newly developed fuels are still considered safe for use by service members and any potential toxicity does not exceed the toxicity of conventional fuels. The US Air Force and Navy have used existing toxicity testing paradigms to establish an evaluation program for alternative fuels, with the goal of developing a comparative toxicity database (to include petroleum-derived jet fuels) that can be used to recommend occupational exposure limits (OELs). A variety of fuels have undergone testing in recent years, including a Synthetic Paraffinic Kerosene (SPK) jet fuel generated using a Fischer-Tropsch (FT) process (FT SPK); hydro-treated renewable jet (HRJ) fuel based on oils extracted from the camelina plant (*Camelina sativa*) or bioderived from Hydroprocessed Esters and Fatty Acids (referred to generally as *HEFA*); biologically produced hydrocarbon liquids, such as the bioderived Gevo Jet Blend Stock fuel (Gevo); and the direct-sugar-to-hydrocarbon process that resulted in farnesane made by Amryis Inc. The toxicity of the various fuels was evaluated under a toxicity test protocol described in the DoD Handbook for Aerospace Fuels Certification (MIL-HDBK-510A). The toxicity tests included sensory and dermal irritation and genotoxicity, as well as the extensive short-term and 90-day inhalation exposures with multiple endpoint analyses (in compliance with DODI 3216.01). A summary of these studies will be presented, as well as a discussion of the future direction for jet fuels toxicity studies.

3269 Cannabidiol Science, Safety, and Societal Impacts: Where Do We Stand?

S. Bobst. *ToxSci Advisors LLC, Houston, TX.*

Current market predictions indicate cannabis-derived cannabidiol (CBD) product markets will be over $22 billion by 2022. Because of large demand and market pressures, several national retailers already selling CBD products to consumers, ignoring current Drug Enforcement Administration (DEA) and US Food and Drug Administration (US FDA) restrictions on cannabis-derived products. US states continue to update cannabis legalization laws to align with CBD product popularity and demands from consumers. Federal restrictions on obtaining and funding cannabis and CBD-related research and commerce have placed significant limitations on the traditional safety and efficacy characterizations of CBD use in consumer products. This session will present current CBD basic and clinical research, describe challenges and opportunities for consumer product safety, as well as development of cannabis-derived medical treatments, and lay out legal, regulatory, and social dilemmas created by the complex landscape of commercialization of cannabis-based products.

3270 An Overview of the Pharmacology, Toxicology, and Popularity of CBD

H. Kamendi. *Rx Remedies Inc., Baltimore, MD.*

Cannabidiol, more commonly known as CBD, has gained ever-accelerating popularity over the last three years due to changes in state and local laws and wide-reaching claims that it prevents inflammation, improves appetite, relieves anxiety, aids sleep, and supports or improves many other medical conditions. Hemp-derived CBD sales are on track to become a $1 billion market by 2020. During this time, pharmaceutical preparations will account for nearly 40% of all products. Complex CBD oil extracts are sold online and in natural food stores. They have made their way into national brick-and-mortar establishments, including convenience stores and pharmacies, where they are sold as dietary supplements. Such widespread availability of CBD oils raises many concerns, including the number of poorly characterized cannabinoids and terpenes present in full spectrum extracts. Little is currently known about many effects, mechanisms, and side effects of CBD, for either short- or long-term use, let alone the mechanisms and side effects of complex CBD mixtures.

3271 Assessing Toxicity, Mechanisms of Action, and Therapeutic Potential of Cannabidiol Using Zebrafish

K. Willett. *University of Mississippi, Oxford, MS.*

Recent clinical trials have supported cannabidiol (CBD; Epidiolex) efficacy in helping control seizures in pharmaco-resistant forms of epilepsy such as Dravet syndrome. Largely outside the clinical realm and federal oversight (in the US), CBD use is being popularized for ailments as diverse as anxiety, acne, arthritis and chronic pain, insomnia, and cancer. Zebrafish as a research organism provide a relatively high-throughput model by which both the efficacy and the potential toxicity of CBD can be assessed. For example, using zebrafish that carry a mutation in the voltage-gated sodium channel Nav1.1 (scn1a) to replicate the human Dravet syndrome, we found significant anti-seizure activity with 1μM CBD after 24 h larval exposure. Despite the significant therapeutic potential of CBD, toxicity assessments, particularly for developmental or chronic exposures, are lacking. To assess both the acute and developmental consequences of CBD, zebrafish were exposed through the larval stage to 0.02 to 0.5μM CBD. Developmental deformities, behavioral analysis, and RNA-seq analysis of the transcriptome are being used to identify potential target organ and toxicity pathways (e.g., liver and PXR/RXR). Furthermore, transgenic cannabinoid receptor null (cnr1-/-, cnr2-/-) fish are used to assess receptor-mediated toxicity and/or therapeutic potential. In zebrafish, important differences in cannabinoid bioavailability were identified—specifically, the bioaccumulation of CBD was significantly higher than Δ-9-tetrahydrocannabinol in zebrafish larvae. Adult fish that were developmentally exposed to CBD showed decreased fecundity, supporting the need to consider the developmental origins of health and disease of CBD. Zebrafish offer a good initial tool to measure safety and toxicity and inform policy considerations related to CBD expanded use.

3272 Cannabidiol: Safety, Monitoring, and Drug-Drug Interactions

T. Gaston. *University of Alabama at Birmingham, Birmingham, AL.*
Sponsor: S. Bobst

In June 2018, US FDA approved the first drug composed of an active ingredient of cannabis—a highly purified oral solution of cannabidiol—and with rescheduling, it is now available for use in clinical practice with an indication to treat refractory seizures associated with two severe childhood onset epilepsy syndromes: Lennox-Gastaut syndrome (LGS) and Dravet syndrome (DS). This talk will focus on safety issues as they apply to this pharmaceutical-grade CBD product. First, a brief review of the pharmacology of CBD as it is relevant to the treatment of seizures will be presented, including proposed mechanisms of action and metabolism. Based on the various actions of CBD on the cytochrome P450 system, this raises several concerns toward possible drug-

drug interactions. Next, the available data in both animal models and humans regarding potential pharmacodynamic and pharmacokinetic drug-drug interactions with CBD will be discussed. CBD has been shown to have a significant interaction with the anti-epileptic drug clobazam in particular, which causes increased sedation and elevated blood levels of clobazam's active metabolite. There has been some controversy regarding if this interaction with clobazam is responsible for the efficacy of CBD in treating seizures, and the data to support and refute this will be presented. Next, adverse effects and special populations will be discussed in regard to CBD treatment; this will largely be drawn from the randomized placebo-controlled trial data. Finally, based upon the noted drug-drug interactions and adverse effects, recommended safety monitoring in patients taking CBD will be discussed, particularly from the drug label of highly purified CBD.

W 3273 Cannabidiol: Pain, Pleasure, Potential, and Problems

D. Fox. *Robson Associates LLC, Lancaster, PA.*

The legalization and use of marijuana (tetrahydrocannabinol: THC) and cannabinoid-based products are increasing rapidly in the United States and other North American countries. Currently, 33 states and the District of Columbia have laws that broadly legalize it in some form, although THC is still classified as a Schedule 1 drug by the DEA. In contrast to THC, the non-psychoactive cannabidiol (CBD) was recently rescheduled as a Schedule 5 drug. The marketing, distribution, and widespread availability of CBD raise serious ethical, legal, forensic, and societal issues. Scientific research and discussions about the beneficial clinical, pharmacological, and psychological effects associated with regulated CBD intake are in a controversial and embryonic state. In addition, the acute and long-term potential adverse toxicological effects of chronic CBD in different aged populations are relatively unexplored. This talk will address the biochemical/cell biological mechanisms of CBD and its use for the treatment/management of clinically definable and relevant issues, focusing on pain management and relief and reduction of opioid use/abuse, and including treatment of post-traumatic stress syndrome and other anxiety disorders, convulsion, inflammation, and insomnia.

W 3274 Cannabidiol Incorporation into Consumer Products in the US: Regulatory Challenges to Commercialization

L. Plunkett. *Integrative Biostrategies LLC, Houston, TX.*

This talk will focus on the regulatory concerns related to cannabidiol (CBD) commercialization and build on the information conveyed by preceding speakers related to the science behind CBD as an ingredient with biological properties that impart desirable effects. The ever-changing regulatory landscape surrounding use of cannabis-related ingredients in consumer goods in the US was further complicated in 2019 by the passage of the Farm Bill, which has legalized and expanded the cultivation of hemp and the production of hemp-derived CBD across the US. This talk will provide an update on the regulatory oversight of CBD as it relates to its incorporation into a wide variety of consumer products (e.g., homeopathic drug products, foods, dietary supplements, beverages, and cosmetics), as well as its production as an ingredient for addition to this wide variety of consumer goods. Both federal and state regulatory bodies are involved in various aspects of CBD product production, distribution, and marketing; this talk will focus on public health and safety concerns related to CBD commercialization. Examples of regulatory actions that have been taken by either the federal government or state governments will be discussed, with these examples taken from the most recent regulatory actions. Examples may include (1) recent US FDA actions to crack down on the use of certain unsupported health claims on consumer products containing CBD; (2) US FDA actions in the area of analytical testing of CBD-containing products and findings that certain products contained "unapproved new drug products"; and (3) actions by States like New York and Maine to seize/embargo consumer products sold as foods (baked goods, beverages, etc.) because CBD is not a legal food additive that has been proven safe for use.

W 3275 Have *In Vitro* Teratogenicity Assessments Come of Age in the Pharmaceutical Industry?

M. McNerney. *Bristol-Myers Squibb Company, New Brunswick, NJ.*

The earliest reference to *in vitro* teratogenicity assessment is now 40 years old, and the intervening history of *in vitro* assays represents unwavering interest in their ability to detect serious developmental toxicity, most recently while minimizing animal usage. In the pharmaceutical industry, such assays are routinely used to screen compounds for liability in early development; of late, *in vitro* methods have been pursued for their potential to defer or replace *in vivo* regulatory studies in rats and rabbits. This Workshop has been convened to review the state-of-the-science and to make recommendations for the path forward. After a brief overview of the history of alternative assays for developmental toxicity, the first speaker will present the experience and perspective of the Dutch Medicines Board with *in vitro* assays, and their place in the 2025 framework to eliminate animal studies. The second speaker will present the Merck experience with rat whole embryo culture and mouse embryonic stem cell tests, including developing and characterizing an integrated prediction model that has been used for routine screening for most of the past decade. The third speaker will contribute the perspective of a Center for Drug Evaluation and Research reviewer on the utility of *in vitro* teratogenicity assays. The fourth speaker will discuss data collected and analyzed by the DruSafe/IQ Consortium, comparing findings from 90 compounds that were tested both *in vitro* and *in vivo*. Importantly, this session will segue from presentations into discussion/Q&A among audience members and speakers, with the expectation that the contributions of many in the audience (whether experts, novices, or data consumers) will lead to a fuller and more nuanced understanding of the ways that such assays can be successfully employed.

W 3277 Alternative Methods for Developmental Toxicity Testing of Pharmaceuticals: An EU Regulatory Point of View

P. Theunissen. *CBG-MEB, Utrecht, Netherlands.* Sponsor: M. McNerney

In the current regulatory framework, embryo-fetal developmental toxicity (EFDT) testing is primarily performed in two species. Recently, the need of testing EFDT in two species and the reproducibility of these EFDT studies have been questioned. Alternative assay strategies for EFDT testing can be a (partial) substitute for animal data, but currently they are only sporadically provided as evidence for first-in-human trials and marketing authorization applications (MAA). In the (drafted) revision of the ICH S5(R3) Guideline, for the first time alternative testing strategies are proposed as an approach for addressing EFDT risk. Upon adoption, it is expected that alternative testing strategies will be increasingly provided for regulatory qualification and, subsequently, at MAA. In addition, it is expected that within predefined contexts of use, including a known mode of action, within class potency ranking, and for certain indications, alternative assays for EFD toxicity testing will provide sufficient scientific evidence for regulatory decisions, resulting in more mechanistically driven decisions and reduced animal testing. However, how will these data contribute to risk assessment and labeling? Current European use of animal data and experience with alternative assays for EFD toxicity testing for risk assessment and labeling will be discussed in perspective of the expected paradigm shift by ICH S5(R3).

W 3278 Putting Alternative Developmental Toxicity Assays to Work

K. Brannen. *Merck & Co. Inc., West Point, PA.*

The scientific community has sought predictive alternatives to embryo-fetal development (EFD) studies for decades, but translating the concept into reality has presented challenges. Determining whether such an assays will actually improve drug discovery and development has been even more complicated. This presentation will use one pharmaceutical company's experience designing, characterizing, and using two *in vitro* assays as an example to illustrate the potential utility of these screens individually and in combination. Rat whole embryo culture (WEC) and a mouse transcriptional embryonic stem cell test (mTEST) were evaluated individually and in combination. These assays were refined to maximize sensitivity for detecting developmental toxicants (specifically molecules that induce malformations and/or embryo-fetal lethality), and an integrated model was developed that incorporated results from both assays and provided an exposure-based prediction based on the WEC results. The assays and the associated exposure-based prediction model were initially tested with more than 50 compounds with known *in vivo* outcomes, and in the almost 10 years since, they have been used routinely in discovery programs to screen for developmental toxicity potential and determine timing of *in vivo* studies. Based on an analysis of 83 compounds with known *in vivo* outcomes (Green et al. 2018, *Appl in vitro Toxicol* 4(1):44-53), sensitivity and specificity for the WEC model alone was 78% and 78%, respectively, and 64% and 57% for the mTEST prediction model. The integrated prediction model provided improved sensitivity of 89% compared with either assay individually, but the resulting specificity was 54%. Case examples of discovery compounds that were tested in WEC and mTEST and subsequently evaluated in preliminary and/or definitive EFD studies will be presented. Implications of

assay and prediction model designs will be discussed, and several questions that remain to be answered will be raised to spur discussion with the panel and audience.

3279 The Role of Alternative Assays in Informing DART Risk Assessment for Pharmaceuticals

R. Wange. *US FDA/CDER, Silver Spring, MD.*

In opening up the ICH S5 guidance for revision, the participating drug regulatory authorities and regulated industry committed to providing guidance on the attributes that alternative assays should have, if they are to be used for regulatory purposes. In addition, per the Concept Paper, the guidance is to identify the circumstances under which results from alternative assays would be considered to be sufficiently informative as to permit regulatory decision-making without negatively impacting trial subject or patient safety. As currently drafted, the revised guidance indicates that each region will independently assess whether a submitted alternative assay is qualified for the intended context of use. This presentation will discuss the current approach of CDER to conducting qualification assessments for DART alternative assays dossiers, as well as presenting an analysis of our experience to date with the use of alternative assays in IND, NDA, and BLA submissions, focusing on the types of assays received and whether the assays have had any impact on the nonclinical or clinical development programs.

3280 Concordance between *In Vitro* Teratogenicity Assessments and *In Vivo* Findings: The IQ DruSafe Assessment

M. McNerney. *Bristol-Myers Squibb Company, New Brunswick, NJ.*

IQ DruSafe established a working group to evaluate concordance of three *in vitro* assays with findings reported from rat or rabbit EFD studies. Eight companies contributed 90 compounds to a database; each entry has at least one *in vitro* and one *in vivo* pair. *In vivo* findings with malformations or mortality were deemed positive; otherwise, they were considered negative. Too, each company was asked to indicate whether its *in vitro* assay data predicted positive or negative *in vivo* findings. First-tier queries examined whether a given assay predicted that one or both species was positive or negative, with subsequent analyses by species and type of toxicity. Acceptable Sensitivity and Specificity were set at 70%. Positive and negative predictive values (PPV and NPV) were adjusted for the companies' portfolio prevalence of 30%; likelihood ratios (LR) also were calculated. Acceptable rates of false negatives were set at = 10%. Fifty-six compounds had zebrafish embryo culture data. Apical analyses yielded 68% sensitivity, 32% specificity, 30% PPV, and 69% NPV; LR for PPV and NPV were each ~1. Individual analyses (by toxicity type or species) were not further optimized. The overall rate of false negatives for this assay was 21.4% and did not improve by further 2x2 analyses. Murine embryonic stem cell data were available for 48 compounds (including 47 rat and 32 rabbit studies). Apical analyses yielded 72% sensitivity, 37% specificity, 33% PPV, and 76% NPV. The LR for PPV and NPV were ~1. The apical rate of false-negative predictions for embryonic stem cells was 16.6%. Subsequent 2x2 analyses yielded similar results. Rat whole embryo culture data were available for 29 compounds (including 29 rat and 20 rabbit studies). Apical analyses yielded 82% sensitivity, 68% specificity, 51% PPV, and 90% NPV. The LR for PPV and NPV were ~2.5 and 3.8, respectively. LR for NPV were invariably improved with subsequent 2x2 analyses, the most significant of which was the assessment of rat malformations or mortality (LR ~9.3). The apical rate of false negatives was 10.3%, and most 2x2 assessments were at least equivalent (exception: the rate of false negatives for rat or rabbit mortality was 34.5%). The limitations and implications of these findings will be discussed.

3281 Immune-Mediated Adverse Drug Reactions: State-of-the-Art Learnings from Preclinical and Clinical Drug Development

A. Sharma. *Genentech Inc., San Francisco, CA.*

Adverse drug reactions (ADR) are a major cause for attrition resulting in termination of drug development, denied commercialization, market withdrawal, or restricted prescribing of new pharmaceuticals. Some ADRs are considered predictable as the injury results from excessive pharmacology at the intended target of the drug. The term *idiosyncratic* is assigned to ADRs where injury is unrelated to drug's mechanism of action and often immune mediated in nature. Immune mediated adverse drug reactions (IM-ADR) represent less than 20% of all ADRs, but they can be severe in clinical terms and have the poorest concordance between man and preclinical species. These are usually not detected until late in development, after significant investment in development and after large numbers of patients have been put at risk. Affected patients may present with fever, rash, hematologic abnormalities, or damage to a variety of internal organs. IM-ADRs can be associated with small molecule-based drugs and are characterized by activation of drug-antigen specific T and B cells of the acquired immune system. Reactive metabolites covalently bind to proteins that are processed to form neoantigens. Alternatively, they establish noncovalent interactions on class I or II MHC molecules that lead to immunogenic complexes. Large molecule drugs (e.g., monoclonal antibodies) also represent a unique type of risk. Recent clinical reports have highlighted the possibility of increased severity and incidence of IM-ADRs for specific immune checkpoint inhibitor monoclonal antibodies when given in combination with small molecule drugs or with other antibody-based immune checkpoint inhibitors. Despite much progress, understanding of the underlying mechanisms of IM-ADRs is incomplete, and qualified tools for risk assessment are lacking. The goals of this discussion are (1) to bring together in one session the IM-ADR-related preclinical and clinical development learnings for both small and large molecule drugs as an attempt to identify synergies between these modalities, and (2) to discuss the state-of-the-art models as well as future approaches and biomarkers that will enable improved prediction and prevention of IM-ADRs. The first presentation will review the chemistry of small molecule-based drug antigens and the molecular basis of IM-ADRs mediated by the adaptive immune system. The second presentation will discuss the role of drug metabolism and the immune biology of skin, a frequent target organ of IM-ADRs. The third presentation will review the role of the innate immune system in IM-ADRs. The fourth presentation will illustrate how humanized preclinical animal models can advance our mechanistic understanding of IM-ADRs. The fifth presentation will shift the focus of the session to large molecule-based drugs and present data obtained from patients experiencing IM-ADRs. The final presentation will discuss preclinical models used to predict the immunogenicity of large molecule-based drugs. All speakers will emphasize what are the tools currently available for improving risk assessment to enable the development of safer drugs.

3282 The Chemical Basis of Drug Hypersensitivity and Development of *In Vitro* Assays to Predict Intrinsic Immunogenicity

D. J. Naisbitt. *University of Liverpool, Liverpool, United Kingdom*. Sponsor: A. Sharma

T cell-mediated drug hypersensitivity reactions represent a major impediment to the drug development process, as they are currently impossible to predict. Susceptibility is dependent on three critical factors: (1) exposure to the drug antigen in a relevant form, (2) the availability of a T cell repertoire for the drug antigen, and (3) the availability of HLA molecules for drug antigen binding. It most be noted, however, that most individuals who express all three factors don't develop hypersensitivity when exposed to drugs. This is because immune regulatory pathways also contribute to susceptibility through controlling the strength, nature, and duration of the immune response. Since expression and activity of these pathways are determined by the genetic makeup of the individual, alongside environmental factors and disease, the outcome of drug exposure, be it a health benefit or hypersensitivity, is currently impossible to predict. This presentation will review the chemical basis of drug hypersensitivity and how immune regulatory pathways impact the development of a drug-specific T cell response. The discovery of strong associations between expression of single HLA alleles and susceptibility to specific forms of drug hypersensitivity and the development of T cell priming assays have allowed researchers to show that certain drugs bind selectively to HLA risk alleles to activate T cells. However, using currently available T cell priming assays, it is not possible to predict the intrinsic immunogenicity of new drugs and chemicals. Thus, the second component of the presentation will detail how we are developing a stepwise screening approach for drug immunogenicity assessment using lymphocytes from HLA-typed healthy donors.

3283 Bioactivation of Drugs in the Skin: Examining the Concepts of Necessity and Sufficiency in Drug-Induced Dermal Toxicity through Metabolism, Immunology, and Host-Dependent Factors

A. M. Sharma. *Genentech Inc., San Francisco, CA.*

Advances in the understanding of drug-induced skin toxicities have been slow given the skin's complex anatomical nature. Current advances in the study of cutaneous adverse drug reactions are attributable to recent developments in our ability to dissect individual layers of skin and study discrete components. This has led to a deep appreciation for the skin as both a metabolically and immunologically competent organ. It is now understood that

the skin not only serves as a protective barrier with limited drug biotransformation ability, but also possesses high immune activity/function, capable of myriad responses. While the immune response of the skin to drugs is vastly different from that of the liver due to evolutionary conditioning, it frequently occurs in response to various drug classes and manifests as a spectrum of hypersensitivity reactions. Association of other factors such as human leukocyte antigen (HLA) polymorphisms may play a significant role for particular drugs. This presentation aims to introduce the concept of what is necessary in causing adverse skin reactions from what may be sufficient. Emerging findings will be translated into proposed mechanisms of drug metabolism and immunity in the skin that are likely responsible for rashes and other local allergic responses. These unique biological aspects of the skin, and their translation into implications for drug development and the use of animal models, will be discussed. The concept of necessity versus sufficiency in drug-induced skin toxicity is an emerging topic of high interest to both academics and drug developers alike.

3284 Role of the Innate Immune System in Adaptive Immune Mediated Idiosyncratic Drug Reactions

J. Uetrecht. *University of Toronto, Toronto, Canada.*

Idiosyncratic drug reactions (IDRs) represent a significant source of morbidity and mortality and significantly increase the risk of drug development. An accurate method to predict the risk that a drug candidate would cause IDRs would be a major advance. There are multiple lines of evidence that most IDRs are immune mediated. The most severe IDRs appear to be due to cytotoxic T cells, but antibody-mediated reactions also are significant. Most people do not have a serious IDR to culprit drugs and the major response, especially in the liver, appears to be immune tolerance. An adaptive immune response depends on the recognition of antigens by a combination of HLA on antigen presenting cells and T cell receptors. The HLA genotype is inherited, but even if a patient has the HLA genotype associated with a specific IDR, it is unlikely they will have an IDR to that drug. Presumably they lack T cells with the required T cell receptor. The T cell receptor repertoire is produced by recombination of genes, and it is shaped by everything that an individual has been exposed to. The generation of an adaptive immune response requires an innate immune response. The innate immune response can vary between species and between individuals in a species, but it is much less idiosyncratic. For example, clozapine-induced agranulocytosis does not occur in most patients, but most patients do have a transient innate immune response with increases in IL-6, C-reactive protein, and a paradoxical neutrophilia. We have shown that clozapine also induced an innate immune response in rats. Clozapine also leads to an activation of inflammasomes. Olanzapine, which is very similar to clozapine and forms a reactive metabolite, does not cause an innate immune response in rats and does not activate inflammasomes. Penicillamine causes a variety of autoimmune reactions in humans and in Brown Norway rats. About 50% of rats develop the autoimmune syndrome, with a transient spike in serum IL-6 at 24 hours that is back to baseline in three days. The height of the transient IL-6 spike predicts which animals develop autoimmunity three weeks later. It is plausible that testing the ability of drug candidates to induce an early innate immune response, first in animals and later in humans, will predict which drug candidates are likely to cause serious IDRs. New data will be presented that tests this hypothesis.

3285 Animal Models for HLA-Linked Adverse Drug Reactions

M. Norcross. *US FDA/CDER, Silver Spring, MD.* Sponsor: A. Sharma

Adverse drug reactions (ADRs) are a major obstacle to drug development, and some of these, including hypersensitivity reactions to the HIV reverse transcriptase inhibitor abacavir (ABC), are associated with HLA alleles, particularly HLA-B*57:01. However, not all HLA-B*57:01+ patients develop ADRs, suggesting that in addition to the HLA genetic risk, other factors may influence the outcome of the response to the drug. Animal models that express the HLAs that are linked to drug reactions could provide *in vivo* systems to study both genetic and host factors that control adverse reactions. To study HLA-linked ADRs *in vivo*, we generated HLA-B*57:01-Tg mice and show that, although ABC activated Tg mouse CD8+ T cells *in vitro* in a HLA-B*57:01-dependent manner, the drug was tolerated *in vivo*. In immunocompetent Tg animals, ABC induced CD8+ T cells with an anergy-like phenotype that did not lead to ADRs. In contrast, *in vivo* depletion of CD4+ T cells prior to ABC administration enhanced DC maturation to induce systemic ABC-reactive CD8+ T cells with an effector-like and skin-homing phenotype along with CD8+ infiltration and inflammation in drug-sensitized skin. B7 costimulatory molecule blockade prevented CD8+ T cell activation. These HLA Tg mice provide a model for ABC tolerance and for the generation of HLA-B*57:01-restricted, ABC-reactive CD8+ T cells dependent on both HLA genetic risk and immunoregulatory host factors.

3286 Understanding Autoimmunopathies from Immunotherapy: Biomarkers and Mechanisms

J. Balko. *Vanderbilt University Medical Center, Nashville, TN.* Sponsor: A. Sharma

Immune checkpoint inhibitors induce durable antitumor responses across cancer types but may simultaneously unleash autoimmune-like toxicities affecting nearly all organs. The molecular underpinnings of these toxicities have not been well characterized but likely vary with specific immunotherapies and sites of toxicity. T cell receptor sequencing (TCRseq) performed on sites of fulminant or aggressive immunopathies (e.g., myocarditis and encephalitis) has demonstrated highly oligoclonal T cell repertoires that may hint at antigens from which peripheral tolerance has been released, or that mimic tumor-specific antigens associated with immunologic responsiveness to therapy. Preclinical and anecdotal clinical data suggest that therapeutic responsiveness can be uncoupled from checkpoint inhibitor-induced autoimmunity via inhibition of pathways such as type-I interferon or TNFa, although this has yet to be demonstrated in controlled trials. This talk will focus on current findings surrounding the molecular features and biomarkers associated with distinct autoimmunopathies as well as strategies to improve risk:benefit ratios in the treatment of cancer with immune checkpoint inhibitors.

3287 Immune-Mediated Adverse Events in Preclinical Toxicology Species: Role of Immune Complexes Formed from Therapeutic Protein-Antibody Complexes

V. Jawa. *Merck & Co. Inc., Kenilworth, NJ.* Sponsor: A. Sharma

The immune response to human therapeutic proteins (TP) in preclinical species is often excessive and can lead to immune complex mediated adverse events like hypersensitivity. These reactions need to differentiate pharmacology from an immunogenicity mediated event, especially when the pharmacology could be further modified by the engagement of immune modulatory receptors on immune cells. Some accompanying events associated with immunogenicity would be presence of anti-drug antibodies and loss of exposure due to accelerated clearance based on kinetics of immune response. Based on their size and composition of TP: anti-therapeutic antibodies (ADA), the immune complexes can deposit in the vasculature or kidneys, leading to vasculitis or renal pathology. This talk will propose strategies for a proactive risk assessment strategy and design of the relevant assays to support a proactive assessment of immunogenicity mediated adverse events.
