Cyp1b1 has minimal expression in hepatocytes but is robustly expressed in endothelia and in mesenchymal progenitors including in bone marrow (BM). Cyp1b1 in BM mesenchymal progenitor cells (MPC) mediates suppression of BM hematopoietic progenitors by PAH within 6h. Cyp1b1 also has many such effects on endogenous mediators of inflammatory processes often in unexpected places. Thus, Cyp1b1 deletion suppresses diet induced obesity in combination with a specific set of gene responses related to growth hormone and leptin signaling. Restriction to macrophage selected by Lyz2-CRE fully reproduces systemic Cyp1b1 deletion responses. Here we characterize macrophage originating from respectively BM (BMM) and peritoneal cavity (PM) of separate sets C57Bl/6J mice (Age 6 weeks, n=3). BMM macrophage (28 percent of BM cells) were selectively expanded by M-CSF for 6 days. PM were optimally cultured from other individual C57Bl/6J mice. M-CSF expanded BMM expressed only low Cyp1b1 but substantially elevated PPARγ. IL-13 which stimulates PM via LRH-1/Nr5a2 elevated Cyp1b1 mRNA from undetectable to robust expression but with Cyp1a1 undetectable. Three other similar LRH responders (CD36, Arg1 and ym1) were highly stimulated whereas TNfα was suppressed. Responses to IL-13 were unaffected by the specific Cyp1b1 inhibitor tetramethoxystilbene or when stimulated in Cyp1b1-/- PM. M-CSF enriched BMM were characterized for M1 polarization (IFNγ-24h stimulation) and M2 stimulation (IL-4 24h stimulation). Cyp1b1 was elevated 4-fold to significant but low levels in M2 polarization by IL4, again without Cyp1a1 but not by IFNγ. Inflammatory M1 polarization by IFNγ stimulated TNFα, peaked within 3-6h and then declined. IL-1β and iNOS appeared later. The transcription factor Ciita responded linearly over 24 hr preceding increases in Ciita-targeted four H2 histocompatibility factors (H2-Ab). Cyp1b1 deletion decreased the acute stimulation of TNFα (3-6h,$p<0.05$) but not after decline at 24h. M2 polarization of BM macrophage with IL-4 was marked by rapid increases in transcription factors (IRF4, Klf4, Egr2 and Myc) and subsequently by M2 markers (Arg1, Ym1 and Fizz1) at 24h. Other IFNγ responses or IL-4 responses were unaffected by Cyp1b1 deletion. The absence of Cyp1b1 in WT M1 macrophages indicates an indirect effect. Expression changes in Cyp1b1-/- BM have been reported. Effects of Cyp1b1 on obesity are unlikely to arise from these BMM or PM. Macrophages of brain (microglia) where Cyp1b1 metabolism of estradiol is an influence provides a more likely source.

1849 Nuclear Receptor REV-ERB Alpha Augments House Dust Mite-Induced Allergic Asthma in Mice

I. Rahman, and I. Sundar. *University of Rochester Medical Center, Rochester, NY.*

Allergic asthma is a chronic inflammatory disease that displays a time-of-day dependent variation in clinical symptoms and severity. Asthma attacks, particularly in response to household allergens show a time-dependence with most severe attacks occurring in the night/early morning. The molecular clock, nuclear receptor Rev-erbα plays a considerable role in immunity and inflammation. Intriguingly, the impact of allergen-induced dysfunction on molecular clock function and its role in gating the severity of lung immune-inflammatory responses during allergic asthma is not known. We hypothesize that allergen-induced disruption of REV-ERBα expression leads to irregular clock function in the lungs, altered rhythms of clock-controlled genes and augmented immune-inflammatory responses. Wild-type (BALB/c or C57BL/6J) and REV-ERBα global knockout (KO) mice were exposed to acute house dust mite (HDM) allergen model. Mice were administered with PBS (30 µl) or HDM extract (30 µg/30 µl) intra-nasally (i.n.) for 10 consecutive days and euthanized 48 hrs after the last challenge at two different time points (am vs. pm). We measured the severity of asthmatic lung phenotypes including airway inflammation, airway hyperresponsiveness, Th2 cytokines in bronchoalveolar lavage fluid, plasma IgE/IgG, mucous metaplasia, abundance of Muc5ac, Muc5b protein, expression of mucins, *Tslp* (Thymic stromal lymphopoetin), Stat3 and clock-controlled genes (CCGs) in mouse lung. WT mice exposed to HDM show reduced expression of REV-ERBα in airway epithelium associated with increased airway inflammation, airway hyperresponsiveness, elevated Th2 cytokine levels, increased plasma IgE/IgG, mucous metaplasia and increased abundance of Muc5ac/Muc5b. qPCR analysis revealed significant reduction in the expression of *Rev-erbα* and other CCGs (*Clock*, *Bmal1*, *Rev-erbβ*, *Per1*, *Per2*, *Cry1* and *Cry2*) and enhanced expression of *Nfil3*, *Tslp, Muc5ac,* and *Muc5b*

genes in the lungs. REV-ERBα KO mice displayed a significantly greater airway inflammation, enhanced activation of Th2 cytokines and mucous metaplasia compared to WT mice. These findings from acute HDM model show an important role of nuclear receptor REV-ERBα in the pathophysiology of allergic asthma in a mouse model. Thus, REV-ERBα could be used as a novel therapeutic target using selective REV-ERBα agonist to mitigate allergen induced immune-inflammatory response. *Supported by the NIH 1R01 HL142543 (to I.K.S).*

1850 The Development of Pulmonary Inflammation and Injury in a Mouse Model of Non-Alcoholic Steatohepatitis

T. Banota, A. Murray, L. E. Armstrong, B. Kong, G. L. Guo, A. J. Gow, and D. L. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Non-alcoholic fatty liver disease (NAFLD) is a chronic liver condition that affects 42 million individuals in the United States, of which ~20% progress to non-alcoholic steatohepatitis (NASH). NASH is characterized by the accumulation of fat in the liver and persistent inflammation which can progress to fibrosis. Emerging evidence suggests potential effects of NAFLD and NASH on the development of pathologies in the respiratory tract, but the interplay between the liver and the lung remains largely unexplored. In the current study, we assessed the impact of NASH on lung inflammation and fibrosis using a genetically modified mouse model lacking hepatic farnesoid X-receptor (FXR), a nuclear receptor involved in bile acid and lipid homeostasis, and lipocalin-2 (Lcn2), an acute phase protein upregulated in response to stress. Both FXR and Lcn2 are also involved in regulating innate immune responses. Wild type (WT), $Lcn2^{hep-/-}$, and $Lcn2/Fxr^{hep-/-}$ (DKO) mice were fed control (10% kCal) or high-fat (HF) (60% kCal) diets (n=5-10 mice/group). Liver, lung, serum, and bronchoalveolar lavage (BAL) fluid were collected after 1, 3, and 6 months of feeding. Histopathologic evaluation of livers from HFD-fed mice confirmed the development of NASH. In the lung, we observed histopathologic alterations including inflammatory cell infiltration, lipid-laden macrophages, septal damage, and epithelial thickening at 6 months; these alterations were most notable in HFD-fed DKO mice. Additionally, BAL cell counts were increased in HFD-fed DKO mice at 6 months when compared to HFD-fed WT mice, indicating lung inflammation and injury. Further analysis of expression levels of genes related to lung inflammation and lipid metabolism may reveal mechanisms underlying lung injury following the development of NASH. *Supported by NIH Grants ES029258, ES005022, and ES004738.*

1851 Exacerbation of Nanoparticle-Induced Pulmonary Inflammation in a Mouse Model of Metabolic Syndrome

S. Alqatani, L. Kobos, L. Xia, and J. Shannahan. *Purdue University, West Lafayette, IN.*

Engineered nanomaterials (ENMs) have the capacity to revolutionize numerous technologies however exposure-induced health effects are of concern. The majority of ENM safety evaluations have been performed utilizing healthy models. A growing proportion of individuals suffer diseases that may enhance their susceptibility to exposures. Specifically, metabolic syndrome (MetS) is increasingly prevalent and is a risk factor for the development of chronic diseases including type-2 diabetes, cardiovascular disease, and cancer. MetS is a combination of conditions which includes obesity, and the dyslipidemia. Due to the role of lipids in inflammatory signaling, we hypothesize that MetS-associated dyslipidemia may modulate ENM-induced immune responses. To address this hypothesis, mice were fed either a control diet or a high-fat diet for 14-weeks. A subset of mice were treated with atorvastatin for the final 7-weeks to modulate lipids. Mice were exposed to silver nanoparticles via oropharyngeal aspiration, and acute toxicity endpoints were evaluated 24-hours post-exposure. Mice on the high-fat diet demonstrated increased body weight, and cholesterol compared to control-diet mice. Cytometry analysis of bronchoalveolar lavage fluid demonstrated exacerbation of neutrophilic influx in MetS mice while statins reduced neutrophilia in MetS mice. Additionally, enhanced proinflammatory mRNA expression and protein levels of monocyte chemoattractant protein-1, macrophage inflammatory protein-2, and interleukin-6 were observed in MetS mice. These markers were reduced due to statin therapy. In contrast, ENM exposure reduced mRNA expression of enzymes involved in lipid metabolism, such as arachidonate 5-lipoxygenase, and arachidonate 15-lipoxygenase while statin treatment inhibited these alterations. A lipidomics approach was utilized to investigate lipid mediators of pulmonary inflammation. This assessment demonstrated reduced levels of lipids involved in inflammatory resolution (resolvins, maresins, EPA, DHA, etc.) in the MetS model compared to healthy following ENM exposure. Statin treatment inhibited these MetS-induced lipid alterations following ENM exposure. Taken together our data suggests that MetS exacerbates the acute toxicity induced by ENM exposure via a disruption of lipid mediators of inflammatory resolution leading to enhanced pulmonary inflammation.

1852 Anti-Inflammatory Role of Rosmarinic Acid against Cisplatin-Induced Acute Kidney Injury through Blockage of Caspase-1

J. Akhter, J. Khan, S. Ahmad, A. K. Najmi, and S. Raisuddin. *Jamia Hamdard, New Delhi, India.*

Cisplatin (CP) is one of the effective antineoplastic drugs used to treat solid tumors effectively. However, it induces acute kidney injury (AKI). Several signaling pathways are responsible to induce severe inflammation in renal proximal convoluted tubule cells leading to AKI. In this study, we investigated the therapeutic role of rosmarinic acid (RA) against the inflammation in AKI. RA has been demonstrated to have antioxidant, free radical scavenging and anti-inflammatory effects. In our study, RA was administered orally with the dose of 100mg/kg/d for consecutive four days after a single shot of cisplatin at the dose of 20mg/kg administered intraperitoneally in Swiss albino mice. We found that CP causes the oxidative stress by increasing the level of lipid peroxidation and decreasing the level of reduced glutathione (GSH) in kidney tissue, creating a favorable environment for AKI. CP exposure also increased the levels of serum creatinine and blood urea nitrogen (BUN) which indicates the alteration in the normal renal functions in the exposed mice. Inflammasomes are signaling complexes consisting of caspase-1 and nucleotide-binding oligomerization domain-like receptor with pyrin domain protein (NLRP). We found that inflammasome was activated by CP administration promoted the activation of caspase-1 and resultantly increased the secretion of IL-1β and IL18 in kidney tissue creating a proinflammatory environment. Treatment of RA inhibited the activity of the caspase-1 and other downstream molecules such as IL-1β and IL18, nuclear factor-kB and NLRP3. Also, elevated protein expression of COX-2 has been found to be down-regulated in RA treated mice. These findings show that blocking a critical step by RA in inflammation may be a useful strategy to prevent the AKI induced by cisplatin.

1853 Treatment with Cannabidiol Ameliorates Experimental MS by Regulating Expression of Gasdermins (GSDMs) and Regenerating Islet-Derived (Reg)-4 in the Intestinal Epithelial Cells

N. Dopkins, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

Cannabidiol (CBD) is a recently legalized nonpsychoactive ingredient of Cannabis that has garnered attention in the media, medical community and general public due to its anti-inflammatory properties and therapeutic potential. CBD has become popular among individuals with autoimmune disorders due to its potential as complementary and alternative medicine, especially in patients with side effects associated with immunosuppressive regimens. There has been little work done on risk assessment and the mechanism of action of CBD. In order to better define how CBD may be beneficial, we studied the effects of oral administration of CBD (20mg/kg) in chronic progressive multiple sclerosis (MS) using a murine model of experimental autoimmune encephalomyelitis (EAE). We found that CBD significantly reduces the inflammation-related paralysis in EAE and that this was primarily due to the induction of myeloid derived suppressor cells (MDSCs). In CBD treated EAE mice, flow cytometric analysis revealed increase in the granulocytic MDSCs (CD45+CD11b+Ly6C+Ly6G+) and monocytic MDSCs (CD45+CD11b+ Ly6C+Ly6G-) in the CNS and spleen respectively. CBD treatment additionally led to significant decrease in the inflammatory neutrophils (CD45+CD11b+Ly6C-Ly6G-) in the mesenteric lymph nodes. In order to better understand the mechanism of action of CBD, we performed the transcriptomics of the intestinal epithelial cells (IECs). We found that the IECs from EAE mice treated with vehicle demonstrated several dysregulated genes, of which 3 of the most upregulated genes were Gsdmc3, Gsdmc3 and Gsdmc4 belonging to the Gasdermin (GSDM) family, and CBD treatment decreased their expression. GSDMs have been shown to drive inflammation through induction of pyroptosis of IECs and pyroptosis/NETosis of myeloid cells infiltrating the periphery. Another upregulated gene was regenerating islet-derived family member 4 (Reg4) in EAE+Veh group which was decreased in EAE+CBD. Reg4 has been shown to be a driving factor in inflammation by altering microbial composition and promoting the expression of pro-inflammatory cytokines. These results suggest a novel anti-inflammatory function of CBD in inflammatory disorders by altering gut-microbiota and preventing pyroptosis in the IECs by inhibition of GSDMs and Reg4 expression.

1854 Involvement of Galectin-3 in Maintaining Barrier Integrity of Lung Vasculature

M. Han, R. Rancourt, D. L. Laskin, and J. Andres. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Galectin-3 (LGALS3; Gal-3) is a 35-kDa carbohydrate-binding protein used as a diagnostic biomarker for cardiovascular disease. Recently, a role for Gal-3 in the pathophysiology of heart failure and lung fibrosis has been suggested. Histological examination of lung sections from unchallenged Gal-3 -/- KO mice revealed elevated levels of perivascular inflammation relative to wild type mice. Normal lung vasculature typically exhibits a size selective permeability that permits small solutes to enter the airway but limits the influx of large plasma molecules. We hypothesized that Gal-3 -/- mice would also exhibit a disruption in airway vascular barrier function. To assess for "leakiness", we analyzed bronchoalveolar lavage for high molecular weight IgM (900 kDa) and performed immunohistochemical analysis to screen for the presence of plasma-derived fibrinogen and inflammatory cells in lung tissue. Both Gal-3 -/- and corresponding wild-type (WT) C57/bl6 mice were exposed to nitrogen mustard or phosphate buffered saline (PBS) by intratracheal instillation. Fourteen days after exposure, mice were terminally anesthetized and airway-capillary leak was estimated by the detection of IgM levels in bronchoalveolar lavage fluid (BALF). Left lung lobes from these mice were also paraffin embedded, sectioned at 5 µm thickness, and immunostained for the plasma protein fibrinogen. Deposition of fibrinogen in airways was assessed by use of an Allred scoring system. Additional sections were also immunostained for myeloperoxidase (MPO) to assess numbers of activated inflammatory cells in lung. In contrast to PBS-treated wild type mice, immunohistochemistry performed on Gal-3 -/- mice after PBS treatment, revealed prominent perivascular fibrin deposition, increased numbers of MPO-expressing inflammatory cells, and a four-fold elevation IgM plasma protein in BALF. GAL-3 may be an essential factor for maintaining hemostasis and barrier integrity of lung vasculature. *This work supported by Rutgers University CounterACT Center of Excellence - U54AR055073, and pilot grant funding from the Center for Environmental Exposures and Disease (CEED).*

1855 Modulation of TRP Channels by Lipids in Chronic Pain Models

L. Sun, C. E. Deering-Rice, M. Almestica-Roberts, K. Rose, and C. A. Reilly. *University of Utah, Salt Lake City, UT.*

Chronic pain is pain lasting beyond the time required to heal an injury, which can severely affect a person's life. Chronic pain therapies include NSAIDs, opioids, and TNFα inhibitors. However, none are universally efficacious, or without risks. New therapeutic options are needed for chronic pain. Transient receptor potential (TRP) ion channels are integral to inflammation and pain following injury. Thus, understanding how endogenous TRP ligands change during inflammation and during the development of chronic pain may provide new insights on how to prevent or treat chronic pain. We are using transcripomics and targeted lipidomics to determine how changes in endogenous lipids affect TRP ion channels known to be involved in acute inflammation and in the development of chronic pain. RNA sequencing of mouse dorsal root ganglia (DRG) neurons following spinal nerve ligation (SNL) revealed an induction of cytochrome P450 1B1 and CYP4B1 in injured neurons. CYP1B1 and CYP4B1 produce hydroxyeicosatetraenoic acids (HETEs) which have pro-inflammatory properties. Moreover, screening of lipid extracts of spinal cord from sham and SNL groups demonstrated significant differences in the activation of TRPA1, M8 and V1. Notably, at day 14 post SNL, lipid extracts were less potent TRP agonists suggesting a down-regulation of TRP-mediated signaling following nerve injury. Collectively, these data suggest that alterations to TRP signaling in pain may involve a pool of endogenous TRP channel ligands that are synthesized and degraded in a dynamic manner. Targeted lipidomics studies are ongoing and should reveal specific endogenous lipids that modulate TRP channel activity over the course of development of chronic pain phenotypes. These results could advance our understanding of specific molecular processes that contribute to pain pathogenesis, as well as reveal new targets for potentially preventing and/or treating pain. *Support: DoD W81XWH-17-1-0413.*

1856 Beneficial Effects of the Immunomodulatory Glycan LNFPIII on the Microbiota in a Mouse Model of Gulf War Illness

R. S. Mote[1], J. M. Carpenter[1], A. J. Steinberger[2], G. Suen[2], R. L. Dockman[1], D. A. Harn[1], J. J. Wagner[1], and N. M. Filipov[1]. *[1]University of Georgia, Athens, GA; and [2]University of Wisconsin–Madison, Madison, WI.*

Gulf War Illness (GWI) is a chronic, multi-system disorder that presents in almost a third of the GW veterans. Stemming from exposures to pesticides, prophylactics and, in some cases, nerve agents, GWI affects the nervous, immune, and gastrointestinal systems, potentially dysregulating the gut-brain-immune axis. Developments in our understanding of the microbiota's influence on host physiology have sparked interest in the role the microbiota might play in GWI. By rebalancing the immune system, the immunomodulatory glycan Lacto-N-fucopentaose III (LNFPIII), might be beneficial to GWI veterans. Given the crosstalk between the microbiota and the immune system, this study sought to understand whether LNFPIII treatment is beneficial to the gut microbiota in a GWI context. We examined the short- and long-term effects of GWI chemical exposures using an established GWI model (PB/PM). Male C57BL/6 mice were treated with the neuro-prophylactic pyridostigmine bromide (PB; 0.7 mg/kg IP) and the insecticide permethrin (PM; 200 mg/kg) for 10 days. In the short-term study, LNFPIII (35 ug; SC) or dextran vehicle was given concurrent with GWI chemicals. In the long-term study, LNFPIII treatment (twice/week) started 4 months after PB/PM treatment ended and it was given until study completion. Fecal microbiota analysis (16S rRNA sequencing) was performed 6 and 48 h (short-term study) or 9 months (long-term study) post PB/PM exposure. GWI chemicals affected the global microbiota profile in both the short and long-term. Limited specific effects were observed in the short-term, but the genus *Sutterella* was increased by PB/PM in both short and long-term samples. PB/PM had multiple long-term effects, with most significantly affected OTUs aligning to *Lachnospiraceae* and *Ruminococcaceae* families. LNFPIII treatment increased the relative abundance of butyrate producing bacteria (e.g., *Butyricoccus*, *Ruminococcous*) in PB/PM-treated mice, indicating positive selection pressure for these potentially beneficial bacteria. Additionally, two *Ruminococcaceae Oscillospira,* four *Lachnospiraceae*, one *Rikenellaceae*, and one *S24-7* OTUs correlated in opposite directions with lipocalin II (LCN2), a marker of intestinal inflammation in PB/PM vs PB/PM/LNFPIII samples. Overall, we found that the most significant GWI effects on the microbiota occurred in long-term studies and that LNFPIII promotes microbiota changes that could be explored as a GWI therapeutic. *Support: Department of Defense grant number W81XWH-16-1-0586.*

1857 A Novel Macrophage Containing Organotypic Small Intestinal Tissue for Modeling Gut Inflammation

S. Ayehunie[1], H. Scott[1], Z. Stevens[1], K. Marengo[1], T. Landry[1], M. Klausner[1], A. Langerveld[2], E. Lehigh[2], S. Wheeler[2], A. Armento[1], and Y. Kaluzhny[1]. *[1]MatTek, Ashland, MA; and [2]Genemarkers, Kalamazoo, MI.*

As gate keepers of intestinal immune homeostasis, macrophages play a critical role in inflammation in the gut. In this study, we reconstructed a new macrophage-containing primary cell-based full-thickness small intestinal (SMI+M) tissue model and characterized it for 1) macrophage incorporation (immunohistochemistry, IHC), 2) barrier properties (TEER), and 3) functionality by measuring inflammatory responses following exposure to ligands for TLR4 (lipopolysaccharide; LPS), NOD-1 (C12-iE-DAP) and NOD-2 (L18-MDP) either individually or synergistically. For identification of inflammatory responses, we utilized Affymetrix GeneChip arrays. Results showed that SMI+M tissues have 3D polarity and their morphology and physiological barrier property mimics that of native *in vivo* tissues. IHC of SMI+M tissues showed CD14+ (macrophage marker) cells in the underlying fibroblast layer. Using gene upregulation level of >1.9 fold as a cut-off following ligand stimulation, tissues without macrophages (SMI-M) showed fewer upregulated genes (1400 genes) compared to SMI+M (4400 genes). Furthermore, when gene upregulation levels by ligand-induced SMI+M were compared against stimulated SMI-M even higher differences in upregulated genes (> 5200 genes) were noted. In SMI+M, upregulated genes include chemokines, chemokine receptors, FC receptors, co-stimulatory molecules, interferons, and HLA's which are characteristic of immune cells. When we looked at 13 upregulated genes (>6-fold) in SMI+M, the synergistic effect of ligands in inducing inflammatory gene upregulation was much more pronounced compared to stimulated SMI-M tissues. Furthermore, increased cytokine release of IL-6, IL-8, and TNF-α into the culture medium from ligand exposed SMI+M was also confirmed by BioPlex ELISA. In summary, our results demonstrate that the 3D SMI+M tissue model can serve as an *in vitro* tool to study the complex cellular interactions manifested during inflammation in the gut microenvironment.

1858 The Effect of Circadian Disruption on Hepatic Inflammation and Cancer Formation

N. D. Carrillo, M. T. Walcheck, P. B. Schwartz, and S. Ronnekleiv-Kelly. *University of Wisconsin–Madison, Madison, WI.*

Incidence of hepatocellular carcinoma (HCC) has steadily increased over the last several decades and has proven to be one of the least responsive to current therapeutic options. Recently, circadian disruption has been shown to induce non-alcoholic steatohepatitis that often progresses to HCC. Circadian rhythms are normal biologic processes that coordinate cell and organ function with a 24-hour period. The disruption of these rhythms has been shown to promote inflammation and cancer development, but the effect on HCC development is largely unknown. To investigate a potential pathway for development of liver inflammation and HCC, we began by evaluating C57BL6/J (WT) mice under normal circadian (WT_N) and circadian disrupted (WT_D) conditions and compared transcriptomic profiles between the groups. A total of 144 mice were divided into 2 age-matched, cage-matched groups comprised of equal representation of male and female mice. At 4 weeks of age, the WT_N group was kept on a standard 12:12, light-dark cycle to establish a "normal" circadian rhythm and the WT_D group began a jet-lag protocol consisting of a 4-hour time shift every 2 days for 4 weeks to induce circadian disruption. At 8 weeks of age, 6 WT_N and 6 WT_D of equal males and females were sacrificed every 4 hours over a 48-hours window. Hepatic mRNA was immediately isolated from the 12 time-points in order to illustrate gene expression throughout the day. Core Clock Genes (CCGs) were analyzed with real time quantitative polymerase chain reaction (RT-qPCR). We found that the jet-lag protocol did not have a major impact on the relative expression of Nuclear Receptor subfamily 1 group D member 1 (NR1D1) and Cryptochrome Circadian Regulator 2 (*Cry2*). Opposingly, Cryptochrome Circadian Regulator 1 (*Cry1*) and Nuclear Factor Interleukin 3 (*Nfil3*) were significantly disrupted experiencing rhythm loss and phase shift respectively. The time point 22:00 was identified as the most sensitive time point with significant fold change and max peak heights for both *Cry1* and *Nfil3*. This study identifies CCGs and select inflammatory regulators were disrupted in the liver. This information is crucial to establish a baseline for circadian disruption in the liver, guiding future studies into the development of HCC in inducible transgenic mouse models.

1859 Ampakine CX546 Ameliorates Gulf War Agents Exposure and Stress-Induced Exosomal HMGB1 That Causes Neurological Ailment in Experimental Gulf War Illness

R. K. Seth[1], D. Bose[1], P. Saha[1], D. Kimono[1], S. Sarkar[1], A. Mondal[1], M. S. Albadrani[1], P. Janulewicz Lloyd[2], R. D. Horner[1], J. P. O'Callaghan[3], K. Sullivan[2], and S. Chatterjee[1]. *[1]University of South Carolina, Columbia, SC; [2]Boston University School of Public Health, Boston, MA; and [3]NIOSH, Morgantown, WV.*

Gulf War Illness (GWI) is a medically unexplained, multisymptomatic condition that includes chronic pain, gastrointestinal and neuroinflammation, and cognitive difficulties. Exposure to Gulf War (GW) agents pyridostigmine bromide (PB) and permethrin (Per), and war theater stress were key contributors to the etiology of GWI post-deployment to the Persian GW. In this study, we examined the role of circulatory exosomal high mobility group box-1 (HMGB1) protein in neuroinflammation, neuroimmunotoxicity, and neuroplasticity in the mouse model of GWI. Here, we used an established mouse model of GWI. The C57BL/6 mice were exposed to GW agents (PB+Per) along with restraint stress for one week. Results show that GW agent exposure along with stress causes exosomal biogenesis and HMGB1 expression in the small intestine and concurrently increase circulatory exosome loaded with HMGB1. Data also show decrease Zonal Occludin-1 (ZO1) and Claudin-1 mRNA expression, and serum albumin accumulation in frontal cortex suggests blood-brain barrier (BBB) integrity loss that enables entry of circulatory exosomal HMGB1 in the brain. Increase HMGB1 in both the frontal cortex and hippocampus activate microglia (M1 phenotype), thus induces an inflammatory response. We observed that HMGB1 induced neuroinflammation suppress brain-derived neurotropic factor (BDNF) and thus causing neuroplastic and cognitive impairment. The GW agents exposed mice co-treated with exosome inhibitor (Nexinhib20), or glutamate activator (ampakine, CX546) show improvement in BBB integrity, neuroinflammation, neuroplasticity, and cognitive function. In summary, our findings suggest that the circulatory exosomal HMGB1 plays a key role in GWI pathogenesis, and Nexinhib 20 and CX546 might be promising therapeutics in GWI. *This study was supported by W81XWH1810374 and VA merit award I01 CX001923-01 to Saurabh Chatterjee.*

1860 The Effects of Age, Sex, and Genotype on LPS-Induced Neuroinflammation in Humanized Targeted Replacement APOE Mice

I. Mhatre[1,2], A. Eid[1], Y. Han[1], and J. R. Richardson[1]. *[1]Florida International University, Miami, FL; and [2]Kent State University, Kent, OH.*

Neuroinflammation is implicated in the progression and pathogenesis of several neurodegenerative diseases including Alzheimer's disease (AD). While AD presents differently in individual patients, advancing age and the presence of the strongest known genetic risk factor, Apolipoprotein E4 genotype, have been shown to contribute greatly to the increased risk of AD. In addition, females have an increased risk of developing AD at a younger age when compared to males and this risk is modified by the Apolipoprotein E (APOE) genotype. Here, we sought to determine age, sex and APOE genotype susceptibility to neuroinflammation following administration of lipopolysaccharide (LPS; 0.5 mg/kg for 4 hours) in humanized targeted replacement APOE3 and APOE4 mice. Using quantitative PCR, we evaluated the proinflammatory cytokines Il1b and Tnfa in the cortex and hippocampus. LPS caused a higher induction of pro-inflammatory cytokines, Il1b and Tnfa mRNA expression in both the frontal cortex and hippocampus of young (3-month-old) and aged (16-month-old) APOE4 mice compared to APOE3. Il1b mRNA levels were increased in the frontal cortex by ~30-fold in aged APOE4 males and ~17-fold in APOE4 females. In contrast, Il1b expression only increased ~5-fold and ~7-fold in APOE3 males and females, respectively. In the hippocampus, there were no differences by genotype in the young mice, but aged APOE4 males and females exhibited a higher Il1b response than the young mice. Similar effects were observed for Tnfa expression in both regions, with differences apparent at 16 months for both APOE4 males (~9-10-fold increase in both, the frontal cortex and hippocampus) and females (~10-fold in both, the frontal cortex and hippocampus). These data indicate that a peripheral LPS challenge induces a higher increase in pro-inflammatory cytokine mRNA expression in older APOE4 targeted replacement mice compared to APOE3 and this effect appears to be sex-specific at different age groups. *Supported in part by NIH R01ES026057.*

1861 Redox-Associated Modulation of O-GlcNAcylation Signaling Ameliorates Liver Injury Induced by Co-exposure to Ethanol and Lipopolysaccharide in Mice

F. Wan[1,2], D. Orlicky[3], V. Vasiliou[1], and Y. Chen[1]. *[1]Yale School of Public Health, New Haven, CT; [2]Guangxi Medical University, Nanning, China; and [3]University of Colorado Anschutz Medical Campus, Aurora, CO.*

Both alcohol consumption and endotoxin [lipopolysaccharide (LPS)] exposure can induce oxidative liver injury, the synergetic effect of which is hypothesized to contribute significantly to the deleterious progression of alcoholic liver disease (ALD). O-GlcNAcylation of protein is an emerging form of post-translational modification, where a single O-linked N-acetylglucosamine moiety is added to Ser and Thr residues of nuclear, cytoplasmic and mitochondrial proteins. This process is controlled by a pair of enzymes, O-GlcNAc transferase (OGT) and O-GlcNAcase (OGA). O-GlcNAcylation of protein is increasingly recognized as playing an important role in stress sensing and fine-tuning of inflammatory response. To date, little is known about the role of O-GlcNAcylation in ALD pathogenesis. In the current study, we investigated the impact of binge alcohol drinking in combination with LPS exposure on hepatic O-GlcNAcylation pathway in a mouse model of chronic glutathione (GSH) deficiency. Female wild-type (WT) and GSH-deficient *Gclm*-null (KO) mice received ethanol for 3 consecutive days (5 g/kg i.g. per day), followed by a single LPS administration (10 mg/kg i.p.). At 0, 6,12 and 24 hr post LPS treatment, liver injury, expressions of inflammatory genes and the O-GlcNAcylation pathway in the liver were examined. Compared to WT mice, KO mice had a lower injury score at 24 hr post LPS treatment. The expression profile of inflammatory genes and O-GlcNAcylation-related genes revealed differential changes between WT and KO livers at 12 and 24 hr post LPS treatment. There was an overall increase of O-GlcNAcylation of liver proteins in KO mice by ethanol binge feeding alone and by ethanol-LPS co-treatment at 24 hr. In conclusion, GSH-deficient mice display a partial protection against liver injuries caused by acute ethanol-LPS co-exposure. We speculate that modulation of O-GlcNAcylation signaling by low GSH may serve as a protective mechanism. *This work was supported, in part, by NIH grants K01AA025093, P30DK034989, R24AA022057 and International Communication of Guangxi Medical University Graduate Education.*

1862 Microplastics Pose a Serious Risk to the Gut Immune System

S. Merkley, M. Campen, and E. F. Castillo. *University of New Mexico Health Sciences Center, Albuquerque, NM.*

Plastic pollution has increased exponentially for the past 70 years; in 2015 we passed a watershed mark of *1 metric tons of plastic per person on earth*. Slow breakdown of plastic materials primarily leads to smaller and smaller microplastic particles (MP), but not actual degradation or decomposition of the material. We now face extensive microplastic contamination of our food and water sources, raising ecological and public health concerns. MP ingestion by humans is now an inevitable consequence of global plastic pollution, and we are only now becoming aware of this burgeoning crisis. Currently, there is inadequate research available to fully comprehend how MP impact human health (WHO). There is also an important gap in knowledge regarding how MP affect the major direct organ of contact, the gastrointestinal (GI) tract. We provide compelling evidence that MP affect both intestinal epithelium and macrophages. We show: a) MP increase intestinal permeability in human intestinal organoid monolayer cultures as well as impede wound healing in Caco-2 monolayers; b) MP are engulfed by macrophages which leads to an activated state; c) MP engulfment by macrophages induces a metabolic shift towards glycolysis, an immunometabolic active state; d) autophagy, a cellular degradative catabolic process, can dampen the glycolytic shift in macrophages after MP engulfment; and e) MP ingestion affects the weight of mice and this weight modulation is independent of intestinal epithelial TLR4 expression. In summary, our findings indicate MP ingestion poses a serious human health hazard by disrupting oxidative metabolism in both intestinal epithelial cells and macrophages subsequently causing intestinal permeability, dysbiosis, and an immunometabolic active state which could lead to intestinal and systemic inflammation.

1863 Homogeneous, Bioluminescent Cytokine Assay Applied to a Monocyte Activation Test for Pyrogen Detection

M. O'Brien, D. Thompson, J. J. Cali, and D. Lazar. *Promega Corporation, Madison, WI.* Sponsor: T. Riss

Pyrogens cause cytokine release from cells such as monocytes as a protective response to infection and injury. However, an exaggerated pyrogen response can cause systemic inflammation, shock, organ failure and death. Injectables and implanted devices are tested for pyrogens, especially endotoxins from gram-negative bacteria, because they can be left as residuals after manufacturing and disinfection processes. Non-endotoxin pyrogens are also a concern, and increasingly so with the expanded use and complexity of biologic drug formulations that may carry pyrogen contamination. Standard pyrogen tests include the endotoxin-selective, limulus amebocyte lysate (LAL) test and the broad-spectrum rabbit pyrogen test (RPT). Monocyte Activation Tests (MAT) were recently approved as an alternative pyrogen test to detect endotoxin and non-endotoxin pyrogens and avoid animal use. MATs measure IL-1β or IL-6 cytokines released from monocytes by ELISA. To simplify the MAT workflow, we developed a homogeneous cytokine assay method without transfer or wash steps to replace the ELISA. For a given target, two selective antibodies are respectively labeled with complementary subunits of Nanoluc® luciferase. When labeled antibody pairs bind their target, the subunits are brought into proximity to reconstitute a bright luciferase that generates light with the substrate furimazine. Appropriate antibody pairs for either IL-1β or IL-6 were selected and applied to 4-donor pools of peripheral blood mononuclear cells (PBMCs). Release of IL-6 or IL-1β from PBMCs was detected after treatment with several pyrogens, including LPS, R848, lipoteichoic acid, Pam3CSK4, and heat-killed *Staphylococcus aureus*. Both assays are sensitive with limits of detection of ~10 pg/ml for IL-1β and ~5 pg/ml for IL-6 and have large linear dynamic ranges of greater than 3 logs. However, the IL-6 assay had greater sensitivity for all tested pyrogens and a larger response (3-15 fold greater, depending on pyrogen). Bacterial flagellin, another pyrogen, was only detected in the IL-6 immunoassay. The IL-6 immunoassay had a limit of detection of ~0.03 endotoxin units/ml. This homogeneous IL-6 assay enables a sensitive MAT in an add-and-read format that reduces ELISA workflow steps and facilitates assay automation. This simplified MAT is an attractive RPT alternative that detects a broad spectrum or pyrogens.

1864 Cytochrome P450 (CYP) 2C8*3 Alters Lipid Biosynthesis and Inflammatory Responses of Human Lung Epithelial Cells

M. Almestica-Roberts, E. Rapp, K. L. Burrell, L. Sun, C. E. Deering-Rice, and C. A. Reilly. *University of Utah, Salt Lake City, UT.*

Asthma causes chronic airway inflammation and bronchial hyper-reactivity. Despite appropriate treatment, many patients experience suboptimal symptom control, in part, due to variability in genes that dictate drug disposition. A total of 170 single SNPs in genes associated with asthma, as well as variants of unknown significance, were assayed for effects on asthma control in a pediatric asthma cohort. The presence of one or more copy of the cytochrome P450 (CYP) 2C8*3 (R139K/K399R) allele was found to correlate with improved asthma control: Mean asthma control scores were 3.5 [n=184] vs. 4.4 [n=909] for the CYP2C8*1/*1 genotype. Furthermore, when data were stratified by treatment with montelukast, patients with the CYP2C8*3 allele exhibited a mean asthma control score of 3.56 [n=55] vs. 5.44 [n=214] for the CYP2C8*1/*1 genotype (p=0.0017). This effect was not observed for several other asthma medications. CYP2C8 is the principal enzyme involved the clearance of montelukast, a cysteinyl leukotriene receptor (CysLTR) antagonist prescribed for moderate to severe asthma. Using human lung epithelial cells engineered to over-express equivalent levels of either CYP2C8*1 or *3, it was found that CYP2C8*3 exhibits greater intrinsic activity towards montelukast, suggesting that increased or prolonged inhibition of the CysLTR due to decreased clearance of montelukast was likely not a basis for CYP2C8 genotype-dependent differences in asthma symptom control. CYP2C8 also metabolizes endogenous long-chain polyunsaturated fatty acids. Results from lipid profiling show differences in the production of specific lipid mediators of inflammation by human lung epithelial cells, and effects on epithelial wound repair *in vitro*. Further, expression of CYP2C8*3 alters mRNA abundance of several additional mediators of inflammation with relevance to asthma pathogenesis. These, and future findings should further our long-term goal of improving treatment of asthma through better understanding of the mechanisms associated with sub-optimal responses to current therapies. *Support: GM121648.*

1865 The Inflammatory Role of the Infrapatellar Fat Pad in a Model of Spontaneous Osteoarthritis

M. F. Afzali, L. H. Burton, L. B. Radakovich, J. Sanford, M. Campbell, A. Marlof, and K. S. Santangelo. *Colorado State University, Fort Collins, CO.*

Osteoarthritis (OA), particularly knee OA, is a painful and debilitating disease affecting millions of people worldwide. Currently, there are no therapeutic regimens that halt or repair this joint degeneration. The knee is a unique joint due to the large amount of adipose present, which serves as a rich source of lipids. Lipids provide a diverse range of physiologic functions, including energy storage, endocrine signaling, and structural components of cells. However, lipid-mediated signaling also drives a plethora of pathologic processes. Despite the infrapatellar fat pad (IFP) being the largest adipose deposit in the knee, its role in joint homeostasis is not clearly defined. It is hypothesized to provide lubrication, shock absorption, and stability, but may also serve as a source of inflammation. It is similar to white adipose tissue and contains a number of resident and circulating immune cells. We recently completed transcript expression analysis of the IFP in the Hartley guinea pig model of non-traumatic/primary OA at 3 key ages. We demonstrated that peroxisome proliferator-activated receptor gamma (PPARgamma) and adiponectin decreased in expression throughout aging, while tumor necrosis factor (TNF) and interleukin - 1 beta (IL-1B) increased. Thus, the IFP may become a lipotoxic adipose depot with age. To assess the role of the IFP in OA, we conducted a study to determine the influence of IFP removal on disease progression. We postulate that, if the IFP is lipotoxic, removal would be beneficial to OA. Prior to OA-onset, 3-month-old guinea pigs underwent surgical removal of the IFP from one knee (sx) while the contralateral knee received a sham surgery. Animals were harvested at 7 months of age. Histologic analysis of the sx knee indicated the development of fibrous connective tissue (FCT) in place of the removed IFP. Relative to the knee containing the IFP, the FCT was decreased in OA-associated structural changes to both the cartilage and bone. Further, protein expression of the FCT versus IFP confirmed a marked decrease in monocyte chemoattractant protein-1 (MCP-1) expression. This data suggests that the IFP plays an inflammatory role in the pathogenesis of OA in Hartley guinea pigs and that removal prior to disease onset appears to have short-term benefits on joint health.

1866 Altered Gut Virome-Bacteriome Diversity Regulates Inflammatory Phenotype and Neuronal Immunotoxicity in Experimental Gulf War Illness

R. K. Seth[1], R. Maqsood[2], A. Mondal[1], D. Bose[1], D. Kimono[1], L. A. Holland[2], P. Janulewicz Lloyd[3], N. Klimas[4], R. D. Horner[1], K. Sullivan[3], E. S. Lim[2], and S. Chatterjee[1]. *[1]University of South Carolina, Columbia, SC; [2]Center for Fundamental and Applied Microbiomics, Biodesign Institute, Arizona State University, Tempe, AZ; [3]Boston University School of Public Health, Boston, MA; and [4]Nova Southeastern University, Fort Lauderdale, FL.*

Gulf War illness (GWI) is characterized by the persistence of inflammatory bowel disease, chronic fatigue, neuroinflammation, headache, cognitive impairment, and other medically unexplained conditions. Results using a murine model show that enteric viral populations especially bacteriophages were altered in GWI. The increased viral richness and alpha-diversity correlated positively with gut bacterial dysbiosis and proinflammatory cytokines. Altered virome signature in GWI mice also had a concomitant weakening of intestinal epithelial tight junctions with a significant increase in Claudin-2 protein expression and decrease in ZO1 and Occludin mRNA expression. The altered virome signature in GWI, decreased tight junction protein level was followed by the presence an activation of innate immune responses such as increased Toll-like receptor (TLR) signaling pathways. The altered virome diversity had a positive correlation with serum IL-6, IL-1β, and IFN-γ, intestinal inflammation (IFN-γ), and decreased Brain-Derived Neurotrophic Factor (BDNF), a neurogenesis marker. The co-exposure of Gulf War chemical and antibiotic (for gut sterility) or Gulf War chemical and Ribavirin, an antiviral compound to suppress virus alteration in the gut showed significant improvement in epithelial tight junction protein, decreased intestinal-, systemic-, and neuroinflammation. These results showed that the observed enteric viral dysbiosis could activate enteric viral particle-induced innate immune response in GWI and could be a novel therapeutic target in GWI. *This study was supported by W81XWH1810374 and VA merit award I01 CX001923-01 to Saurabh Chatterjee.*

1867 Mechanisms of Ectopic TRPA1 Expression by Human Lung Epithelial Cells with the TRPV1 I585I/V Genotype

E. Rapp, Z. Lu, C. E. Deering-Rice, and C. A. Reilly. *University of Utah, Salt Lake City, UT.*

Asthma is a chronic inflammatory disease that is often exacerbated by environmental pollutants. Transient receptor potential ankyrin-1 (TRPA1) and vanilloid-1 (TRPV1) are activated by multiple environmental pollutants including coal fly ash and diesel exhaust particles. Studies have examined roles for TRPA1 and V1 in asthma and have shown that the expression of these channels is elevated in epithelial cells and neurons in people with asthma. Our previous studies demonstrated that the I585I/V genotype of TRPV1 affected asthma symptom control. Moreover, the TRPV1 I585I/V genotype was associated with increased TRPA1 expression and sensitivity of primary human lung epithelial cells to diesel exhaust particles. Specifically, increases in the expression of mRNA for IL-8 and DNA damage-inducible transcript-3 (DDIT3), a pro-apoptotic ER stress response gene, were greater among donor cells with the I585I/V genotype (n=6) versus wild-type (I585I/I) donors (n=7). Cytokines like IL-8 regulate key facets of pulmonary inflammation, and ER stress plays a fundamental role in the pathogenesis of inflammatory diseases, such as asthma. Cells with the I585I/V genotype also show differential expression of NF-κB regulatory factors including NLRP2, which is a negative feedback inhibitor of the NF-κB/HIF-1α signaling pathway and potential regulator of TRPA1 expression during inflammation. Studies are ongoing to understand how TRPA1 expression is influenced by the I585I/V genotype, and elucidating this relationship will advance our understanding of a phenomenon that may represent a risk factor for asthma pathogenesis. *Support: ES017431, ES027015, and GM 121648.*

1868 Cell and Molecular Biology of Autoimmunity Affecting Behavior of Mice with Deviant Behaviors

D. A. Lawrence, M. N. Uddin, Y. Yao, and K. Manley. *Wadsworth Center, New York State Department of Health, Albany, NY.*

Female and male mice of the BTBR T^{+} *Itpr3*^{tf}/J (BTBR) strain have behaviors that resemble autism spectrum disorder. BTBR mice have better humoral immunity than cell-mediated immunity, in that they have naturally high serum IgG levels and generate high levels of IgG antibodies, including antibodies to brain antigens, but they have poor host defense against *Listeria*. Focus is on induction of an autoimmune-like phenotype. BTBR IgG autoantibodies bind to neurons better than microglia and with highest titer to nuclear antigens. BTBR thymi have more single-positive T cells and fewer double-positive T cells than C57BL/6/J (B6) mice. In blood and spleen, BTBR mice have more T cells ($CD4^{+}$ and $CD8^{+}$) than B6 mice, but they have fewer B cells and NK cells. Since BTBR have an increased number of T-bet^{+} and GATA-3^{+} T cells their low defense against *Listeria* may be due to fewer NK cells. Their higher levels of autoantibodies is likely due to more splenic T follicular helper (Tfh) cells and plasma cells (PCs), which are higher in BTBR than B6 mice. Increased B cell differentiation to PCs may relate to the increased splenic mRNA expression of Notch1, 2 and 3, Jag1, Dll1/4, Hey1 and 2, and IL-21R. Less anti-oxidant response capacity measured as low glutathione and leukocyte surface thiol levels may be responsible for the BTBR's immunity. An elevated level of stress like stress-induced sympathetic nervous system skewing of immunity is suggested to be responsible for the oxidative changes causing the altered immunophenotype and the autoimmune problems.

1868a Elevated Expression of Inflammatory Pathways Resulting from Dysregulated WNT Signaling Prior to Trauma Exposure Is a Predictor of Development of PTSD

M. Bam. *University of South Carolina School of Medicine, Columbia, SC.*

Posttraumatic stress disorder (PTSD) used to be considered a psychiatric disorder until a few years ago when reports showed that PTSD patients have dysregulated immune functions and experience chronic inflammation. It is a disorder which develops after a traumatic experience but the molecular mechanism of the disease pathophysiology is still not clear. It is very interesting to note that only some of the trauma-exposed individuals develop the disorder. To understand this biased mechanism, we analyzed blood transcriptome data generated from individuals before trauma exposure and compared with those who did not develop PTSD even after exposure to trauma. We observed that interferon signaling pathway was significantly dysregulated. In particular, Th1 signaling pathway genes, including STAT1, STAT2 and JAK1 were significantly upregulated in PTSD patients prior to trauma exposure. We also observed that genes downstream of JAK/STAT signaling were significantly upregulated. In the past, we have shown that increased WNT signaling activity was evident in PBMCs collected after PTSD development. Moreover, we showed that increased WNT signaling can drive elevated expression of IFNG and IL17 in pre-activated PBMCs. In line with this, in the present study, we observed that Axin1 (WNT signaling inhibitor) was significantly down regulated even before trauma exposure indicating that WNT signaling pathway could be dysregulated even before trauma exposure in individuals that develop PTSD. Altering the levels of Axin1 either by siRNA based knockdown or employing AXIN1 stabilizers as WNT signaling inhibitor provided further evidence that downregulation of AXIN1 could strongly favor the elevated expression of inflammatory genes. These results collectively imply that individuals that develop PTSD have an elevated activity of proinflammatory signaling pathway including the JAK/STAT mediated Th1 pathway even before exposure to trauma. Our data also indicates that increased activity of WNT signaling drives the elevated expression of Th1 pathway genes possibly leading to inflammatory state in these patients. Therefore, we conclude that elevated pro-inflammatory biomarkers could probably predict those individuals who are predisposed to developing PTSD. *Supported by NIH grants P01AT003961, P20GM103641, R01AT006888, R01ES030144, R01AI129788 and R01AI123947.*

1869 Interplay of Oxidative Stress, Toll-Like Receptor, and Nrf2 in Trichloroethene-Mediated Autoimmunity

G. Wang, H. Wang, N. Banerjee, and F. Khan. *University of Texas Medical Branch at Galveston, Galveston, TX.*

Oxidative stress is involved in trichloroethene (TCE)-mediated autoimmunity, as evident from our earlier studies in MRL+/+ mice. However, molecular mechanisms underlying the autoimmunity remain to be fully elucidated. Even though Toll-like receptor (TLR) signaling and nuclear factor erythroid-derived 2-like 2 (Nrf2) pathway have been implicated in autoimmune diseases (ADs), the role and interplay of oxidative stress, TLR and Nrf2 in TCE-mediated autoimmune response remain unexplored. This study was, therefore, aimed to better understand the role of oxidative stress in TCE-induced autoimmunity and its link with TLR and Nrf2. Groups of female MRL+/+ mice were treated with TCE, sulforaphane (SFN, an antioxidant) or TCE+SFN for 6 weeks (TCE, 10 mmol/kg, i.p., every 4th day; SFN, 8 mg/kg, i.p., every other day). TCE exposure led to significant increases in serum antinuclear antibodies (ANA) along with greater formation of hydroxynonenal (HNE)-specific circulating immune complexes as well as enhanced protein oxidation (carbonylation), suggesting an association of increased oxidative stress with autoimmune

response. Moreover, TCE exposure also resulted in increased expression of TLR4, Myeloid differentiation primary response 88 (MyD88), Interleukin-1 receptor-associated kinase-like 4 (IRAK4), NF-kB and reduced expression of Nrf2 and HO-1 in the spleen. Remarkably, SFN supplementation not only attenuated the TCE-induced oxidative stress, upregulation in TLR4 and NF-kB signaling, as well as downregulation of Nrf2, but also the autoimmunity marker ANA. These results, in addition to providing further support to a role of oxidative stress, also suggest that an interplay among oxidative stress, TLR4 signaling and Nrf2 pathway contribute to TCE-mediated autoimmune response. Furthermore, attenuation of TCE-induced autoimmunity by SFN provides an avenue for preventive and/or therapeutic strategies for ADs. *Supported by NIH ES016302 and ES026887.*

1870 Dysregulation of Nrf2 Signaling Contributes to Trichloroethene-Mediated Autoimmunity: Protective Role of Sulforaphane

N. C. Banerjee, H. Wang, G. Wang, and F. Khan. *University of Texas Medical Branch at Galveston, Galveston, TX.*

Trichloroethene (TCE), an occupational and ubiquitous environmental contaminant is associated with the induction of autoimmune diseases (ADs). Although oxidative stress plays a major role in TCE-mediated autoimmunity, the underlying molecular mechanisms still need to be delineated. Nuclear factor (erythroid-derived 2)-like2 (Nrf2) is an oxidative stress-responsive transcription factor and provides protection by regulating cytoprotective genes. However, the potential of Nrf2 in the regulation of TCE-mediated autoimmunity is not known. This study was, therefore, focused on establishing: (1) status and contribution of Nrf2 in TCE-mediated inflammatory and autoimmune responses during disease progression, and (2) protective role of antioxidant sulforaphane against trichloroethene-mediated autoimmunity. Female MRL+/+ mice were treated with TCE (0.5 mg/ml) for 24, 36 and 52 wks. Evaluation of samples from these mice showed that TCE exposure led to reduction in Nrf2 and HO-1, but significantly increased phos-NF-κB (p65) and iNOS along with increased p38 MAP kinase and pJNK expression in the liver. TCE exposure also increased hepatic protein carbonyl expression, further supporting the role of oxidative stress in TCE-mediated autoimmunity. To explore the role of Nrf2 in TCE-mediated autoimmunity, we treated female MRL+/+ mice with TCE (10 mmol/kg) along with/without antioxidant sulforaphane (8 mg/kg) for 6 wks. Interestingly, sulforaphane treatment led to Nrf2 activation and amelioration of TCE-mediated effects, as evident from reduction in inflammatory and autoimmune responses such as phos-NF-κB (p65) and iNOS along with suppression of anti-dsDNA antibodies. Furthermore, we observed that TCE treatment modulated inflammatory miRNA expression, including miRNA-690, miRNA-125a-5p and miRNA-21, which potentially target NFkB, and the changes in these miRNAs were attenuated by sulforaphane treatment. Our results show that TCE mediates an impairment in Nrf2 regulation. Attenuation of TCE-mediated autoimmunity via activation of Nrf2 supports that antioxidant sulforaphane could be a potential therapeutic candidate for autoimmune diseases. *Supported by NIH RO1 grants ES026887 and ES016302.*

1871 Protein Allergenicity Assessment Using Proteomic and Bioinformatic (AllerCatPro) Analyses

N. Krutz[1], C. Ryan[2], J. Winget[2], D. McMillan[2], S. Maurer-Stroh[3], I. Kimber[4], and F. Gerberick[5]. *[1]Procter & Gamble, Strombeek-Bever, Belgium; [2]Procter & Gamble, Mason, OH; [3]Bioinformatics Institute, A*STAR, Singapore, Singapore; [4]University of Manchester, Manchester, United Kingdom; and [5]GF3 Consultancy LLC, Mason, OH.*

Proteins in natural substances used in consumer products may present a risk for IgE-mediated respiratory allergies, especially when used in spray products. If no data are available to prove otherwise, 100% of the total protein content is considered allergenic. Here, we describe a novel approach to refine the risk assessment, exemplified with a theoretical consumer spray, an occupational exposure benchmark and exposure assessment using ConsExpo. Proteins are identified and semi-quantified by label-free proteomics analysis: normalized amount of protein was suspended (4% Sodium dodecyl sulfate, 100 mM dithiothreitol, 100 mM Tris, pH 7.6) and digested. Eluted peptides were introduced to a QExactive HF mass spectrometer (Thermo). Identified sequences were matched with UniProt database and quantified as sum of fragment ion intensities for all spectra counted for a protein, normalized by length and number of unique peptides. Allergenic potential is predicted based on FASTA sequences and AllerCatPro (allercatpro.bii.a-star.edu.sg), which predicts the allergenic potential of proteins based on comparison of 3D structure and amino acid sequence to a dataset of 4180 unique sequences derived from the union of the major databases FARRP, COMPARE, WHO/IUIS, UniProtKB and Allergome. The corn-derived material contains 0.22% total protein, 2009 unique proteins and the most abundant proteins comprise each 9.7% of total protein content. Exposure assessment with 10% protein content (0.055 ng/m^3/day) compared to the benchmark (1 ng/m^3/day) results in a Margin of Safety of 18, which is sufficient to protect from IgE-mediated respiratory allergies. The new information generated on the protein content and potential for allergenicity of natural substances can be used to refine the IgE-mediated respiratory allergy safety assessment and opens new opportunities for IgE-mediated allergy research of protein-containing materials.

1872 Classification of Human Reference Data for Skin Sensitization

J. Strickland[1], D. G. Allen[1], A. M. Api[2], J. Gordon[3], N. C. Kleinstreuer[4], H. Ko[5], J. Matheson[3], H. Thierse[6], J. Truax[1], and M. Herzler[6]. *[1]Integrated Laboratory Systems Inc., Research Triangle Park, NC; [2]Research Institute for Fragrance Materials, Woodlake, NJ; [3]Consumer Product Safety Commission, Rockville, MD; [4]NIEHS/NICEATM, Research Triangle Park, NC; [5]US FDA/CDER, Silver Spring, MD; and [6]Bundesinstitut für Risikobewertung (BfR), Berlin, Germany.*

To support the evaluation of non-animal approaches for skin sensitization assessment, we collected data for over 2500 human predictive patch tests (human maximization test and human repeated insult patch test) from more than 1500 publications. Each test was evaluated for reliability. Results from 1900 tests considered to be sufficiently reliable were classified using the Globally Harmonized System of Classification and Labeling of Chemicals (GHS). Human predictive patch test data based on single doses makes identification of thresholds uncertain and difficult to use as reference data. To overcome this challenge, classification criteria from the GHS were extended using a decision tree to partly resolve ambiguity in the results. If individual chemicals had multiple discordant test results, a weight-of-evidence approach was used to arrive at a single classification for each chemical. This classification approach was applied to a Cosmetics Europe reference list of 128 substances to support the evaluation of defined approaches for skin sensitization proposed for inclusion in a new OECD guideline. While 79 substances could be classified, the data for 49 substances were not sufficiently reliable. Classifications for the 79 substances included: eight strong sensitizers (1A), four strong sensitizers with some likelihood of over-classification (1A-), one moderate sensitizer with some likelihood of under-classification (1B+), 28 moderate sensitizers (1B), 10 non-sensitizers with some likelihood of under-classification (NC+), and six non-sensitizers (NC). Twenty-two substances could not be classified as sensitizers or non-sensitizers, but a potential for strong sensitization could be ruled out (NC/1B). The entire human skin sensitization patch test database will be made publicly available in the future for additional evaluation of alternative skin sensitization methods and development of new models. *This project was funded with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C. The views expressed above do not necessarily represent the official positions of any federal agency.*

1873 Development of a Screening Assay System to Predict the Intrinsic Immunogenicity of a Drug or Compound

M. O. Ogese[1], J. Watkinson[1], A. Lister[1], A. Gibson[2], L. Faulkner[3], A. E. Hillegas[4], B. Park[1], M. Z. Sakatis[5], and D. J. Naisbitt[1]. *[1]University of Liverpool, Liverpool, United Kingdom; [2]Murdoch University, Perth, Australia; [3]University College London, London, United Kingdom; [4]GlaxoSmithKline plc, Collegeville, PA; and [5]GlaxoSmithKline plc, Ware, United Kingdom.*

Drug hypersensitivity is an unexpected and difficult to predict adverse event that occurs during clinical trials or clinical use. *In vitro* T-cell priming assays that assess the intrinsic immunogenicity of drugs have been developed; however, their application domain is limited due requirements for (i) large blood volumes, (ii) two batches of autologous dendritic cells, and (iii) an experienced researcher. Hence, we aimed to develop a simplified assay, termed the T-cell multiple well assay (T-MWA) that permits assessment of whether drugs activate T-cells, alongside analysis of the strength of the induced response and the number of cultures that respond. Dendritic cell T-cell priming was conducted in multiple wells of a 96-well U-bottomed plate, for two weeks with model haptens (nitroso sulfamethoxazole (SMX-NO), Bandrowski's base (BB) or piperacillin (PIP)). Cultures were then re-challenged with hapten and T-cell proliferation was measured using [3H]-thymidine incorporation. Priming of naïve T-cells was observed with SMX-NO in all experiments, with no requirement for dendritic cells during restimulation. Greater than 65% of cultures were activated with SMX-NO; 8.0, 30.8 and 27.2% of cultures displayed weak (stimulation index SI=1.5-1.9), good (SI=2-3.9) and strong responses (SI greater than 4), respectively. The number of responding cultures and strength of the induced response was reproducible when separate blood

donations from the same donors were compared. Checkpoint blockade with anti-PD-L1 and anti-CTLA4 antibodies increased the strength of the proliferative response against SMX-NO, but not the number of responding cultures. Good to strong priming responses were detected with BB, while PIP stimulated only a small number of cultures to proliferate weakly. Inducible CD4+CD25+FoxP3+CD127LOW Tregs were generated during priming to the haptenic compounds. In conclusion, this new form of priming assay offers improvements over existing assays. Furthermore, with development it could be used to study multiple HLA-typed donors in a single plate format.

PS 1874 Generation and Characterization of Clozapine-Specific T Cells from Drug-Naive Individuals and Patients with Agranulocytosis

M. O. Ogese, A. Lister, R. Jenkins, X. Meng, A. Alfirevic, M. Pirmohamed, B. Park, and D. J. Naisbitt. *University of Liverpool, Liverpool, United Kingdom.*

Clozapine, an atypical antipsychotic previously withdrawn due to agranulocytosis, was re-introduced due to the lack of efficacious alternatives. Extensive monitoring of patients' neutrophil counts before, during and after therapy, suggests an unresolved drug safety issue to which the molecular mechanisms are poorly understood. The delayed onset agranulocytosis (3-4 weeks) after the initial clozapine exposure, rapid onset of symptoms upon rechallenge and the association of HLA-DQB1 and HLA-B variants suggest an immunological mechanism. The aims of this study were (i) to generate clozapine/metabolite-specific T-cell clones from HLA typed clozapine-naïve individuals and patients with agranulocytosis by serial dilution and mitogen stimulated expansion and (ii) to characterise the molecular mechanisms and pathway(s) involved in T-cell activation, using functional assays, including cytokine secretion and proliferation, and for cross reactivity studies with *N*-desmethylclozapine, clozapine *N*-oxide and olanzapine. Five clozapine-specific CD4+ clones and one CD8+ clone were generated from patients and clozapine naïve individuals; activation required the presence of antigen presenting cells, with clozapine interacting directly with MHC class II or MHC class I. Clones secreted a combination of Th1 (IFN-gamma), Th2 (IL-5, IL-13), Th22 (IL-22) and IL-10 (anti-inflammatory) cytokines, as well as cytotoxic molecules (Granzyme B and Fas ligand), and expressed 3 distinct T-cell receptors (TCR Vβ 5.1, 20 and 22) and CXCR3, CCR6, CCR4, CCR9, CCR8 and E-cadherin. Cross reactivity with N-desmethyl clozapine and olanzapine, but not with clozapine *N*-oxide was observed. Clozapine interacted with several HLA-DR molecules, including HLA-DRB1*07:01 and HLA-DRB1*15:01 to activate the CD4+ clones. *In silico* molecular docking with HLA-DRB1*15:01 revealed that clozapine, N-Desmethyl clozapine and olanzapine appear to bind in a similar confirmation to the P4 and P6 peptide binding pockets. Clozapine *N*-oxide occupied the P6 pocket in a different binding orientation. This study is the first to characterize clozapine-specific T-cells from patients and drug-naïve individuals. Additional work is required to delineate their precise role in the pathogenesis of clozapine-induced agranulocytosis.

PS 1875 Characterization of T Cell Responses in Patients with Liver Injury following Treatment with the BACE Inhibitor Atabecestat

P. J. Thomson[1], L. Kafu[1], J. Snoeys[2], L. Leclercq[2], R. De Vries[2], P. Vinken[2], and D. J. Naisbitt[1]. [1]*University of Liverpool, Liverpool, United Kingdom; and* [2]*Janssen Research & Development, Beerse, Belgium.*

Atabecestat is an orally administered BACE inhibitor which was in development for the treatment of Alzheimer's disease. Patients in clinical studies with atabecestat exhibited elevations in hepatic ALT and AST, without a suggestion for cholestasis. In most cases ALT/AST levels reduced upon cessation of atabecestat treatment, however in a limited number of patients ALT/AST levels continued to increase following cessation of atabecestat treatment prior to an eventual reduction. The delayed onset of liver enzyme elevation suggests an immune pathogenesis; thus, the aim of this study was to generate and characterize atabecestat and atabecestat metabolite-specific T-cells from patients with liver injury. PBMC were isolated from the whole blood of fourteen patients selected from atabecestat clinical studies. From the 14 selected patients, 12 exhibited elevations in liver enzymes. These cells were first subjected to the lymphocyte proliferation and ELIspot assays in the presence of atabecestat and metabolites (diaminothiazine [DIAT], *N*-acetyl-DIAT and epoxide). Furthermore, T-cell lines generated against atabecestat and metabolites were subjected to serial dilution to generate T-cell clones. Phenotypic analyses were conducted using flow cytometry, while functional studies characterized cross-reactivity, cytokine release and pathways of T-cell activation. Despite negative PBMC proliferation and ELIspot results, seventeen drug-responsive, primarily CD4+, T-cell clones were generated from five atabecestat DILI patients. Clones displayed reactivity against atabecestat (n=4), DIAT (n=10) and *N*-acetyl-DIAT (n=3). The drug-responsive CD4+ clones were activated in an HLA class II-restricted manner and displayed a Th1/2 cytokine secretion profile. All clones were activated through a direct interaction with HLA, with no requirement for antigen processing. Finally, a subset of atabecestat- and DIAT-responsive clones cross-reacted with the *N*-acetyl-DIAT metabolite. In conclusion, the detection of atabecestat(metabolite)-responsive T-cell clones from patients with DILI is indicative of an immune-mechanism for the observed hepatic enzyme elevations.

PS 1876 The Incidence of Infusion Reactions Associated with Monoclonal Antibody Drugs Targeting the Epidermal Growth Factor Receptor in Metastatic Colorectal Cancer Patients: A Systematic Literature Review and Meta-Analysis of Patient and Study Characteristics

L. C. Bylsma[1], R. Dean[2], K. Lowe[3], L. Sangare[3], D. Alexander[4], and J. Fryzek[5]. [1]*EpidStrategies, A Division of ToxStrategies Inc., Ann Arbor, MI;* [2]*Precision Xtract, Boston, MA;* [3]*Amgen Inc., Thousand Oaks, CA;* [4]*MetaMethod, South Lyon, MI; and* [5]*EpidStrategies, A Division of ToxStrategies Inc., Rockville, MD.* Sponsor: D. Proctor

Infusion reactions have been reported in studies of metastatic colorectal cancer (mCRC) patients treated with anti-EGFR therapies, including cetuximab and panitumumab, with incidences ranging from 0-33%. A systematic literature review and meta-analysis were conducted to estimate the incidence of infusion reactions in this population and identify variations in this incidence by patient and study characteristics. Multiple scientific databases were searched to identify observational studies or clinical trials of mCRC patients treated with anti-EGFR therapies that reported rates of infusion reactions, hypersensitivity, or allergy/anaphylaxis. Random effects models were used to meta-analyze the incidence of infusion reactions overall and stratified by therapy, study design, geographic location, *KRAS* mutation status, and grade of reaction severity. Among 48 studies included in this meta-analysis, the pooled estimate for infusion reaction incidence was 0.049 (95% CI: 0.036 - 0.065), or nearly 5%. Reactions of grades 1 or 2 were more common than reactions of grades 3-5 (0.089 vs. 0.028) No significant variations in infusion reaction incidence were observed by study design, KRAS status, or study location. Infusion reactions occur in approximately 5% of mCRC patients treated with anti-EGFR therapies and the incidence varies significantly by grade and severity. Future studies should consider investigating survival outcomes for only those patients with infusion reactions to determine its prognostic relevance.

PS 1877 Delineation of the Role of Gut Microbiome in Trichloroethene-Mediated Autoimmunity

H. Wang, G. Wang, Y. Liang, N. Banerjee, J. Sun, P. J. Boor, and F. Khan. *University of Texas Medical Branch at Galveston, Galveston, TX.*

Exposure to trichloroethene (TCE) is associated with autoimmune diseases (ADs), including systemic lupus erythematosus (SLE) and autoimmune hepatitis (AIH). However, mechanisms contributing to TCE-mediated autoimmunity are not well-established. Although gut microbiome dysbiosis has been implicated in the pathogenesis of ADs, whether TCE induces gut microbiome modification and if it is a causal factor or an outcome of the disease remains unknown. This study was, therefore, focused on determining (1) the composition of gut microbiome in female MRL+/+ mice at 24 and 36 weeks (W) post TCE exposure, and (2) the involvement of gut microbiome in lupus pathogenesis using unique SLE mouse models with varying degrees of disease progression (C57BL/6 as negative control, SLE-prone MRL+/+ with slow disease development or MRL-lpr mice with aggressive disease). Feces collected from these mice at 6 and 18 W as well as TCE-treated mice were subjected to 16S rRNA sequencing to determine the microbiome composition. Intestinal barrier functions and mucosal immune changes were analyzed by testing colonic tight junction proteins, cytokines, IgG production, fecal albumin and IgA levels. Serum autoantibodies and histology were evaluated to monitor disease progression. Our data showed that TCE exposure had distinct bacterial community revealed by β-diversity, and was accompanied by increases in phylum *Verrucomicrobia* at 24 and 36 W. TCE exposure also led to increased antinuclear antibodies (ANA) at 36 W. Studies using three mouse strains showed a lower Firmicutes/Bacteroidetes ratio in 6 W MRL-lpr mice, evidenced by a reduction in abundance of *Clostridiales* and significant increase in *Rikenellaceae* families. In 18 W MRL-lpr mice, altered microbiome composition was associated with increased gut permeability, inflammation, and AD markers (ANA and ASMA), along with immune cell infiltration in liver and severe glomerulonephritis. Our data indicate that TCE exposure leads to

gut dysbiosis and autoimmunity in MRL+/+ mice, and mechanistic studies showed that microbiome dysbiosis was associated with increased gut permeability, inflammatory responses and autoimmunity markers of SLE/AIH-like diseases. Our findings clearly indicate a role of gut dysbiosis in ADs and provide an intriguing mechanism for TCE-induced autoimmunity.

1878 Evaluation of Contact Sensitization Induced by Four Ionic Liquids

R. Frawley[1], K. Ryan[1], V. Johnson[2], T. Gulledge[2], W. Manheng[3], K. Shockley[1], S. Harris[4], and D. Germolec[1]. *[1]NIEHS, Research Triangle Park, NC; [2]Burleson Research Technologies, Morrisville, NC; [3]Virginia Commonwealth University, Richmond, VA; and [4]Social and Scientific Systems Inc., Durham, NC.*

Ionic liquids (ILs) are synthetic solvents used in chemical production processes and have been labelled as "green" replacements for volatile organic solvents. Recent reports indicate that ILs may induce oxidative stress, dermal toxicity, irritation, and sensitization in rodents which is a concern because human exposure is anticipated to occur via dermal or oral routes. The objective of this study was to assess the contact sensitization potential of four common ILs: 1-ethyl-3-methylimidazolium chloride (EMIM, dose 6.25-50% v/v), 1-butyl-3-methylimidazolium chloride (BMIM, dose 3.12-12.5% v/v), 1-butyl-1-methylpyrrolidinium chloride (BMPY, dose 0.825-6.25% v/v), and N-butylpyridinium chloride (NBuPY, dose 0.825-12.5% v/v). The test article, or vehicle control, was applied to the dorsa of both ears of female Balb/c mice daily for three days in a combined local lymph node (LLNA)/primary irritancy assay. In the mouse ear swelling test (MEST), the mice were sensitized on the back for 3 days, rested for 4 days, and challenged on the right ear. Sensitization was also assessed *in vitro* in the Direct Peptide Reactivity Assay (DPRA), the KeratinoSens™ Assay, and the Human Cell Line Activation Test (hCLAT). EMIM was neither an irritant nor a sensitizer in any assay. *In vivo*, BMIM and BMPY were not irritants. However, dermal treatment with 12.5% BMIM or 6.25% BMPY induced an increase ($p<0.01$) in lymph node cell proliferation in the LLNA, but the increase did not achieve the SI3 level associated with sensitizers. Sensitization (3.12%) and challenge (6.25%) with BMIM induced an increase ($p<0.05$) in ear swelling (82-183%) in the MEST, however there was no effect following exposure to BMPY. *In vitro*, BMIM was classified as a sensitizer by the hCLAT but was negative in the DPRA and KeratinoSens™ assays. BMPY was classified as a sensitizer by the hCLAT and KeratinoSens™ assay, but negative in the DPRA. NBuPY induced contact irritation *in vivo* at >3.12% ($p<0.01$), and sensitization *in vitro* in the KeratinoSens™ assay and hCLAT, but failed to induce sensitization *in vivo* and was negative for peptide reactivity in the DPRA. In summary, the butylated ILs, BMIM, BMPY, and NBuPY, were more potent than the ethylated EMIM. An integrated analysis of the *in vivo* and *in vitro* data suggests that BMIM and BMPY may induce sensitization at higher concentrations.

1879 Identify Structure Alerts Associated with Drug-Induced Autoimmune Diseases

M. Chen, J. Zhu, and Y. Wu. *US FDA/NCTR, Jefferson, AR.*

Drug induced autoimmune diseases is an adverse event that could lead to severe clinical outcome. Due to its complicated pathogenesis, no effective approach is available to assess a drugs' liability to induce autoimmune disease. Some drugs with specific substructures were frequently observed to cause autoimmune diseases. Here, a data mining approach was developed to identify structure alerts associated with the possibility to cause autoimmune diseases. 61 drugs were assigned as the culprit with evidence causing autoimmunity and another set of 593 drugs was defined as negative after filtering out 46 autoimmunity preferred terms in their drug labels. Furthermore, a maximum common substructure (MCS) method was applied in this dataset and 10 structure motifs that were statistically significantly associated with presence of autoimmune diseases were identified. Some motifs (e.g. quinoline) were reported associated with the high possibility to generate reactive metabolites, a mechanism that induces hypersensitivity and immune responses. The structure alerts identified here could be applied to screen out future drug candidates with the potential to cause autoimmune diseases. Further validation is warranted.

1880 The Androgenic Impact of AKR1C3 and 11-Ketoandrogens on Polycystic Ovarian Syndrome (PCOS)

R. D. Paulukinas, J. R. Murray, and T. M. Penning. *University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.*

Polycystic ovarian syndrome (PCOS) is the most common endocrinopathy in women of reproductive age affecting 10% of all women and at least 30% of all infertile women. PCOS is characterized by hyperandrogenism and leads to obesity and type 2 diabetes. Our goal is to identify targets for endocrine disrupting chemicals (EDCs) that could influence this disease. Aldo-keto reductase family 1 member C3 (AKR1C3; type 5 17β-hydroxysteroid dehydrogenase (HSD) and prostaglandin F synthase) is the prominent peripheral enzyme involved in androgen biosynthesis and the production of prostaglandins of the F series. AKR1C3 overexpression in adipocytes in response to insulin could lead to increased androgen receptor (AR) signaling, increased *de novo* lipogenesis, and decreased PPARγ signaling leading to reduce adipogenesis. This lipid overflow could exacerbate insulin resistance through a feedforward mechanism and promote the lipotoxic profile seen in PCOS. In adipocytes, the 11-oxygenated androgens of adrenal origin may be a potential source of peripheral androgens leading to the androgen excess. Serum samples from PCOS patients have increased levels of 11β-hydroxyandrostenedione (11βOH-A4), 11-ketoandrostene-3,17-dione (11K-A4), and 11-ketotestosterone (11K-T). 11K-T and 11-ketodihydrotestosterone (11K-5α-DHT) have the same potency as testosterone and dihydrotestosterone in AR reporter gene assays. To determine whether AKR1C3 can convert 11K-A4 to 11K-T and 11-keto-5α-androstane-3,17-dione (11K-5α-dione) to 11K-5α-DHT, kinetic parameters for these reactions catalyzed by recombinant AKR1C3 were estimated using discontinuous UV RP-HPLC enzymatic assays. Detection of UV transparent compounds was accomplished by dinitrophenylhydrazine derivatization. AKR1C3 was found to have catalytic efficiencies for 11K-A4 and 11K-5α-dione that were 5 times greater than its normal substrate A4. By contrast 11βOH-A4 was found to be a poor substrate indicating that it must be converted to 11K-A4 first by 11β-HSD2. The kinetic analysis helps to elucidate the involvement of AKR1C3 and 11β-HSD2 in the formation of the 11-oxygenated androgens. The study identifies AKR1C3, 11β-HSD2, AR and PPARγ as targets for EDCs that may affect PCOS onset.

1881 Exploring Reproductive Toxicological Dosing Schemes: Effects of Environmentally Relevant Dibutyl-Phthalate Exposures on Terminal Estrous-Stage Gene Expression

J. Beltran-Gastelum, F. Nuñez, E. Jaurequi, and Z. Craig. *University of Arizona, Tucson, AZ.*

Dibutyl phthalate (DBP) is a plasticizer commonly used in cosmetics and oral medications which have been detected in human urine and ovarian follicular fluid. In women, phthalates are associated with follicle loss, infertility and early menopause. Previous studies analyzing phthalate-induced ovarian toxicity have exposed mice for a specific number of days resulting in collection of ovaries at variable terminal stages of the mouse estrous cycle (e.g. estrus vs. diestrus), yet this does not account for sensitivity of genes to estrous changes during chemical exposures. Previously, following an estrous dosing regimen we have shown that DBP does not alter the folliculogenesis and steroidogenesis related genes, insulin-like growth factor 1 (*Igf1)* and aromatase (*Cyp19a1),* in estrus ovaries. We hypothesized that ovarian gene expression will be sensitive to *in vivo* DBP treatment according to terminal stage at collection. To test for differences between stages and treatments we dosed CD-1 females for 20-25 days (equivalent to ~4 estrous cycles) with environmentally relevant doses of DBP (10 and 100 µg/kg/d) and a classical high dose (1000 mg/kg/d) to measure ovarian *Cyp19a1* and *Igf1*. Treatment alone had no effect on *Igf1* and *Cyp19a1* mRNA, but higher DBP treatments of 100 µg/kg/d and 1000 mg/kg/d caused differential *Igf1* mRNA expression between metestrus/diestrus stages compared to proestrus/estrus. Interestingly, uterus weight was significantly decreased in the proestrus/estrus ovaries only with all DBP treatments, a difference that was not observed at metestrus/diestrus. There were no differences in other tissue weights or overall weight gain in response to DBP exposure. These results reveal that *Igf1* and uterus weight sensitivity to DBP exposure varies according to terminal stage. These findings support the idea that analysis throughout the estrous cycle should be considered when using female mouse models in reproductive toxicological studies. *Supported by NIH R01ES026998.*

1882 Aldosterone Secretion in a Human Adrenal Cell Line Is Enhanced by the Endocrine-Disrupting Chemical Di-(2-ethylhexyl) Phthalate (DEHP)

C. D. Schupbach, and P. G. Kopf. *Midwestern University, Downers Grove, IL.*

Di-(2-ethylhexyl) phthalate (DEHP) is an endocrine-disrupting chemical that is widely used as a plasticizer in the production of polyvinyl chloride containing plastics. DEHP is a component of many common household items (toys, packaging, furniture, etc.) and medical devices, resulting in significant and chronic human exposure. Human exposure to DEHP has been linked to androgen disruption and developmental toxicity, including cryptorchidism, decreased anogenital distance, and decreased testosterone levels. Other adrenal corticosteroids are also susceptible to the endocrine-disrupting effects of DEHP. One study has demonstrated that fetal exposure to DEHP results in altered adrenal aldosterone production in adult rats. Due to these potential effects of DEHP on adrenal cortex steroidogenesis, the focus of our studies is to characterize the effect of DEHP on aldosterone secretion in a human adrenocortical cell line. HAC15 cells were exposed to vehicle or various concentrations of DEHP (10 nM-30 μM). After 72 h, cell viability, aldosterone secretion, and gene expression of enzymes and cofactors involved in aldosterone synthesis was examined. No effects on cell viability were observed with the concentrations studied. Basal aldosterone secretion was significantly increased from 100 nM-30 μM DEHP, with maximal secretion at 10 μM (in pg/mL: vehicle, 75.6±3.5; 10 μM DEHP, 7735.2±151.3; n=8). Ang II-stimulated aldosterone secretion was significantly increased from 100 nM-30 μM DEHP, with maximal secretion at 10 μM (in pg/mL: vehicle, 4278.9±110.2; 10 μM DEHP, 18651.7±572.2; n=8). ACTH-stimulated aldosterone secretion was significantly increased from 100 nM-30 μM DEHP, with maximal secretion at 10 μM (in pg/mL: vehicle, 124.0±3.7; 10 μM DEHP, 23455.8±272.7; n=8). Gene expression of most enzymes and cofactors involved in aldosterone synthesis were increased by 10 μM DEHP. Aldosterone synthase (CYP11B2) had the greatest induction at 175.2±2.0 fold. These data support the evidence that DEHP disrupts the regulation of aldosterone secretion and provides further evidence that DEHP is an endocrine disruptor.

1883 *In Vitro* Impact of the Endocrine Disruptors Genistein and Mono–(2–Ethylhexyl) Phthalate (MEHP) on the Eicosanoid Pathway in Spermatogonial Stem Cells

A. Tran, and M. Culty. *University of Southern California, Los Angeles, CA.*

Perinatal exposure to endocrine disrupting compounds (EDCs) at environmentally relevant doses can alter the male reproductive system. Infants may be exposed to the EDC genistein (GEN), an isoflavone found in soy-based infant formulas, and MEHP, metabolite of the plasticizer DEHP, prevalent in plastics from medical equipment. We have shown that fetal exposure of rats to GEN and DEHP mixtures altered germ cell markers and increased infertility and abnormal testis phenotypes. In addition, mast cell and macrophage markers were also altered, which is indicative of inflammatory events in testes and can be linked to infertility in men. Inflammation is mediated by the eicosanoid biosynthesis pathway, where prostaglandins (PGs) are synthesized via several enzymatic steps starting with the release of arachidonic acid from membrane phospholipids. The rate limiting enzymes, cyclooxygenases (COXs), are associated with pain, fever and chronic inflammation. Moreover, PGs regulate physiological processes such as cell growth, female reproduction and fertilization. We propose that GEN and MEHP disruption of the eicosanoid pathway in germ cells might contribute to their adverse effects. The mouse C18–4 cell line is a model for undifferentiated spermatogonia, including spermatogonial stem cells (SSCs) which expresses similar eicosanoid pathway genes as found in primary rat spermatogonia by gene array. The cells were treated with GEN and/or MEHP at 10^{-5} or 10^{-4} M for 24 hours, with normal or charcoal-stripped 10% fetal bovine serum. While *Cox2* gene expression was increased by 10^{-4} M GEN and GEN+MEHP, *Cox1* mRNA was decreased with 10^{-5} M and 10^{-4} M GEN and GEN+MEHP treatments. Moreover, EDC-treated cells produced higher levels of PGD2 than controls. The transcripts of the undifferentiated spermatogonia markers *Foxo1* and *Mcam* increased, indicating remodeling of spermatogonia transcriptome by GEN and the EDC mixture. Silencing COX1 expression with shRNA resulted in cells expressing higher levels of the differentiated spermatogonia marker *cKIT*, suggesting a role of COX1 in maintaining spermatogonia in an undifferentiated state. Thus, GEN and MEHP exposure might disrupt spermatogonia status by altering COX1 expression. These data suggest that exposure to environmentally relevant doses of GEN and GEN+MEHP can disrupt the eicosanoid pathway and interfere with the mechanisms regulating self–renewal and differentiation processes in SSCs.

1884 Exposure to Acetaminophen Is Associated with Modified Aromatase Activity and Estrogen Synthesis in Human Placenta JEG-3 Cells

K. A. Addo, N. Palakodety, and R. Fry. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Acetaminophen is the most widely used drug for the treatment of pain and fever. It is taken by nearly two-thirds of pregnant women, making it the most commonly used over-the-counter medication during pregnancy. Of concern, several recent studies have reported an association between *in utero* acetaminophen exposure and adverse birth outcomes including cryptorchidism, short anogenital distance and reproductive abnormalities. Additionally, acetaminophen has endocrine disrupting properties and has been shown to reduce testosterone production in human fetal testes. As the placenta is an endocrine organ and a mediator of maternal-fetal interaction, exposure to acetaminophen during pregnancy could perturb placenta morphology, physiology, gene expression and epigenetic machinery. Highlighting a fundamental research gap, the effects of acetaminophen on the placenta have never been thoroughly studied. The goal of this study was to determine the effect of acetaminophen on placental steroidogenesis. Human placental JEG-3 cells were exposed to clinically-relevant concentrations of acetaminophen for 24 hours. mRNA expression as well as protein levels of steroidogenic genes were assessed. Acetaminophen was associated with decreased mRNA and protein levels of aromatase (CYP19A1), an enzyme involved in the conversion of androgen to estrogen. The results of the present study highlight that acetaminophen may potentially modulate estrogen levels by inhibiting CYP19A1 activity in the placenta.

1885 The Enhanced Predictive Assessment of Effects on Steroidogenesis (OECD TG 456) by Analyzing a Broadened Steroid Panel by LC-MS/MS

T. Walk[1], C. Gomes[2], C. Rülker[2], J. Fischer[1], R. Fuchs[1], R. Landsiedel[2], and B. van Ravenzwaay[2]. *[1]BASF Metabolome Solutions GmbH, Berlin, Germany; and [2]BASF SE, Ludwigshafen am Rheim, Germany.*

The regulatory accepted method to identify compounds that interfere with the steroid hormone system claims quantitative determination of testosterone (T) and estradiol (E2) in supernatant of human adreno-carcinoma cell line H295R (OECD TG 456). H295R is the cell line of choice, as it harbors the genes encoding key enzymes for steroidogenesis. Changes in estradiol and testosterone levels in the supernatant of treated cells are detected by the assay indicating a potential unwanted impact of the dosed substance on E2 and T. The aim of toxicology scientist worldwide is the determination of endocrine disruptions with the highest reliability in an *in vitro* approach. For that reason, the analytics for E2 and T was further developed from the classical immunoassays approach to analytical methods such as LC-MS/MS, minimizing the risk of cross-reactivity of the test substance with the test system. The next evident development step on the way to a best possible recognition rate of effects on the endocrine system is the broadening of analytes covered by the analytical system, which becomes important in the corresponding hormone pathways. Many additional improvement steps have been taken, both in analytics (e.g. online solid phase extraction, chemical derivatization) and cell culturing (e.g. enhanced growth conditions), to optimize this important assay. Here we show the results of our longstanding technical development of the enhanced steroidogenesis assay, based on the initial approach described in the OECD TG 456. Additionally, we share our experience out of more than 10.000 measurements of individual H295R-supernatant samples. The enhanced online LC-MS/MS method delivering absolute quantitative results from 16 hormones relevant in this context is described in detail to share with the scientific community. Analytical quality is shown androstenedione, testosterone, progesterone, deoxycorticosterone, deoxy cortisol, cortisol, estradiol, estrone, cortisone, hydroxyprogesterone, dehydroepiandrosterone, hydroxy pregnenolone, estriol, pregnenolone, 18-hydroxy deoxycorticosterone and corticosterone by validated values for the sensitivity and the reportable range (lower/upper limits of quantitation, LLOQ, ULOQ) for each individual analyte completed by accuracy and precision. Examples for the enhanced potential in identification and prediction of endocrine disruptive events will be discussed.

1886 Bisphenol A Induced Steroidogenic Enzyme Hsd17b2 through Activation of Orphan Nuclear Receptor Err Gamma V1

P. Bu[1], C. Zheng[2], and T. Fadlou Allah[2]. *[1]Rosalind Franklin University of Medicine and Science, North Chicago, IL; and [2]St. John's University, Queens, NY.*

Endocrine disruptors interfere with the normal functioning of the endocrine system. Bisphenol A (BPA) is a widely used industrial plasticizer with known endocrine disrupting property. Environmental exposure to BPA and their accumulation in human body present toxicological concerns. Over the past several decades, male reproductive functions have been declining in human and wildlife. The present study aims to investigate whether exposure to BPA adversely impacts the functions of the male reproductive system. Methods: Two commonly used mouse Leydig cell lines (I-10 and MLTC-1) were screened to determine whether BPA exposure would alter the expression of key enzymes involved in testicular steroidogenesis. Then, a correlation between the expression of orphan nuclear receptors Err family members and the induction of steroidogenic enzymes in response to BPA were assessed. Furthermore, overexpression of Err family members was employed to assess their direct impact on BPA-responsive steroidogenic enzymes. BPA concentration-dependently induced Hsd3b6 expression in both I-10 and MLTC-1 cell lines. I-10 cells seemed to be more sensitive to BPA exposure than MLTC-1 cells, as two additional steroidogenic enzymes, Cyp17a1 and Hsd17b2, were also concentration-dependently induced by BPA only in I-10 cells. Correlating to the differential BPA responsiveness between the two cell lines, two Err family members, alpha and gamma V1, have higher basal expression levels (2.9-fold and 8.7-fold, respectively) in I-10 cells compared to MLTC-1 cells. In addition, Err gamma V1 was markedly induced by BPA in I-10 cells in a concentration-dependent manner. Furthermore, overexpression of Err gamma V1, but not other Err family members, caused further induction of Hsd17b2 in response to BPA treatment. BPA induced the expression of Hsd3b6, Cyp17a1, and Hsd17b2 in Leydig cells, all of which are conserved and key enzymes in steroidogenesis. In addition, the induction of Hsd17b2 by BPA seemed to depend on the orphan nuclear receptor Err gamma V1. Taken together, our findings suggest that BPA may serve as a novel ligand for the orphan nuclear receptor Err gamma V1 and through its activation BPA up-regulates Hsd17b2 expression.

1887 Chemicals That Increase Synthesis of Estradiol and Progesterone Are Potential Risk Factors for Breast Cancer

R. A. Rudel, and B. Cardona. *Silent Spring Institute, Newton, MA.*

Established breast cancer risk factors such as hormone replacement therapy and reproductive history are thought to be related to increased estrogen and progesterone levels or activity. While most research about endocrine-active chemicals has focused on chemicals that bind to and activate the estrogen receptor, little attention has been paid to chemicals that may affect steroidogenesis, for example by increasing synthesis of estradiol or progesterone systemically or in the breast. Using publicly available data from EPA's ToxCast, we identified chemicals that increased levels of estradiol (E2-up) and/or progesterone (P-up) in a H295R steroidogenesis assay -which uses adrenal cortical cells to measure chemical effects on steroidogenesis *in vitro*. We prioritized active chemicals based on potency using their lowest active concentration (LAC), ToxCast AC50s, and an integrated measure of effects on the steroid synthesis pathway (adjusted maximum mean Mahalanobis distance, or adj.maxmMd). We further prioritized chemicals based on expected general population exposures using EPA's high throughput exposure modeling. Based on the ANOVA at each dose, OECD hit call logic, and limiting to chemicals with adj.maxmMd greater than zero, 270 chemicals increased E2 and 280 increased P, with 139 increasing both. Of these chemicals, 161 (54 E2-up, 125 P-up) were also identified as positive using ToxCast's data processing pipeline. The rest included 22 E2-up and 35 P-up chemicals with LAC less than 1 micromolar and 136 E2-up and 84 P-up chemicals with LAC between 1 and 33 micromolar. Median general population exposure predictions are above 0.01 mg/kg-day for 59 of the 270 E2-up and 47 of the 280 P-up chemicals. *In vivo* outcomes reported for some of these chemicals include mammary gland tumors and effects on vaginal opening as might be expected, but *in vivo* confirmation is hindered by lack of relevant endpoints in guideline studies and incomplete reporting of mammary gland effects. ToxCast data processing appears to obscure some non-monotonic responses in this assay. This work highlights chemicals that are a priority for exposure reduction, biomonitoring, and further study of health effects based on their ability to increase levels of estradiol and progesterone. Effects on breast development and breast cancer risk are of special interest. Current toxicity guideline studies do not include adequate endpoints that are sensitive to effects on mammary gland, and so additional assessments and more comprehensive reporting are needed to detect these effects.

1888 Bisphenol A and Bisphenol F Exposure Alters Brood Size and Decreases Food Availability for *C. elegans*

K. Rivenbark[1], R. Frye[1], V. Fitsanakis[2,3], and L. K. Vaughan[1]. *[1]King University, Bristol, TN; [2]Northeast Ohio Medical University, Rootstown, OH; and [3]Robson Forensic Inc., Charleston, SC.*

Bisphenol A (BPA) is a commonly used chemical in the synthesis of polycarbonate plastics. Because of growing concern for the estrogenic and neurological effects, some federal governments have implemented strict regulations on the use of BPA, which have increased the use of other common bisphenol analogues. Due to the structural similarity, Bisphenol F (BPF) is hypothesized to induce reproductive toxicity similar to BPA. Previous bisphenol toxicity studies have been conducted in polystyrene petri dishes. While companies (VWR, ThermoFisher) report no BPA in their petri dishes, bisphenol compounds may be leaching into the media. To eliminate this potential confounding factor, we utilized glass petri as an additional control. Wild type *Caenorhabditis elegans* were exposed to 250μM or 500μM BPA or BPF for 2 days (concentrations required to provide internal concentrations similar to those observed in human studies). After 2 days, adult hermaphrodites were moved to individual plates for quantification of brood size. All groups displayed a significant decrease in brood size compared to the glass petri dish control group. Specifically, the control plastic group laid 13% less eggs (p= 0.0028) and the BPA and BPF 500μM groups laid 22.1% and 23.9% less eggs (p0.0001); suggesting that BPA and BPF display estrogenic activity and reduced fecundity. *C. elegans* populations are typically 99.99-99.999% hermaphroditic. Male *C. elegans* were observed during treatment, which motivated the development of an experiment to assess the effects of bisphenol compounds on male fertility. The effect of BPA and BPF on the growth of *E. coli*, the food source for *C. elegans,* also indicated that bisphenol exposure altered normal growth. After 24-hour bisphenol exposure, control *E. coli* populations grown in plastic labware cultured a population size 23.61% less than that cultured in glass labware (p0.0001); BPA and BPF 500μM exposure caused a 40.10% and 50.7% decrease in population size (p0.0001). Results from this study indicate that BPF induces toxic effects similar to BPA in *C. elegans* as well as diminishing the viability of *E. coli*. This effect was also seen in the polystyrene petri dish controls, which brings the suitability of their use for bisphenol research. Further research is needed to determine the extent and potential mechanisms of toxicity.

1889 *In Vitro* Bioassay and Screening Model for Pre- and Post-Distribution Chicago-Area Treated Waters

E. Medlock Kakaley[1], M. Cardon[1], N. Evans[1], P. Bradley[2], L. Iwanowicz[3], E. Gray[1], P. Hartig[1], and V. Wilson[1]. *[1]US EPA, Research Triangle Park, NC; [2]US Geological Survey, Columbia, SC; and [3]US Geological Survey, Kearneysville, WV.*

Recent contamination of urban water supplies have highlighted the importance of screening tap water after drinking water treatment and distribution. Our goals were to efficiently screen for potential sources of estrogenic, androgenic and glucocorticoid receptor-active compounds in water samples from residential sites in the greater Chicago, Illinois metropolitan area. Sampling sites were based on community volunteers and were selected for broad coverage of the Chicago Department of Water Management service areas. Known endocrine active compounds were measured in water samples using LC/MS-MS and endocrine activity was measured using luciferase reporter transcriptional activation (TA) and chemiluminescent yeast (CLY) bioassays. Tap water samples were not expected to produce bioassay responses great enough to accurately estimate biological equivalency concentrations. Therefore, we screened sample extracts initially to identify the samples with detectable concentrations of activity and then performed a secondary dose-response screen to generate sample extract EC_{50} values. Estrogenic activity was detected above method detection limits, in untreated water samples only, using the TA (5/39 sites; median: 0.21 ng E2Eqs/L) and CLY (5/39; 1.78 ng E2Eqs/L) bioassays. Androgenic activity was detected using a novel TA bioassay in untreated and treated pre-distribution samples (4/39; 0.93 ng DHTEqs/L), but there were no androgenic activity detects using the CLY. No glucocorticoid activity was detected above method detection limits in either bioassay. Known estrogen receptor agonists estrone (0.72-1.4 ng/L), 17α-estradiol (1.3-1.5 ng/L), and 17β-estradiol (1.4 ng/L) were detected in a limited number of extract samples and did not necessarily correlate with estrogen TA and CLY bioassay detections. Overall, we applied a new and highly sensitive method for detecting androgenic activity and provide a tiered model for tap water bioassay screening that increases screening speed without increasing the false negative rate. These novel and highly sensitive approaches are necessary especially while screening low activity generally present in tap water samples. *Abstract does not necessarily reflect US EPA policy.*

1890 Computational Identification and Analysis of Nonmonotonic Concentration Responses in Tox21 Estrogen Receptor Assays

Z. Shi[1], M. Xia[2], and Q. Zhang[1]. [1]*Emory University Rollins School of Public Health, Atlanta, GA; and* [2]*NIH/NCATS, Bethesda, MD.*

Environmental endocrine disrupting chemicals (EDCs) interfere with the metabolism and actions of endogenous hormones. It has been well documented that EDCs can exhibit nonmonotonic dose response (NMDR) behaviors in numerous *in vivo* and *in vitro* studies. Not conforming to the conventional linear or linear no threshold response paradigm, these NMDR relationships pose practical challenges to the risk assessment of EDCs. Yet, the endocrine signaling pathways and biological mechanisms underpinning NMDR remain incompletely understood. The US Tox21 program has developed *in vitro* cell-based assays for estrogen receptors (ER), androgen receptors (AR), and other nuclear receptors, and screened 10K chemicals for potential agonist or antagonist activities in a high-throughput screening platform. Containing fifteen concentration points across several orders of magnitude of concentration range and run in both agonist and antagonist modes, these Tox21 assay data contain valuable quantitative information that can be explored to evaluate the nonlinearities in the effects of EDCs and potential cellular mechanisms. In this study we analyzed the concentration-response curves from the Tox21 screening data of ERα and ERβ assays in both agonist and antagonist modes as well as cell viability readout. We used both unsupervised and supervised machine learning algorithms to identify and cluster various shapes of concentration-response curves. The machine-learning method customized to the dataset is able to identify hundreds of NMDRs with high accuracy and high confidence. Even after eliminating nonmonotonic responses likely caused by cytotoxicity or auto-fluorescence, significant numbers of U- and inverted U-shaped concentration-response curves remain in both the agonist and antagonist assays. For a given chemical, the unique concentration-response profile appearing in both agonist and antagonist assays provides important insights into the potential pathway mechanisms that may underpin the observed nonmonotonic response. These profiles can be better understood via dynamic modeling of the interplay between the ligand, receptor monomer and dimer, DNA promoter, coactivator, and corepressor. The developed computational methods for NMDR identification in ER assays can be applied to other high-throughput biological response assays.

1891 Chronic Exposure to Bisphenol S Causes Thyroid Hormone Disruption and Reproductive Dysfunction in Zebrafish with Sex Difference

S. Cho[1], C. Park[2], and C. Kim[1]. [1]*Korea Research Institute of Chemical Technology, Daejeon, Korea, Republic of; and* [2]*Korea Institute of Toxicology, Gyeonsangnam-do, Korea, Republic of.* Sponsor: F. Guengerich

Zebrafish (*Danio rerio*) has been used as a model for behavioral research, genetics, physiology, disease modeling, drug discovery, and toxicology due to similarity of tissue-specific physiological processes between zebrafish and humans. Metabolic study using zebrafish provide important information regarding molecular-level effects and toxicity of xenobiotic chemicals. Bisphenol S (BPS) is commonly used in curing fast-drying epoxy resin adhesives. The aim of the present study was to examine whether chromic exposure to BPS disrupts thyroid endocrine system and causes reproductive dysfunction in zebrafish. In this study, zebrafish was chronic exposed to different concentrations of BPS (8, 40, and 200 μg/mL) for 21 days. To investigate the metabolic alteration induced by BPS, thyroid hormones and steroids in the whole-body of zebrafish analyzed by liquid chromatography-tandem mass spectrometry (LC-MS/MS) after sample preparation steps. In both female and male zebrafish treated with BPS, whole-body T3 levels were significantly increased. In female zebrafish treated with BPS, estradiol (BPS 8 μg/mL; $P < 0.005$, 40 μg/mL; $P < 0.005$, 200 μg/mL; $P < 0.003$) and progesterone (BPS 40 μg/mL; $P < 0.01$, 200 μg/mL; $P < 0.03$) were significantly increased. In male zebrafish treated with BPS, estradiol (BPS 8 μg/mL; $P < 0.002$, 40 μg/mL; $P < 0.004$, 200 μg/mL; $P < 0.01$) was significantly increased as in female zebrafish treated with BPS. On the other hand, testosterone (BPS 8 μg/mL; $P < 0.03$, 40 μg/mL; $P < 0.02$, 200 μg/mL; $P < 0.01$) and 11keto-testosterone (BPS 40 μg/mL; $P < 0.05$, 200 μg/mL; $P < 0.03$) were significantly decreased in male zebrafish treated with BPS. These results demonstrate that chronic exposure to BPS alters whole-body contents of thyroid hormones and steroidogenesis related to reproduction with sex difference, thus exerting reproductive toxicity.

1892 Validation of a Multiplex Assay to Detect Thyroid Hormones in Rat Serum

V. Williams. *Sequani Limited, Ledbury, United Kingdom.* Sponsor: V. Williams, EUROTOX

Endocrine disruptors are substances that can cause harmful effects to the endocrine system. Thyroid hormones, triiodothyronine (T3), thyroxine (T4), and thyroid stimulating hormone (TSH) are involved in development of central nervous and skeletal systems. Test guidelines on the screening and testing of chemicals published by the Organisation for Economic Co-operation and Development (OECD) have been updated to include thyroid hormone measurements for assessing endocrine disrupter potency. It's therefore important that non-clinical toxicology studies are able to provide data assessing potential adverse effects on endocrine endpoints. Several guidelines require analysis of circulating levels of thyroid hormones in juvenile rats. Sample volume and assay sensitivity can become limiting factors. Traditional enzyme-linked immunosorbent assays (ELISA) require relatively large sample volumes and suitability can be limited by poor sensitivity, inaccuracy, and biologically irrelevant assay ranges. The Rat Thyroid Hormone Panel (Merck), enables multiplexing of thyroid hormones in a single analysis, minimising required sample volumes. The panel operates using internally colour coded microspheres, coated with a specific capture antibody. Sample analyte is captured by the bead and biotinylated detection antibody is introduced. The reaction mixture is finally incubated with Streptavidin-Phycoerythrin conjugate. Each microsphere is identified, and the result quantified based on fluorescent reporter signals. A validation was performed evaluating kit performance in both multiplex and singleplex protocols for the relative quantification of T3, T4 and TSH in rat serum. Data capture was performed using a Luminex MAGPIX and xPONENT software. Method limitations for standard parameters were investigated. The panel was acceptable with respect to parallelism, intra and inter run precision, accuracy, recovery, carry-over and calibration standards. The functional range determined was: 194.0 to 10,000.0 pg/mL (T3), 751.6 to 100,000.0 pg/mL (T4), 15.8 to 4,000.0 pg/mL (TSH) and were suitable for the analysis of changes in circulating levels of endogenous analyte. The validation facilitated sample volume reduction to 12μl for measurement of 3 analytes simultaneously, reducing sample volume requirements by 90%. The method is fit-for-purpose for measuring relative serum concentrations of T3, T4 and TSH in support of toxicological studies with acceptable precision and accuracy.

1893 Sexually Dimorphic Thyroid Gene Expression Can Lead to Sex-Specific Responses to Thyroid-Disrupting Compounds

A. K. Rosenmai, L. Ramhøj, H. Johansson, and T. Svingen. *National Food Institute, Kgs. Lyngby, Denmark.*

The thyroid hormone (TH) system is central to brain development and is susceptible to perturbation by environmental chemicals. Testing of chemicals for TH disruption is often done in animals, but to allow for the use of alternative test methods, mechanism of effects must be better described. *Ex vivo* thyroid culture is a tractable model, as it can be used both as an intermediate model system and for characterizing mechanisms-of-action. In this project, we aim to characterize sex differences in thyroid development and developmental windows of TH system vulnerability to chemical exposure to facilitate better design and interpretation of *ex vivo* thyroid culture. Initial studies using explanted rat fetal thyroids exposed for 72 and 120 h to 100 μM propylthiouracil (PTU) revealed that i) key genes are dysregulated by PTU exposure and ii) the thyroids have sex-specific transcriptional profiles that give rise to sex-specific responses to chemical insult. Genes, including *Tshr* and *Nkx2-1*, displayed sexually dimorphic expression patterns after 72 h culture, a sex difference that disappeared after 120 h culture. After exposure to PTU, a thyroperoxidase (TPO) inhibitor, we observed compensations in both males and females. In males, these compensatory mechanisms were identified as upregulated *Nis* expression in response to PTU exposure, as well as a trend for upregulated *Tpo* and *Tg* expression with no effects on *Tshr*. In females, there was only a trend towards upregulated *Nis* expression, no effect on *Tpo* and *Tg*, and a downregulation of *Tshr*. These findings suggest sexually dimorphic effects in response to chemical exposure. These sex differences have implications for interpretation of thyroid disruption in animal studies and for further development of test methods for TH disruption.

1894 Use of FRTL-5 Cells in a Secondary Assay following High-Throughput Screening (HTPS) for Sodium Iodide Symporter (NIS) Inhibitors

A. R. Buckalew[1], S. Laws[1], A. S. Murr[1], D. DeVane[1,2], J. Wang[1,2], C. Deisenroth[1], W. Stewart[1], and T. Stoker[1]. *[1]US EPA, Research Triangle Park, NC; and [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN.*

Iodide uptake in the thyroid via the sodium-iodide symporter (NIS) is the first step in the biosynthesis of thyroid hormones. Potential NIS inhibiting chemicals were previously screened in our laboratory using a human hNIS-HEK293T-EPA (hNIS) cell line and a radioactive iodine uptake assay (RAIU). Approximately 1800 ToxCast ph1_v2, ph2, and e1K chemicals were screened with this HTPS assay and ranked for potency and cytotoxicity. Because the Fischer rat thyroid follicular (FRTL-5) cell line endogenously expresses NIS, we evaluated an FRTL-5 RAIU as a secondary screening tool to further clarify and prioritize potential NIS inhibitors. Following assay validation, results from controls, reference and chemical tests indicated a highly robust and reproducible secondary assay. Test chemicals included; 30 top-ranked ToxCast chemicals from hNIS HTPS and 10 additional chemicals, which were then tested in parallel FRTL-5, hNIS, and Cell Titer Glo cell viability assays. An orthogonal propidium iodide cytotoxicity assay was also conducted to identify effects on cell membrane integrity. Test chemicals were run at six concentrations (0.001-100µM) in 3 independent biological replicates. The majority of the test chemicals showed IC50 values within one order of magnitude for NIS inhibition. This data demonstrates the utility of a secondary RAIU assay in a more physiologically relevant assay that also provides a species comparison and strengthens the confidence for further prioritization. Several chemicals displaying strong NIS inhibition in both the FRLT-5 and hNIS assays with minimal cytotoxicity will be moved forward for additional testing in short-term *in vivo* assays, including etoxazole, methoxyfenozide, cyprodinil and oxyfluorfen. *This abstract does not necessarily reflect US EPA policy.*

1895 Optimization and Standardization of a Human Microsomes Based DIO Inhibition *In Vitro* Assay

A. Weber[1], B. Birk[1], H. Huener[1], K. Renko[2], S. Coecke[3], S. Schneider[1], B. van Ravenzwaay[1], and R. Landsiedel[1]. *[1]BASF SE, Ludwigshafen am Rhein, Germany; [2]Charité-Universitätsmedizin Berlin, Berlin, Germany; and [3]European Commission Joint Research Centre, Ispra, Italy.*

Thyroid hormones are relevant for metabolic homeostasis and impairment of homeostasis has been associated with several adverse effects. Increased regulatory requirements combined with the need to identify different mode of actions (MoA) will result in increased animal testing. To reduce this need as well as to establish screening models for compound development, relevant *in vitro* assays to identify thyroid active substances are needed. The European Centre for the Validation of Alternative Methods (ECVAM) is evaluating and validating numerous *in vitro* methods focusing on different MoA by cooperating with a network of EU laboratories (EU-NETVAL). One of the important regulators of systemic and local thyroid hormone balance are deiodinases (DIO) by activation of T4 to T3 and degradation of thyroid hormones via deiodination. DIO1, one of the three isoforms, serves as one main source for circulating T3 via deiodination of T4 in liver, kidney and thyroid and has a role in rescuing thyroid hormone bound iodide from biliary excretion. Jointly with the original developer (Charité Berlin), a non-radioactive approach to determine substance-induced DIO1 inhibition based on iodide release in liver microsomes was established. The released iodide was measured via colorimetric change in the Sandell-Kolthoff reaction. Several sources of human microsomes as well as the inhibitory effect of various substances on the DIO activity were investigated for standardization of the test protocol. The testing of several human liver microsomes showed differences in DIO activity which was addressed by microsome-batch specific adjustment of protein quantity resulting in a turnover value of 1,53 pmol iodide/min for further testing. A concentration dependent decrease in DIO activity after incubation with the noncompetitive, specific DIO1 inhibitor 5-Propyl-2-thiouracil (IC50: 2,7 µM; n=5, R^2=0,93) and DIO inhibitor Aurothioglucose (IC50: 0,78 µM; n=5; R^2=0,98) was shown. The DIO inhibitor Xanthohumol which inhibits DIO1 in purified enzyme showed no inhibition of DIO1 activity in human liver microsomes. PTU addition and heat inactivation reduced the iodide release in a similar amount indicating complete DIO inhibition through PTU. In total up to 10 different potential inhibitors were tested to show DIO1 inhibition and assay reproducibility. The optimized and standardized human liver microsome based DIO inhibition assay is a suitable medium-throughput method for testing the DIO-inhibiting properties of chemicals. Further 30 reference items are planned to investigate the predictivity and the suitability for interlaboratory validations as well as regulatory purposes.

1896 Differential Effects of the Agricultural Fungicide Imazalil in Various Experimental Models

S. Christiansen, T. Svingen, M. Axelstad, J. Boberg, C. Taxvig, H. L. Frandsen, M. Pedersen, and A. M. Vinggaard. *National Food Institute, Kgs. Lyngby, Denmark.*

The fungicide imazalil (enilconazole) is designed to disrupt fungal growth by targeting CYP enzymes of the ergosterol biosynthesis pathway. Imazalil may however also affect CYP enzymes in humans, including CYP19 (aromatase) of the reproductive system. In human fetal testis culture (*ex vivo*), imazalil can reduce testosterone production, probably by inhibition of additional enzymes such as CYP17. In line with this, we show that Imazalil markedly inhibits steroidogenesis in the H295R cell line. Based on this, we tested Imazalil for its endocrine disrupting potential in rats. Pregnant Sprague-Dawley rats were exposed to vehicle or two doses of Imazalil (0; 8; 24 mg/kg bw/day) by oral gavage from gestational days (GD) 7 to postnatal day (PND) 16 (n=14-16). An additional cohort was exposed to vehicle or three doses of Imazalil (0; 8; 24; 72 mg/kg bw/day) from GD 7-21, followed by caesarean section (N=4). This cohort was included for kinetic investigations, and to test a higher dose where we previously had seen severe maternal toxicity (dystocia). Despite its known inhibition of key CYP enzymes, we observed no significant changes to androgen sensitive endpoints. Neither anogenital distance (AGD; assessed at GD21 or PND1) nor nipple retention (NR; assessed at PND14) were affected. We found large variations between individual animals with regard to Imazalil concentrations in dams, fetal plasma and amniotic fluid, as well as large variations in intra-testicular testosterone levels. Overall, these individual differences in internal exposure and the lack of anti-androgenic effects *in vivo* indicates more complex toxicokinetic- and toxicodynamic-related issues of Imazalil, leading to differential effects in various experimental models.

1898 Determination of the Antidiabetic Property of the Aqueous Extract of *Biophytum sensitivum* on Streptozotocin-Induced Diabetic Rats

L. C. Domkat[1], Y. S. B[1], I. G[1], and M. M. H[2]. *[1]University of Jos, Jos, Nigeria; and [2]Federal University Wukari, Taraba, Nigeria.*

Diabetes mellitus, a common endocrine disorder of man, is considered one of the major health concerns all over the world. *Biophytum sensitivum* is used traditionally in the treatment of several diseases including diabetes. This study was aimed at investigating the antidiabetic property of *Biophytum sensitivum* aqueous extract on streptozotocin induced diabetic rats. Twenty (20) male albino rats weighing 180g - 200g were divided into five groups of four rats each: Group = A- normal control, B- diabetic control, C- diabetic treated with glibenclamide, D- diabetic treated with 200mg/kg of the extract, E- diabetic treated with 400mg/kg of the extract. Diabetes was induced by intraperitoneal injection of streptozotocin at (55mg/kg) in all groups except the normal control group. The aqueous extract of *B. sensitivum* was administered orally for 14 consecutive days. The blood glucose, albumin, total protein, lipid profile, electrolytes and serum enzymes concentrations were investigated after the administration of aqueous extract of *B. sensitivum*. From the results, diabetic control group showed significant ($p<0.05$) increase in the levels of blood glucose, total cholesterol, triglycerides, LDL, serum liver marker enzymes, serum kidney marker enzymes, direct bilirubin, potassium ions (K^+) while a significant ($p<0.05$) decrease in albumin, total protein, HDL, total bilirubin, indirect bilirubin, sodium ions (Na^+), chloride ions (Cl^-) and bicarbonate ions (HCO_3^-) when compared to the normal control group. Oral administration of aqueous extract of *B. sensitivum* to diabetic rats resulted in a reversal of the above diabetic conditions. However, the 400mg/kg was more effective than the 200mg/kg of the extract. Phytochemical screening of the crude extract of *B. sensitivum* revealed the presence of Alkaloids, Flavonoids, Tannins, Saponins, Terpenes/steroids, Cardiac glycosides, Balsam, Carbohydrates, Phenols and Resins. In conclusion, *B. sensitivum* aqueous has shown to possess hypoglycaemic, hypolipidemic, renoprotective and hepatoprotective effects, and can therefore be used for the management of diabetes at the said dosage.

1899 Multidrug Resistance-Associated Protein 4 (Mrp4) Is a Novel Genetic Factor in the Pathogenesis of Obesity and Diabetes

A. C. Donepudi[1], J. Lee[1], J. D. Schutez[2], and J. E. Manautou[1]. *[1]University of Connecticut, Storrs, CT; and [2]St. Jude Children's Research Hospital, Memphis, TN.*

Multidrug resistance protein 4 (Mrp4; encoded by Abcc4) is an efflux transporter known to transport several xenobiotics and endogenous molecules, such as prostaglandins and cyclic nucleotides. We recently identified that the lack of Mrp4 increases adipose tissue and body weights in mice. Interestingly, the expression of Mrp4 in the adipose tissue; and its role in adipose tissue physiology are unknown. The current study was aimed at characterizing these specific roles of Mrp4 using wildtype (WT) and knockout ($Mrp4^{-/-}$) mice. Additionally, we performed adipogenesis experiments using NIH-3T3L1 cells and human pre-adipocytes. Our studies determined that Mrp4 is expressed in the adipose tissue; and that the lack of Mrp4 resulted in adipocyte hypertrophy. In mice, lack of Mrp4 resulted in increased blood glucose and leptin levels, and impaired glucose tolerance. Indirect calorimetry analysis using metabolic cages showed that $Mrp4^{-/-}$ mice have decreased energy expenditure (EE), ambulatory activity (AA) and wheel counts compared to WT mice. Additionally, pharmacological inhibition of Mrp4 function in *in vitro* models resulted in increased adipogenesis and adipogenic gene expression. Lack of Mrp4 in both *in vivo* and *in vitro* increased phospho- cAMP response element-binding protein (p-Creb) protein levels and decreased levels of circulating prostaglandin E metabolites. Increased activation of adipose tissue Creb coupled with decreased plasma prostaglandin E metabolite levels due to loss Mrp4 may have played an important role in the development of obese and diabetic phenotypes in mice. In conclusion, the lack of Mrp4 increases the risk of the development of metabolic diseases such as obesity and diabetes.

1900 Organophosphate Flame Retardant Alterations to Energy Homeostasis in PPARg and ERa KO Mouse Models of Diet-Induced Obesity

G. Vail, A. Maeng, A. Yasrebi, and T. Roepke. *Rutgers, The State University of New Jersey, New Brunswick, NJ.*

Endocrine disrupting chemicals (EDC) are becoming increasingly prevalent in the environment and many are shown to accumulate within human tissues and interact with endogenous hormone receptors. One such EDC is organophosphate flame-retardants (OPFR). OPFR interact with multiple hormone receptors involved in homeostasis, including estrogen receptors (ER) and peroxisome proliferator-activated receptor (PPAR) γ. We have previously observed that exposure to a mixture of OPFR in adult wild-type (WT) mice induces varying sex-dependent alterations of energy homeostasis, orexigenic and anorexigenic peptide hormones, feeding behavior, and activity. This dysregulation of energy homeostasis can cause an increase in susceptibility to metabolic disorders. In the current study, we repeated the previous adult exposure experiments, this time with knockout mouse strains for ERα (ERKO), and brain-specific knockout of PPARγ (PPARKO). We continued our use of a common mixture of OPFR {tris(1,3-dichloro-2-propyl)phosphate, triphenyl phosphate, and tricresyl phosphate, 1 mg/kg/day each} for 4 weeks continuing the comparison between low-fat diet (LFD, 10% kcal fat) and a high fat (HFD, 45% kcal fat) to generate a diet-induced obesity model. We recorded body weight, crude food intake, body composition, meal patterns, glucose and insulin tolerance, and plasma peptide hormone levels. As in the WT experiments, body-weight gain was increased by HFD for both strains, however, the increased weight-gain for males on a HFD induced by OPFR exposure in WT was absent in both strains, suggesting the lack of these nuclear receptors eliminates OPFR influence on body-weight gain. No weight gain OPFR effects were seen in females. Furthermore, while OPFR altered fat/lean mass in WT male mice, male mice of either KO saw no effects, whereas female ERKO mice exhibited the pattern of male WT OPFR effects. Interestingly, while OPFR decreased feeding efficiency in WT females, in ERKO there was no difference in females, and instead this pattern was now observed in males. Additionally, the OPFR food intake reduction seen in WT was absent in both ERKO and PPARKO. Notably, peptide hormones insulin, leptin, and ghrelin were drastically altered, predominantly in female mice of both KO strains, suggesting both a PPARγ and ERα role in OPFR effects. Lastly, insulin tolerance abolished diet effects in the OPFR exposed ERKO males, while we observed a rescue of HFD effect by OPFR exposure in PPARKO. We are currently processing hypothalamic samples for protein and gene expression. In summary, our data indicates that the influence of adult OPFR exposure on diet-induced obesity is mediated, in part, by ERα and PPARγ.

1901 Metabolic Effects of Endocrine-Disrupting Chemicals: Novel Testing METhods and Adverse Outcome Pathways (EDCMET)

A. Braeuning[1], and A. Levonen[2]. *[1]Bundesinstitut für Risikobewertung (BfR), Berlin, Germany; and [2]University of Eastern Finland, Kuopio, Finland.*
Sponsor: A. Braeuning, EUROTOX

The term "endocrine disrupting chemical" (ED) mostly refers to compounds that interfere with hormone-related signaling pathways, thereby causing adverse health effects. Recently, the concept of endocrine disruption has been extended to alterations at the metabolic level, which may result for example in obesity, fatty liver disease or diabetes, diseases which represent an increasing worldwide health concern. Currently, no validated methods exist to assess metabolic effects of EDs. Thorough understanding of the molecular mechanisms that lead to adverse metabolic effects of EDs is presently lacking. Starting in early 2019, the European Union has funded the EURION cluster of eight projects on the overarching topic 'New testing and screening methods to identify endocrine disrupting chemicals' within the Horizon 2020 framework, in order to address this unmet need and other gaps in the context of ED testing. One of these projects is EDCMET (Metabolic effects of Endocrine Disrupting Chemicals: novel testing METhods and adverse outcome pathways). The project is coordinated by the University of Eastern Finland, and partners from nine European countries contribute to achieving the project's scientific goals. The main objective of EDCMET is to develop validated *in silico*, *in vitro* and *in vivo* methods to assess metabolic effects of EDs. EDCMET will apply the adverse outcome pathway (AOP) paradigm to identify molecular initiating events (MIE) that can be used for the prediction of emergent adverse biological phenotypes. A strong focus is put on energy and fat metabolism, as well as on nuclear receptors as molecular targets that regulate these processes. EDCMET will achieve its goals by utilizing a wide variety of methodologies. The approach comprises computational tools for the prediction of biological activities and interactions, cell culture-based screening tools, up-to-date animal models, multi-layer omics technologies for the identification of molecular mechanisms, and also epidemiological data, in order to associate the exposure to chemicals to ED-related metabolic effects and to identify human biomarkers of exposure to metabolic EDs. Results from EDCMET are expected to substantially contribute to our mechanistic knowledge related to EDCs. Moreover, a tiered strategy for the testing of metabolic effects of EDs will be developed for future implementation in regulatory toxicology studies.

1902 Endocrine Disruptors Exert Cell Type-Specific Effects on Endogenous Glucocorticoid Signaling

D. N. Joseph[1], S. Inayat-Hussain[2], and S. Whirledge[1]. *[1]Yale School of Medicine, New Haven, CT; and [2]Yale School of Public Health, New Haven, CT.*

Endocrine disrupting chemicals (EDCs) are substances that interfere with functions of the endocrine system and can cause adverse developmental, neurological, metabolic, and reproductive effects. Unlike toxic effects that can be evident immediately, endocrine disruption may impact complex signaling pathways that take years or generations to discover. EDCs can affect several pathways in the body, but their potential effects on the glucocorticoid signaling is particularly important to study as the glucocorticoid receptor (GR) is present in almost every cell type and plays a critical role in development, metabolism, reproduction, and overall physiological homeostasis. The objective of this study was to evaluate the endocrine disrupting potential of a broad range of industrial chemicals, focusing on four chemicals with GR activity predicted by the Tox21 database: 4-nonylphenol (4-NP), bisphenol A (BPA), butylated hydroxytoluene (BHT), and phenolphthalein (PP). Exposure was tested in the human liver (HepG2) and uterine (Ishikawa) cell lines to understand potential impacts to metabolism and reproduction, respectively. We determined that these chemicals did not induce cell death at concentrations up to 1 uM, indicating that the dose range employed was not associated with toxicity. Instead, the chemicals tested altered the expression of classic glucocorticoid-responsive genes, *GILZ* and *PER1*. Interestingly, the effect was cell-type specific. For example, BHT significantly induced transcript levels of *GILZ* and *PER1* in HepG2 but not Ishikawa cells. We found that the induction of glucocorticoid-responsive genes by BHT was mediated by GR, as pretreatment with the GR antagonist RU 486 abolished the effect of BHT. Low-dose combinations of BPA and 4-NP or BHT produced additive effects on *GILZ* transcript levels in HepG2 cells, although the combination of BPA and 4-NP did not augment *GILZ* expression in Ishikawa cells. We found that co-treatment of chemicals with glucocorticoids altered the transcriptional response compared to glucocorticoids alone. To explore the mechanism of endocrine disruption, we evaluated the phosphorylation status of GR at two residues associated with GR activity: p211 and p226. The effect was specific to

cell type and chemical, where BPA and 4-NP enhanced p211 in Ishikawa but not in HepG2 cells. These results demonstrate that EDCs exert gene- and cell-type specific effects on glucocorticoid signaling.

1903 Comparative Phenotypic and Transcriptomic Responses to Multiple Endocrine-Disrupting Chemicals in Zebrafish

C. Akemann. *Wayne State University, Detroit, MI.*

Endocrine disrupting compounds (EDCs) are emerging contaminants of concern found ubiquitously in the environment that can cause a wide range of adverse effects, the full extent of which are currently unknown. We used zebrafish as a model to determine and compare the effects of nine EDCs (4-nonylphenol, atrazine, bisphenol-A, chlorpyrifos, dieldrin, estrone, metformin, triclocarban, and triclosan). Zebrafish are an NIH accepted model system for human health that have 70% homology with the human genome, transparent larvae (allowing observation of internal development), large numbers of offspring, and a sequenced genome. We exposed zebrafish to 3 concentrations of EDCs for either 1 or 5 days during early development and identified adverse developmental and behavioral outcomes. RNASeq and pathway analyses was performed to determine specific gene expression changes, as well as the critical pathways affected. Many differentially expressed genes overlapped across chemicals and some of the main pathways affected include reproductive diseases, endocrine system disorders, and estrogen synthesis and regulation. This study brings us closer to identifying the full extent of adverse effects of EDCs and the mechanisms through which these effects occur.

1904 Circadian Gene Expression in Rats is Altered by Repeated Exposure to Tetrabromobisphenol A

S. J. Coulter, G. A. Knudsen, and L. S. Birnbaum. *NIEHS/NTP, Research Triangle Park, NC.*

The brominated flame retardant Tetrabromobisphenol A (TBBPA) is present in the epoxy resin of circuit boards used in electronic devices and has been found at significant levels in house dust. Studies performed by the National Toxicology Program have indicated a potential link between higher exposure levels and uterine tumors in rats, and TBBPA was listed as a probably carcinogen by the International Agency for Research on Cancer (IARC) in 2016. Evidence has also accumulated that TBBPA may have an endocrine disrupting function. In previous studies using Wistar Han rats chronically treated with 250 mg/kg/d for 5 days, our lab has linked TBBPA exposure to disruption in estrogen homeostasis, along with thyroid and immune system dysfunction. A potential effect on expression of the genes comprising the circadian clock was also discovered upon RNA-Seq analysis of liver and uterus from these TBBPA- and vehicle-treated rats. To investigate this effect, a circadian study was undertaken. Female Wistar Han rats were exposed to 250 mg/kg of TBBPA or vehicle for 5 consecutive days, then tissues were collected at 4-hour intervals and RNA was extracted. Expression levels of the core circadian genes Clock circadian regulator (*Clock*), aryl hydrocarbon nuclear translocator-like (*Arntl* or *Bmal1*), neuronal PAS domain protein 2 (*Npas2*), period circadian regulator 1, 2 and 3 (*Per1*, *Per2*, and *Per3)*, and cryptochrome circadian regulator 1 and 2 (*Cry1*, *Cry2*) and circadian-related genes retinoic acid receptor-related orphan receptor a, b and c (*Rora*, *Rorb*, *Rorc*), nuclear receptor subfamily 1 group D member 1 (*Nr1d1*, *Rev-erb*), casein kinase 1d (*Csnk1d*) and 1e (*Csnk1e*), aryl hydrocarbon receptor (*Ahr*), and aryl hydrocarbon receptor nuclear translocator (*Arnt*) were measured in liver and uterus using droplet digital PCR (ddPCR). Results showed differential effects in liver and uterus, including decreased amplitude, phase shift, and suppression of cyclicity, which appeared to be gene- and tissue-specific. These perturbations of the circadian cycle could affect expression of numerous genes which are reliant on circadian signals to regulate expression, including those controlling metabolism and the reproductive cycle. *This research was supported by the Intramural Research Program of NIH [Project ZIA BC 011476].*

1905 Towards Computational Modeling of Estrogen Receptor Alpha-Mediated Signaling in Endocrine Disruption

B. Duijndam[1], T. van den Hoorn[2], J. van der Laan[2,1], and B. van de Water[1]. *[1]Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands; and [2]Medicines Evaluation Board, Utrecht, Netherlands.*

Estrogen receptor alpha (ERα) belongs to the nuclear hormone receptor family of ligand-inducible transcription factors, and regulates gene networks in biological processes such as cell growth and proliferation. Disruption of these networks, for instance with the non-genotoxic carcinogen 17β-estradiol (E2), can result in adverse outcomes such as unanticipated cell proliferation ultimately culminating in tumor formation. Since ER signaling is also involved in normal physiological responses, and not solely activated in adverse outcomes, it is essential to quantify relationships between different key events leading to a particular adverse outcome induced by non-physiological ER activation. To obtain this quantitative information on these key events, a technique is favored which can provide single cell information on all these events. For this purpose, we established fluorescent protein reporter cell lines with bacterial artificial chromosome (BAC) green fluorescent protein (GFP) transgenomics of important players in the ERα signaling pathway in context of cellular proliferation. The human breast cancer cell line MCF7 was used as a model as its proliferation is dependent on ERα. In combination with advanced live cell imaging, these reporters can monitor the spatial and temporal dynamics of key events of ERα pathway activation, i.e. target activation and cell cycle progression, at a single cell level. This adverse outcome pathway-driven reporter platform allows us to quantify relationships between various different key events and the ultimate cellular adverse outcome, and to eventually integrate this dynamic signaling data in a computational model. In addition, these *in vitro* reporters can be used to screen e.g. drug candidates or other chemicals of concern for the potential of modulating ER activity and the likelihood of a non-genotoxic carcinogenic mode of action.

1906 Development of Strategies to Determine the *In Vitro* and *Ex Vivo* Induction of T_4-glucuronidation in Different Species

J. Reinen, M. Smit, and M. Wenker. *Charles River, 's-Hertogenbosch, Netherlands.* Sponsor: H. Emmen

The thyroid hormones (THs) triiodothyroxine (T_3) and thyroxine (T_4) are essential for normal cellular differentiation and growth. The prohormone T_4 can be converted enzymatically into the biologically active T_3 and as such functions as a reservoir for T_3. Xenobiotics can alter the homeostasis of THs through induction of Phase I and Phase II enzymes resulting in increased metabolism. One of the metabolic pathways by which xenobiotics may cause effects on TH homeostasis is induction of hepatic glucuronidation. Both T_3 and T_4 can be glucuronidated and the formed glucuronides can no longer be converted into active T_3 and are biliary excreted. As a consequence, T_3 and T_4 plasma levels may decrease resulting in hypothyroidism which may cause adverse health effects. In the current study, strategies to determine induction of T_4-glucuronidation in different species (mouse, rat, dog and human) were evaluated. First, UPLC-PDA-MS-based analytical methods to monitor T_4 and its metabolites were developed and implemented. To investigate if T_4 metabolism is species- and/or gender-specific, T_4-glucuronidation was determined using male and female liver microsomes from all four species. Subsequently, the metabolism of T_4 was also studied in male and female hepatocytes from all four species during which not only the formation of T_4-glucuronide but also formation of T_4-sulphate, T_3 and 3,3',5'-triiodothyronine (rT_3) was investigated. For *in vitro* induction, the effect of inducers upon the T_4 metabolism was studied using rat and human hepatocytes and conditions were optimized to develop an assay that can be used to determine xenobiotic-induced T_4 metabolism. For the *ex vivo* induction, protein- and time-dependent experiments were performed for selected species to optimize reaction conditions for *ex vivo* experiments. Experiments were also performed to evaluate the activity of commercially available xenobiotic-induced rat liver microsomal fractions. Overall, the current study gives an overview of species-, gender- and inducer-specific differences for the metabolism of T_4. The here presented assays can be used to determine the *in vitro* and *ex vivo* induction of T_4-glucuronidation in different species.

1907 Multi-Endocrine Disruptors Screening in Zebrafish

I. Iturria, C. Martí, A. Muriana, and M. J. Mazón. *Biobide, San Sebastian, Spain.*

In vitro tools are inexpensive and scalable for high-throughput platforms, however they pose low relevance to vertebrate species. On the other hand, work with adult animals is expensive and represent ethical issues. Small fish like zebrafish (*Danio rerio*) are excellent alternative to *in vitro* and *in vivo* model. They offer a unique experimental system where screening assays can be performed at the whole animal level, being at the same time compatible with the 3R principles (replacement, reduction and refinement in animal testing). Endocrine disruptors (EDCs) are chemicals that by interfering with the endocrine system can have an adverse effect at developmental, neurological, immune and reproductive level. Thyroid Disrupting (TD) compounds specifically alter the function of thyroid gland through the interference with the synthesis, transport and/or binding of the thyroid hormones. The negative impact of EDCs is becoming a real public health issue, therefore the necessity of tests to assess the potential risk of new chemicals before they are marketed is increasing. The zebrafish is currently used as a model for the evaluation of acute and developmental toxicity and for the screening and testing of potential thyroid (TD) and endocrine disrupters (EDCs), as described in the OECD Guidelines. The two major endpoints used to evaluate EDCs, vitellogenin concentration and change in sex ratio, have several limitations. With the purpose of expanding the number of tests available to identify estrogenic and androgenic substance, we evaluate gene expression of 4 biomarkers in 5 dpf zebrafish larvae after exposure, from 48 hpf, to 10 compounds reported as EDCs. Expression assay over known markers of thyroid pathway was also developed to evaluate 9 environmentally relevant TD substances. This screening methodology showed to be a sensitive and cost-effective assay to screen and evaluate potential EDCs chemicals.

1908 The Intervention of NLRP3 Inhibitor and Nrf2 Activator Protects against Diethyl Nitrosamine and Thioacetamide-Induced Hepatic Precarcinogenesis in Rats

D. Dwivedi, and G. B. Jena. *National Institute of Pharmaceutical Education and Research (NIPER) S.A.S. Nagar, Mohali, India.*

More than 30% of all malignancies initiated/exacerbated by inflammation and support inflammation as a pivotal component of tumor initiation. Nrf2 plays complex and multicellular roles in hepatic inflammation, carcinoma, fibrosis, and regeneration. Hepatocellular carcinoma (HCC) is the second leading cause of cancer mortality worldwide. Thioacetamide (TAA), a hepatotoxicant precisely mimics the characteristics of human liver damage in animal models and induces liver fibrosis, cirrhosis, and carcinoma. Diethyl nitrosamine (DEN) is a carcinogen, promotes carcinogenesis. Antidiabetic drug glibenclamide (GLB) possesses anti-inflammatory properties and inhibits NLRP3 inflammasome. Dimethyl fumarate (DMF), a multiple sclerosis drug, activates the Nrf2/ARE pathway and maintains the antioxidant status. The aim is to investigate (i) chronic inflammatory condition that affects liver regeneration (ii) the chemo-protective effect of NLRP3 inhibitor glibenclamide and Nrf2 activator dimethyl fumarate on DEN+TAA-induced hepatic precarcinogenesis, in partial hepatectomized Wistar rats. Rats were subjected once to DEN and after two weeks to partial hepatectomy. TAA (100 mg/kg every third day, ip), DMF and GLB (DMF 25 mg/kg/day, po and GLB 0.5 mg/kg/po) were administered for 16 weeks. GLB and DMF intervention improved the DEN+TAA induced reduction in body weight, increased liver weight, and plasma transaminase levels. GLB and DMF treatment improved DEN+TAA-induced foci of altered hepatocytes, fatty degeneration, multifocal steatosis, lymphocyte infiltration, collagen deposition, necrosis, DNA damage, and apoptosis. Further, GLB and DMF treatment significantly restored the DEN+TAA-induced alterations in inflammatory (NLRP3, ASC, caspase1, NF-κB), fibrogenic (TGFβ1, collagen), anti-oxidant (Nrf2, HO-1, SOD1, catalase), and regenerative proliferative stress (PCNA, pSTAT3/STAT3, GST-p, HGF, cMET, TGFα, EGF, AFP) markers. Hepatoprotective responses of GLB and DMF were evident by the restoration of DEN+TAA-induced oxidative stress, inflammatory responses, DNA damage, histopathological changes, and anti-oxidant levels. Simultaneous maintenance of antioxidant status by activation of Nrf2 and reduction of the inflammatory condition by the inhibition of NLRP3 could be a rational strategy for improving liver regeneration and to reduce the development of HCC.

1909 Gene Expression Signature of Dieldrin-Treated Livers in Mice

L. Melo, Z. Wang, W. Qiangen, X. LI, and J. Klaunig. *Indiana University, Bloomington, IN.*

Dieldrin, an organochlorine insecticide, induced liver tumors in mice after chronic exposure. Although no longer manufactured, dieldrin is still present in the environment and in human tissues. Previous work in our lab showed a defined dose response effect of dieldrin on liver cell proliferation and oxidative stress induction suggesting a role of oxidative stress as the mode of action for the observed murine liver tumors. Subsequently as our understanding of nuclear receptor mediated processes in liver carcinogenesis has advanced, we examined a role for nuclear receptor activation in dieldrin induced cancer. The current studies showed CAR (constitutive androstane receptor) activation in dieldrin treated mice. We also examined, using RNA sequencing in both C57BL/6 and B6C3F1 mouse livers, the effect of dieldrin (10 ppm in diet for 14 days). In B6C3F1 mice, there was a significant increase in the expression of genes specific to CAR activation (*Cyp2b6, Cyp2c8, Cyp2c9, Cyp2b6).* A decrease in *Cyp27b1* was noted that suggests a negative vitamin D receptor response. PXR/RXR activation, VDR/RXR activation, and aryl hydrocarbon receptor signaling pathway were also altered. Pathway analysis showed hepatocellular carcinoma pathways were upregulated. Dieldrin treated C57BL/6 mice showed a similar Cyp2c family induction (CAR activation) however no significant alteration of the PXR/RXR pathway was seen. Instead, insulin-dependent diabetes mellitus, diabetes mellitus, and glucose metabolism disorder pathways were downregulated. LPS/IL-1 mediated inhibition of RXR function pathways was altered in both species, and also estrogen biosynthesis pathways was upregulated. Estrogen was shown to be an effective activator of CAR in both female and male mice in the past, supporting dieldrin as a CAR activator. The CAR activation pattern seen with dieldrin mimics that seen with other organochlorine insecticides including toxaphene thus pointing to the mode of action of this group of compounds as CAR mediated mode of action for the observed rodent liver tumors.

1910 NR2E3 Is a Key Component in p53 Activation by Regulating a Long Noncoding RNA DinO in Acute Liver Injuries

T. Khanal[1], Y. Leung[1], J. Wang[1], N. Timchenko[2], S. Ho[1], and K. Kim[1]. *[1]University of Cincinnati, Cincinnati, OH; and [2]Cincinnati Children's Hospital Medical Center, Cincinnati, OH.*

Damage-induced long noncoding RNA (DINO) is a long noncoding RNA that directly interacts with p53 and thereby enhances p53 stability and activity in response to various cellular stresses. Here, we demonstrate that nuclear receptor subfamily 2 group E member 3 (NR2E3) plays a crucial role in maintaining active DINO epigenetic status for its proper induction and subsequent p53 activation. In acetaminophen (APAP)- or carbon tetrachloride-induced acute liver injuries, NR2E3 knockout (KO) mice exhibited far more severe liver injuries due to impaired DINO induction and p53 activation. Mechanistically, NR2E3 loss both *in vivo* and *in vitro* induced epigenetic DINO repression accompanied by reduced DINO chromatin accessibility. Furthermore, compared with the efficient reversal by a typical antidote N-acetylcysteine (NAC) treatment of APAP-induced liver injury in wild-type mice, the liver injury of NR2E3 KO mice was not effectively reversed, indicating that an intact NR2E3-DINO-p53-signaling axis is essential for NAC-mediated recovery against APAP-induced hepatotoxicity. These findings establish that NR2E3 is a critical component in p53 activation and a novel susceptibility factor to drug- or toxicant-induced acute liver injuries.

1911 Control Background Data Collection for Conducting General Toxicity Studies Using PXB-Mice

H. Jeong, A. Matsushita, M. Mishima, T. Yonemitsu, E. Morishige, Y. Sasaki, and H. Tsusaki. *Shin Nippon Biomedical Laboratories Ltd., Kagoshima, Japan.*

PXB-mice, immuno-deficient chimeric mice with humanized liver, have mostly been used in hepatitis-related efficacy studies. Recently, the number of PK and general toxicity studies using this model has increased, and the trend is expected to continue in the future. However, the background data of this model is limited; therefore, we collected data for examinations commonly conducted in general toxicity studies and compared them with male mice from other strains. In male PXB-mice housed at SNBL between 2018 and 2019, clinical signs (n=192, 14-49 weeks old), body weight (n=192, 14-21 weeks old), food consumption (n=16, 14-17 weeks old), ophthalmology (n=17, 28-44

weeks old), hematology, blood chemistry (n=21, 15-21 weeks old), necropsy (n=45, 15-49 weeks old), liver weight (n=23, 15-49 weeks old, liver only), and histopathology (n=6, 23-24 weeks old) data were collected and compared with our background data on male ICR (CD1), C57BL/J, and/or NOG mice. Human-ALT and human-albumin in PXB-mice plasma were also measured. Only the results that are specific to features of PXB-mice are described In clinical signs, of 192 animals, 24 animals (12%) were found dead or euthanized due to moribundity at 19-32 weeks old, and abdominal distension was observed in 15 of these 24 animals (62%). At necropsy of dead or euthanized animals, enlargement of the liver, spleen, and thymus and/or a black focus in the brain were observed in 8 animals. Low values in body weight and hematocrit (HCT), MCV, and MCH in hematology and high values in AST, ALT, ALP, potassium, total protein, albumin, and globulin in blood chemistry were noted. Human-ALT ranged from 5.8 to 24 ng/mL and human-albumin from 0.9 to 1.7 g/dL. In ophthalmology, corneal opacity was observed in 6 of 17 animals (35%), and this was accompanied by angiogenesis in 1 animal. At necropsy, liver weight of all animals was over 2-fold that in other strains. In histopathology, hypoplasia in the lymphoid organs and vacuolation in the hepatocytes were observed in all animals. Lymphoma was observed in 1 of 6 animals. Based on the above, many differences, mainly variations in liver related parameters and histopathological findings in immune-related organs, were observed in PXB-mice. The above mentioned information should be taken into consideration for toxicity evaluation when using PXB-mice as an animal model.

PS 1912 Exogenous Phosphatidic Acid Is a Novel and Widely Available Treatment for Acetaminophen Hepatotoxicity

M. M. Clemens[1], S. Kennon-McGill[1], J. H. Vazquez[1], S. S. McCullough[1], L. P. James[1], B. N. Finck[2], F. D. Allard[1], E. U. Yee[1], and M. R. McGill[1]. *[1]University of Arkansas for Medical Sciences, North Little Rock, AR; and [2]Washington University in St. Louis, St. Louis, MO.*

Acetaminophen (APAP) overdose causes severe liver injury through a mechanism involving metabolism, oxidative stress, and mitochondrial damage, while autophagy and regulatory Kupffer cells (KCs) are protective. We recently discovered that endogenous phosphatidic acid (PA) is increased in the liver after APAP overdose and enhances liver regeneration. PA is also available over-the-counter as a dietary supplement. Thus, we hypothesized that exogenous PA could be used as a readily available treatment for APAP hepatotoxicity. Mice were treated with APAP (250 mg/kg i.p.) at 0h, followed by either PA (20 mg/kg i.p.) or vehicle (i.p.) at 2, 6, 24, and 48h. Blood and liver tissue were harvested at 6, 24, and 52h. Some mice were pre-treated with liposomal clodronate to deplete KCs. APAP metabolism was assessed by liver glutathione and APAP-protein binding. Oxidative stress was assessed by oxidized glutathione. Mitochondrial damage was assessed by mitochondrial protein release. Other parameters were measured by immunoblotting. PA treatment reduced liver injury (serum ALT, histology), but did not affect regeneration (PCNA immunoblot). Surprisingly, there was no difference in APAP metabolism, oxidative stress, mitochondrial damage, JNK activation, or autophagy between Veh and PA-treated mice. Proteomics indicated the involvement of KCs. However, depletion of KCs did not affect the protection by PA. PA is a novel treatment for APAP hepatotoxicity that is immediately available. Exogenous PA treatment protects against acetaminophen toxicity through a novel mechanism. Further exploration of the mechanism may bring new insight into the well-studied pathophysiology of APAP-induced liver injury.

PS 1913 The Role of Secretory Phospholipase A2 (sPLA2) in Mediating the Progression of Injury in Acetaminophen-Induced Acute Liver Failure

N. M. Noor, and V. S. Bhave. *Philadelphia College of Osteopathic Medicine, Suwanee, GA.*

Acetaminophen (APAP) overdose is the leading cause of acute liver failure (ALF) in the United States with limited treatment options. APAP induced hepatotoxicity continues to progress even after the initial toxicant APAP has been eliminated from the body. Following APAP overdose, toxicity is initiated by conversion of APAP to its reactive metabolite N-acetyl-p-benzoquinone (NAPQI), which binds irreversibly to form NAPQI-protein adducts. This irreversible binding of NAPQI-protein adducts leads to hepatocellular necrosis. The focus of this study is to investigate the role of APAP induced ALF through the leakage of cytosolic enzymes and their interaction in recruitment of pro-inflammatory cytokines to the site of injury. We hypothesize that sPLA2 will mediate the progression of APAP induced ALF through the modulation of pro-inflammatory cytokines. Preliminary data from *in vivo* mice studies indicate that following injury there is higher levels of sPLA2 released in the extracellular matrix. We have also observed higher levels of pro-inflammatory cytokines in APAP overdose C57/BL6J mice. However, the mechanism by which the increased sPLA2 contributes to the progression of injury is not clear. Planned experiments aim to investigate the mechanism via which sPLA2 mediates progression of liver injury and whether induced sPLA2 modulates prostaglandins and cytokine pathways to mediate progression of injury. To test our hypothesis, we will dose the HepG2 cells with varying APAP. After treating the cells in a dose dependent manner, we will perform cytotoxicity assay over time course and quantify the cell viability. Then we will quantify the sPLA2 activity in these different experimental conditions from the collected supernatant. We will also test whether addition of sPLA2 to healthy hepatocytes leads to disruption of cell membrane integrity and necrosis. We expect that hepatotoxicity leads to increased sPLA2 activity, and the induced sPLA2 will continue the progression of damage in healthy hepatocytes even in absence of APAP. Via this approach, we can find a novel therapeutic approach to prevent the progression of injury following APAP overdose.

PS 1914 Mode-of-Action Studies for Flupyrsulfuron Methyl Demonstrate Nonhuman Relevance of Mouse Liver Tumors

L. Markell, D. Nabb, M. Battalora, and L. Malley. *FMC Corporation, Stine Research Center, Newark, DE.*

In an 18-month mouse study, increased incidences of hepatocellular adenomas were observed in males and females administered diet containing 2500 or 7000 ppm flupyrsulfuron methyl (FLP). Mode of action studies were conducted to determine if CAR/PXR nuclear receptor activation could be responsible for increased tumor incidence. In a 28-day feeding study to evaluate liver mechanistic parameters, FLP was administered to male and female mice at dietary concentrations of 0, 250, 2500, and 7000 ppm. Parameters included body weight, food consumption, clinical signs, liver weight, hepatic histopathology and cell proliferation, gene expression and enzyme activity for nuclear receptor mediated cytochrome P450. Additional groups were dosed with 1000 ppm of phenobarbital (PB), the positive control for CAR/PXR activation. In a second study, FLP was evaluated for the induction of replicative DNA synthesis (RDS) and expression of *CYP2B* and *CYP3A* in mouse and human hepatocytes *in vitro*. The RDS and gene expression assays were conducted as separate assays, and a corresponding ATP assay was conducted for each to assess the toxicity of FLP. The hepatocyte cultures were exposed for 96 hours to 0.16, 0.8, 4, 20, 100, 500, and 1000 µM FLP or to 100, 500, and 1000 µM PB. The positive controls epidermal growth factor (50 ng/mL- mouse) and hepatic growth factor (100 ng/mL- human) were used in the RDS assay. Exposure of mice to FLP resulted in increased liver weights, hepatocellular hypertrophy, and increased hepatocellular proliferation associated with an increase in mitotic figures at 2500 and 7000 ppm. These findings were of weaker magnitude compared to those observed in 1000 ppm PB mice. Liver changes occurred in association with induction of cytochrome P450 enzyme activities and gene expression consistent with the response seen with PB, albeit much weaker in pattern. In the *in vitro* hepatocyte cultures, FLP induced a statistically significant RDS response in mouse hepatocytes that was highest at 4 or 20 µM due to cytotoxicity at higher concentrations. *Cyp2b10* gene expression was induced at 1000 µM and *Cyp3a11* was induced at 500 and 1000 µM. FLP did not induce an RDS response in human hepatocytes at any concentration evaluated. FLP induced *CYP2B6* and *CYP3A4* in human hepatocytes at 100 µM. Cytotoxicity occurred at higher concentrations. The positive controls also fulfilled the requirements of a valid test. These data support the conclusion that the liver responses to FLP are modulated *via* the CAR nuclear receptor, a mechanism not relevant for tumor induction in humans.

PS 1916 Hepatotoxicity, Lipid Peroxidation, and Perturbation in Antioxidant Defense System Induced by Emamectin Benzoate and Acetamiprid Combination in Male Rats

F. M. El-Demerdash[1], A. B. Juber[1], H. M. Nasr[2], and N. H. Obaid[1]. *[1]Alexandria University, Alexandria, Egypt; and [2]Damanhour University, Damanhour, Egypt.* Sponsor: K. Osman

Pesticides are widely used in agriculture to maintain and increase crop yields, in addition to their use in homes and gardens. Exposure to pesticides is one of the major environmental health problems due to their potential adverse effects on non-target organisms. So, the current study aims to investigate the effect of emamectin benzoate and acetamiprid alone and in combination on lipid peroxidation, enzymatic and non-enzymatic antioxidants, liver functions biomarkers in male rats in addition to histological and immunohistochemical examination. Male Wister albino rats were divided randomly into four groups of seven each, group I used as control; group II treated with emamectin benzoate (EMB; 2.5 mg / kg BW), group III received acetamiprid (ACM; 30 mg/kg BW) and group IV treated with both EMB and ACM, respectively. Rats were

orally administered their respective doses every day for three weeks. The administration of EMB, ACM alone or in combination significantly increased lipid peroxidation (LPO) and reduced the activities of antioxidant enzymes (SOD, CAT, GPx, GR, GST), alkaline phosphatase (ALP), aminotransferases (AST, ALT) in addition to reduced glutathione and protein contents. While, lactate dehydrogenase (LDH) activity was significantly elevated. Histopathological and PCNA-immunoreactivity examinations confirmed the biochemical results and supported the detrimental effect of insecticides. Conclusively, it is clear that EMB and ACM induced pronounced hazardous effects in rat liver especially in the combination group where a synergistic effect was observed.

1917 Mitochondrial Morphology and Functional Alterations in Acetaminophen Hepatotoxicity

D. S. Umbaugh, A. Ramachandran, and H. Jaeschke. *University of Kansas Medical Center, Kansas City, KS.*

Generation of reactive oxygen species (ROS) and mitochondrial oxidant stress are hallmarks of acetaminophen (APAP) overdose, however, the temporal relationship between changes in mitochondrial function and morphology during APAP-induced hepatocyte necrosis has not been delineated. This is important since the crosstalk between mitochondrial morphology and organelle function is now recognized to modulate disease pathophysiology, and we have earlier demonstrated mitochondrial fragmentation after an APAP overdose. To determine the relationship between this change in morphology and mitochondrial function, we isolated mouse primary hepatocytes from 8-week-old C57Bl/6J mice and treated the cells with varying concentrations of APAP (1-10mM). Cells were then stained with Mitotracker Green to visualize mitochondrial morphology changes over time. Initially, isolated hepatocytes display a diverse array of elongated and rounded mitochondria forming a complex network throughout the cell. However, hepatocytes treated with 10 mM APAP undergo a dramatic change in mitochondrial morphology at 4 hr whereby many mitochondria become small and rounded with a "donut" appearance. These morphological changes correspond with a decrease in basal respiration, maximal respiratory capacity, and spare respiratory capacity which occurs prior to overt mitochondrial depolarization. By 9 hr hepatocytes treated with 10 mM APAP exhibit nearly ubiquitous round, donut mitochondria with elongated mitochondria being absent from most of the cells. This morphological phenotype corresponds with a further decrease in respiratory function and mitochondrial membrane potential. These morphological effects seem to be concentration dependent since hepatocytes treated with 1 mM or 2 mM APAP do not exhibit a change in mitochondrial shape. Interestingly, treatment with 5 mM APAP elicits a delayed change in mitochondria morphology, where the donut shaped mitochondria appear ubiquitously by 9 hr. Collectively, this data highlights the complex interplay between mitochondrial morphology and function during APAP-induced hepatocyte toxicity.

1918 Fibrinogen Engagement of Leukocyte β_2 Integrins Balances Monocyte/Neutrophil Accumulation to Inhibit Acetaminophen-Induced Liver Injury

L. G. Poole[1], A. K. Kopec[1], H. M. Cline-Fedewa[1], R. Nault[1], T. R. Zacharewski[1], M. J. Flick[2], and J. P. Luyendyk[1]. *[1]Michigan State University, East Lansing, MI; and [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Leukocytes play a multifactorial role in the injured liver following acetaminophen (APAP) overdose. Specific subsets of leukocytes exacerbate hepatotoxicity while others mediate liver repair. The balance of these activities is controlled in part by the blood clotting protein fibrin(ogen). Prior studies document that fibrin(ogen) engagement of leukocyte β_2 integrins inhibits liver necrosis and promotes repair after APAP overdose. Whether that outcome is a product of altered leukocyte recruitment or impaired local effector function remains unknown. We hypothesized that monocytes recruited to the injured liver are driven to a pro-repair phenotype by fibrinogen-β_2 integrin engagement. Male mice expressing a mutant fibrinogen incapable of engaging β_2 integrins (Fib$\gamma^{390-396a}$ mice) and wild-type mice were challenged with a hepatotoxic dose of APAP (300 mg/kg, i.p.). Hepatic leukocyte populations were quantified by flow cytometry 24 hours later. As expected, hepatic necrosis was increased in APAP-challenged Fib$\gamma^{390-396a}$ mice compared to APAP-challenged wild-type mice. In wild-type mice, there was a dramatic accumulation of monocytes (CD11b+/Ly6G-/Ly6C+) in the injured liver, comprising ~28% of total immune cells compared to ~3% in vehicle-treated mice. Interestingly, hepatic monocytes were reduced in livers of APAP-challenged Fib$\gamma^{390-396a}$ mice. The percentage of monocyte-derived macrophages (CD11b+/Ly6G-/Ly6C-low/F480+/CX3CR1+), which have a pro-repair function in the APAP-injured liver, was also reduced in APAP-challenged Fib$\gamma^{390-396a}$ mice. Unexpectedly, we observed a dramatic increase in hepatic neutrophils (CD11b+/Ly6G+) in APAP-challenged Fib$\gamma^{390-396a}$ mice. Analysis of whole-liver RNA sequencing revealed an imbalance in hepatic chemokine expression, confirmed by qRT-PCR, including diminished induction of monocyte chemokine *Ccl2* and exaggerated expression of the neutrophil chemokine *Cxcl2* in APAP-challenged Fib$\gamma^{390-396a}$ mice. The results indicate that fibrin(ogen)-β_2 integrin engagement plays a critical role in regulating chemokine expression driving leukocyte accumulation in the APAP-injured liver. The absence of fibrin(ogen)-β_2 integrin engagement causes imbalanced leukocyte accumulation disabling liver repair and exacerbating hepatotoxicity.

1919 Omega 3- Fatty Acids and Vitamin E Protect against Diazinon-Induced Oxidative Injury and Biochemical Perturbations in Rat Liver

H. M. Nasr[1], and F. M. El-Demerdash[2]. *[1]Damanhour University, Damanhour, Egypt; and [2]Alexandria University, Alexandria, Egypt.* Sponsor: K. Osman

This study was designed to investigate the possibility of diazinon to induce oxidative stress and biochemical changes in rat liver and the role of Omega 3- fatty acids and Vitamin E in alleviating their toxic effects. Male Wister albino rats were divided randomly into six groups of seven each, group I used as control; group II treated with omega 3- fatty acid (ω3FA; 200 µg/kg BW), group III received vitamin E (VE; 100 mg/kg BW), group IV treated diazinon (DZN; 15 mg/kg BW), group V treated with both ω3FA and DZN while group VI was treated with VE plus DZN. Rats were orally administered their respective doses daily for 30 days. Results revealed that the administration of DZN caused elevation in lipid peroxidation (LPO) and reduction in enzymatic antioxidant activities including catalase (CAT), superoxide dismutase (SOD), glutathione *S*-transferase (GST), glutathione peroxidase (GPx) and glutathione reductase (GR). Also, a decrease in reduced glutathione (GSH) content were also observed. Liver aminotransferases (AST and ALT) and alkaline phosphatase (ALP) were decreased, while lactate dehydrogenase (LDH) was increased. Conclusively, it is clear that DZN -induced oxidative damage in rat liver while ω3FA and VE had powerful effects to protect against DZN induced hepatotoxicity and modulated most of the studied parameters near normal level, and the effect of ω3FA is more pronounced than VE.

1920 Ochratoxin A Induces Hepatic Fibrosis through TGF-β/Smad2/3 Signaling Pathway

K. Lee. *Korea University, Seoul, Korea, Republic of.*

Ochratoxin A (OTA) is a mycotoxin produced by species of *Aspergillus* and *Penicillium*. It is often formed in cereals under high temperatures and humid conditions. In this study, we assumed that OTA causes epithelial-mesenchymal transition (EMT) leading to liver fibrosis. In this study, we investigated that the TGF-β1/Smad2/3 signaling pathway is involved in EMT-induced liver fibrosis. In our *in vitro* and *in vivo* experiments, the mRNA and protein expression of major liver fibrosis markers such as fibronectin, α-SMA, and E-cadherin were measured. Additionally, ALP, ALT, AST, and bilirubin for liver damage were measured. We confirmed the increased mRNA and protein expression of TGF-β1, Smad2, and Smad3. After the expression of Smad2 and Smad3 was knockdown by siRNA, the expression of the liver fibrosis-related markers was inhibited. The liver cells exposed to OTA enhanced TGF-β1 receptor expression on the cell membrane. Then, in the cytoplasm, Smad2 and Smad3 are phosphorylated and translocated to the nucleus, which could contribute to fibrosis due to EMT. These results can provide the basis for the treatment and prevention against OTA-induced hepatic fibrosis.

1921 Late Protective Effect of Netrin-1 in the Murine Acetaminophen Hepatotoxicity Model

L. Duan, A. Ramachandran, B. L. Woolbright, J. Akakpo, and H. Jaeschke. *University of Kansas Medical Center, Kansas City, KS.*

Acetaminophen (APAP) hepatotoxicity is the leading cause of acute liver failure in the United States and the current antidote for APAP overdose is administration of N-acetylcysteine (NAC), which facilitates scavenging of the reactive APAP-metabolite NAPQI and reactive oxygen species. However, NAC has a short early therapeutic window and novel therapeutic intervention strategies are needed for patients who typically present late to the hospital. This is relevant, since the recovery and regeneration capacity of the liver, which typically occurs late after injury, plays a critical role in patient survival after an APAP overdose. Netrin-1 is a laminin-related protein and recent work has

demonstrated that netrin-1 promotes hepatic repair and regeneration during liver ischemia/reperfusion injury. The role of Netrin-1 in acetaminophen hepatotoxicity is unknown and this study evaluated this *in vivo* in a mouse model of APAP overdose. Male C57BL/6J mice were co-treated with exogenous netrin-1 or vehicle control, along with 300mg/kg APAP and euthanized at 6h and 24h. While netrin-1 administration did not influence ALT levels or area of necrosis at the 6h time point. However by 24h, netrin-1 treated animals showed significant attenuation of liver injury as seen by ALT levels and area of necrosis. This protection was accompanied by significant elevations in mRNA and protein level of the adenosine A2B receptor (A2BAR), one of the netrin-1 receptors. Exogenous netrin-1 also promoted infiltration of F4/80 positive macrophages toward areas of necrosis and promoted liver regeneration by 24h. Treatment with the A2BAR antagonist PSB 1115 negated the protective effects of netrin-1, including the enhanced macrophage infiltration and liver regeneration indicating that netrin-1 protection was mediated through the A2BAR. Removal of resident Kupffer cells with clodronate liposomes also prevented the netrin-1 induced increase in liver macrophages and liver regeneration and removed protection against liver injury. In conclusion, our data indicate a previously unrecognized role for netrin-1 in attenuation of APAP hepatotoxicity, which could be mediated by promoting macrophage migration and liver regeneration through the A2BAR.

1922 Mitochondrial Protein Adduct and Superoxide Generation Are Prerequisites for Early Activation of c-Jun N-terminal Kinase within the Cytosol after an Acetaminophen Overdose in Mice

N. T. Nguyen, A. Ramachandran, K. Du, J. Akakpo, and H. Jaeschke. *University of Kansas Medical Center, Kansas City, KS.*

Acetaminophen (APAP) overdose is the most common cause of acute liver failure in the United States and formation of the reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI) is critical for initiating APAP-induced liver injury. Though formation of mitochondrial NAPQI-protein adducts, mitochondrial oxidant stress and activation of the MAP kinase c-jun N-terminal kinase (JNK) have been shown to be critical for APAP-induced cell death, direct evidence for a requirement of mitochondrial adduct formation for the initiation of JNK activation in the cytosol is lacking. We examined mitochondrial protein adduct levels by measuring protein-derived APAP-cysteine by HPLC and JNK activation by Western blotting at very early time points after treatment with 300 mg/kg APAP. The role of oxidant stress in this process was assessed by *in vitro* and *in vivo* experiments. Measurement of mitochondrial protein adducts in C57Bl/6J mice treated with 300mg/kg APAP indicated detectable levels of protein adducts (0.05-0.1 nmol/mg protein) by 15 and 30 min after APAP. After >90% depletion of hepatic GSH levels at 30 min, there was a selective increase (>500%) of mitochondrial protein adducts between 30 and 60 min. However, activation of the MAP kinase JNK in the cytosol was only evident at 60 min, suggesting that mitochondrial protein adduct formation was required for the initial JNK activation. To further confirm the role of oxidant stress exclusively within the mitochondria for cytosolic JNK activation, experiments were repeated after a 1h pre-treatment of mice with either Mito-TEMPO (which scavenges superoxide within mitochondria) or TEMPO (which scavenges superoxide in the cytosol only). Interestingly, both treatments showed significant attenuation of JNK phosphorylation in the cytosol at 60 min after APAP. *In vitro* experiments using primary mouse hepatocytes treated with 10mM APAP showed early superoxide formation from mitochondria by 30 minutes. Our studies provide direct evidence that the early mitochondrial superoxide formation caused by NAPQI-protein adducts within the organelle is a critical requirement for activation of the MAP kinase cascade resulting in the initial JNK phosphorylation in the cytosol and translocation to the mitochondria.

1923 Activation of p62-keap1-Nrf2 Antioxidant Pathway by Rutaecarpine in the Early Stage of Acetaminophen-Induced Acute Liver Injury in Mice

J. Choi, S. Jin, G. Lee, and H. Jeong. *Chungnam National University, Daejeon, Korea, Republic of.*

Rutaecarpine, an indolopyridoquinazolinone alkaloid isolated from the unripe fruit of *Evodia rutaecarpa*, have been used the abdominal pain, amenorrhea, dysentery, headache, hypertension, and postpartum hemorrhage for traditional oriental medicine in East Asia. However, the inhibitory effect of rutaecarpine on p62-keap1-Nrf2 antioxidant pathway in acetaminophen (APAP)-induced hepatotoxicity remains unknown. This study investigated the regulatory effect of rutaecarpine action to attenuate acetaminophen-induced hepatotoxicity in mice. Rutaecarpine significantly decreased the APAP-induced serum ALT/AST activities and hepatic malondialdehyde content, while rutaecarpine prevented hepatic glutathione depletion by APAP. Furthermore, CYP2E1 expression was decreased by rutaecarpine treatment in a dose-dependent manner. Rutaecarpine treatment attenuated the APAP-induced inflammatory cytokines mRNA expression and production through inhibition of NF-κB activation. Also, rutaecarpine promoted activation of Nrf2-mediated target anti-oxidant enzymes, GCLC, HO-1, and NQO1, via APAP-induced Keap1 degradation. Interestingly, rutaecarpine treatment increased the APAP-induced elevation of LC3 I to LC3 II and the degradation of p62, which attenuated acetaminophen-induced JNK1/2 activation. These findings proved perspectives that protective effect of rutaecarpine on acetaminophen-induced acute liver injuries via activation of antioxidant enzymes and autophagy. Therefore, rutaecarpine could be a useful therapeutic agent for the discovery of new chemotherapeutic agents that may contribute to protecting the liver injury by hepatotoxicants.

1924 Effect of the Organophosphorus Pesticide Temephos on Hepatic Function

A. Hernández-Esteris, F. A. Verdín-Betancourt, A. Reyes-Chaparro, M. L. López-González, A. K. Pantaleón-Gómez, I. Camacho-Hernández, B. Quintanilla-Vega, and A. Sierra-Santoyo. *Cinvestav, Mexico City, Mexico.*

Temephos (Tem) is the larvicide of choice to control virus-transmitting vectors, such as dengue, zika, and chikungunya. Tem is considered a low toxicity pesticide by acute exposures. The toxicological information about Tem is limited. The aim of this study was to evaluate the effect of repeated doses of Tem on liver function and its metabolism. Male adult Wistar rats were orally administered with Tem at the dose of 100 mg/kg/d for 7 d emulsified in saline solution and euthanized 1-hour after the last dose. Blood was obtained by cardiac puncture and the liver was removed. Serum was used for the determination of bilirubin, enzyme activities of alanine aminotransferase (ALT), aspartate transaminase (AST), and γ-glutamyl transpeptidase (γ-GTP), and for the analysis of Tem and its metabolites by HPLC-DAD. Tem exposure resulted in a decrease in the weight of the animals from the fourth dose, which led to the death of 41% of the animals, as well as a significant decrease in the relative weight of the liver and serum levels of total lipids, triglycerides, and very low-density cholesterol. Conversely, serum levels of direct, indirect, and total bilirubin significantly increased. At least eight metabolites in extracts of liver were detected, among them Tem-sulfoxide, Tem-oxon, Tem-oxon-sulfoxide, Tem-dioxon-sulfone, Tem-oxon-sulfoxide-mono-hydrolyzed, 4,4´-thiodiphenol, 4,4´-sulfinyldiphenol, and 4,4´-sulfonyldiphenol or bisphenol S (BPS). No significant effect on hepatic total cytochrome P450 levels was observed but in an *in vitro* enzymatic assay using Tem-treated rat liver microsomes, a different profile of Tem metabolites was observed, compared to control microsomes, which indicates that Tem affects its own metabolism. Serum enzyme activities of ALT, AST, and γ-GTP were not altered. These results suggest that the liver is a target organ of Tem since it alters the balance of lipids and the metabolism of endogenous and exogenous compounds. In addition, these data contribute to the toxicological characterization of this pesticide widely used in tropical countries.

1925 Evaluation of Hepatic and Renal Effects of Acute and Subacute Oral Exposure to Bromochloromethane (BCM) in Rats

Y. M. Sey[1], T. Willoughby[2], M. Armstrong[3], A. McDonald[1], and J. Simmons[1]. *[1]US EPA, Research Triangle Park, NC; [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [3]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

BCM is a volatile organic compound that has been used as a fire extinguishing agent as well as an intermediate in the production of solvents. BCM is on EPA's Candidate Contaminant List 4 and is identified as a water disinfection byproduct (DBP). It is a structural analogue to chloroform (CHCl3) and bromodichloromethane (BDCM), DBPs that have been shown to be hepatotoxic and/or nephrotoxic in animal studies. There are limited data on the hepatic and renal effects associated with acute and subacute exposure to BCM. In the current study, male and female Fischer 344 rats received a single dose of 1000 mg/kg body weight BCM by oral gavage in 10% Alkamuls aqueous vehicle at 5 ml/kg gavage volume to assess toxicity over 48 hours. Additional sets of each gender were gavaged daily for 10 consecutive days to assess hepatic and renal effects. A single 1000 mg/kg BCM exposure did not affect body, relative liver and kidney weights in either gender at 24 or 48 hr post exposure. Serum markers of liver damage were not affected at 24 hr in either gender; however, by 48 hr glucose, albumin and total protein were significantly decreased in males. No liver histological damage was evident in either gender at 24 or 48 hr. In females, urinary markers of kidney damage, alkaline phosphatase (ALP), gamma glutamyl transferase (GGT) and aspartate aminotransferase were slightly but significantly increased at earlier time points but

had returned to control values by 48 hr. ALP and GGT changes were sustained over 48 hr in males. Subacute exposure at 1000 mg/kg BCM resulted in unexpected (reported oral LD50 = 5000 mg/kg) high mortality in both genders with the study terminated by day 3. Exposure to 750 mg/kg BCM daily for 10 consecutive days did not affect body, relative liver and kidney weights in either gender. No significant increases in serum markers of liver damage were apparent in either gender which was confirmed histologically. While urinary protein increased significantly in females and disrupted the diurnal cycle of GGT observed in control male rats, subacute exposure to BCM did not result in histologic renal damage. This study indicates that BCM is less overtly toxic to rat liver and kidney than its structural analogues CHCl3 and BDCM. *This abstract does not reflect US EPA policy.*

1926 Deletion of Hepatic Yap Impairs Car-Driven Hepatocyte Proliferation without Altering Induction of Drug Metabolism Genes in Mice

B. Bhushan, and G. K. Michalopoulos. *University of Pittsburgh, Pittsburgh, PA.*

Constitutive androstane receptor (CAR) is known to be activated by several clinically used drugs, environmental pollutants and other exogenous compounds. CAR agonists, such as TCPOBOP, are known to cause robust hepatocyte proliferation and hepatomegaly in mice along with induction of drug metabolism genes, without any associated liver injury. Yes-associated protein (YAP) is a key transcription regulator that tightly controls organ size including that of liver. Ours and other previous studies suggested increased nuclear localization and activation of YAP after TCPOBOP treatment in mice and potential role of YAP in CAR-driven proliferative response. Here, we investigated a direct role of YAP in CAR-driven hepatomegaly and hepatocyte proliferation using hepatocyte-specific YAP KO mice. AAV8-TBG-CRE vector was injected to YAP-floxed mice for achieving hepatocyte-specific YAP deletion followed by TCPOBOP treatment. YAP deletion did not alter protein expression of CAR or CAR-driven induction of drug metabolism genes (including Cyp2b10, Cyp2c55 and UGT1a1). However, YAP deletion significantly reduced TCPOBOP-induced hepatomegaly and more remarkably hepatocyte proliferation. TCPOBOP-driven cell cycle activation was disrupted in YAP-KO mice due to delayed (and decreased) induction of cyclin D1 and higher expression of p21, resulting in decreased phosphorylation of retinoblastoma (Rb) protein. Further, induction of other cyclins, which are sequentially involved in progression through cell cycle (including cyclin E1, A2 and B1) and important mitotic regulators (such as aurora B kinase and polo-like kinase 1) was remarkably reduced in YAP KO mice. Microarray analysis revealed that 26% of TCPOBOP-responsive genes mainly related to proliferation, but not to drug metabolism, were altered by YAP deletion. YAP regulated these proliferation genes via alerting expression of cMyc and FOXM1, two critical transcriptional regulators of CAR-mediated hepatocyte proliferation. Our study revealed an important role of YAP signaling in CAR-driven hepatocyte proliferation; however, CAR-driven induction of drug metabolism genes was independent of YAP.

1927 The Role of Bromodomain and Extra-Terminal (BET) Proteins on APAP-Induced Hepatotoxicity

S. M. Smith[1], S. Toro[2], R. Xue[2], A. C. Donepudi[2], M. Singh[2], G. Sartor[2], and J. Manautou[2]. *[1]College of St. Scholastica, Duluth, MN; and [2]University of Connecticut, Storrs, CT.*

Acetaminophen (APAP)-induced liver injury is a well-known model used to investigate genetic determinants of susceptibility to drug-induced liver injury (DILI) and acute liver failure. Antioxidant gene regulated by Kelch-like ECH-associated protein 1 (KEAP1)-nuclear factor, erythroid 2-like 2 (NRF2) pathway plays an important role in hepatoprotection against APAP-induced hepatotoxicity and oxidative stress. Recent studies have shown that bromodomain-containing protein 4 (BRD4), a bromodomain and extra-terminal motif (BET) protein, is a novel epigenetic regulator of KEAP1-NRF2 pathway. Inhibition of BRD4 using BET inhibitors was shown to upregulate antioxidant gene expression and protect against oxidative stress. Interestingly, the role of BET protein in DILI and acute liver failure is not well-studied. This study aims to understand these specific roles of BET protein using APAP-induced hepatotoxicity as a model. In this study, we used chemical inhibition and gene knock-down techniques to characterize the role of BET proteins against APAP-induced cytotoxicity using the immortalized mammalian cell lines HCO4 cells. Our results show that APAP treatment decreased BRD3 and 4 expression in HC-04 cells in a dose-dependent manner. Cytotoxicity analysis using LDH leakage assay showed that pretreatment of HC-04 cells with JQ1 before APAP administration significantly decreased APAP-induced cytotoxicity. Additionally, knockdown of BRD3 and 4 using siRNA transfections, protected against APAP-induced cytotoxicity. Moreover, gene expression analysis showed that inhibition of BET proteins upregulates the expression of genes involved in APAP detoxification pathways. In summary, our studies suggest that inhibition of BET proteins may confer protection against APAP-induced hepatotoxicity by upregulating genes involved in APAP detoxification pathways.

1928 Expression of Selective Autophagy Markers in Preneoplastic Liver Foci in High Fat Diet-Fed, Streptozotocin-Treated Rats

T. Yoshida, R. Ichikawa, and M. Shibutani. *Tokyo University of Agriculture and Technology, Fuchu, Japan.*

Patients with nonalcoholic fatty liver disease (NAFLD) can be at risk for nonalcoholic steatohepatitis, which can lead to hepatocellular carcinoma. Autophagy protects against pathophysiological changes including steatosis and cancer. We determined the expression of selective autophagy markers in preneoplastic hepatic lesions and the effects of an autophagy inducer carbamazepine (CBZ) in a steatosis and diabetes mellitus-related early hepatocarcinogenesis model. Male F344 rats were fed a basal diet (BD) or high fat diet (HFD), and subjected to initiation and promotion steps with N-nitrosodiethylamine injection at week 0 and a partial hepatectomy at week 3. Several BD- or HFD-fed rats were received 30 mg/kg streptozotocin (STZ) at week 2. Some STZ-treated, HFD-fed rats were administered 200 mg/kg CBZ during week 7 and 8. STZ-treated rats developed diabetes mellitus, decreased body weight gain, and increased NAFLD score. STZ-treated, HFD-fed rats increased the area of glutathione S-transferase placental form-positive preneoplastic liver foci in the liver. CBZ tended to decrease STZ/HFD-increased preneoplastic foci and their Ki-67 labeling indices. An autophagosome marker LC3 and the LC3-binding protein p62 were heterogeneously expressed in the preneoplastic foci. CBZ might induce autophagy by significantly increased LC3 and decreased p62 in preneoplastic foci, in association with decreased expression of autophagy related genes, Atg5, Atg 6, Atg7, Lamp1, and Lamp 2. These results suggest that selective autophagy markers were specifically expressed in preneoplastic liver foci, and CBZ might decrease steatosis/diabetes-related early hepatocarcinogenesis by potentially inducing autophagy in STZ-treated, HFD-fed rats.

1929 Identification of Hepatocyte-Derived Exosome Biomarkers to Predict Idiosyncratic Drug-Induced Liver Injury

N. Vachharajani[1], R. J. Church[1], S. E. Thacker[1], K. A. Rose[1], M. Otieno[2], P. B. Watkins[1], and M. Mosedale[1]. *[1]University of North Carolina at Chapel Hill Institute for Drug Safety Sciences, Chapel Hill, NC; and [2]Janssen Research & Development, Spring House, PA.*

We have previously demonstrated alterations in hepatocyte-derived exosomes (HDEs) prior to and in the absence of overt necrosis associated with idiosyncratic drug-induced liver injury (IDILI). HDEs contain miRNAs and proteins which may possess value in the form of sensitive and specific biomarkers for IDILI liability. The objective of this project was to identify HDE-based biomarkers of IDILI by profiling protein and miRNA changes in primary human hepatocytes exposed to subtoxic and toxic concentrations of IDILI compounds. Primary human hepatocytes were treated with increasing concentrations of 6 compounds known to elicit either idiosyncratic (tolcapone, isoniazid, or bosetan) or intrinsic (rotenone, acetaminophen and ethinyl estradiol) DILI via relevant cellular mechanisms. Subtoxic and toxic concentrations of each compound were selected from dose response curves and used for treatments in N=5 hepatocyte donors. After a 24 h exposure, HDEs were enriched from culture medium by ultracentrifugation, and changes in exosomal protein and miRNA were assessed using global profiling approaches. Significance was determined by an ANOVA model with linear contrasts between each compound concentration and DMSO control ($p<0.05$ and $|\text{fold change}| > 1.5$). Three proteins were significantly changed in response to both concentrations of all IDILI compounds: compliment factor 1 (decreased), inter-alpha-trypsin inhibitor heavy chain 1 (decreased), and vasolin containing protein (increased). All 3 proteins were readily quantifiable in HDEs by ELISA. Four miRNAs were significantly changed in response to the both concentrations of all IDILI compounds: miR-1244, miR-297, miR-548j-3p, and miR-576-3p (all decreased). Only miR-297 was detectable in reasonable sample quantities by qPCR in HDEs. In conclusion, we have identified 4 biomarkers of IDILI in HDEs which we are currently validating in studies with additional donors and eventually additional compounds. The findings of this study are novel as several of the candidate biomarkers have not been previously reported in HDE and/or to be altered in response to IDILI. Importantly, the HDE-based candidate biomarkers identified in this study may be utilized to refine existing *in vitro* assays for improving IDILI predictions.

1930 Vinyl Chloride Impacts Mitochondrial Dynamics and ER-Mitochondria Communication in Mice

R. D. Schnegelberger[1], L. C. Timar[1], A. L. Lang[2], L. Chen[2], G. E. Arteel[1], M. C. Cave[2], and J. I. Beier[1]. *[1]University of Pittsburgh, Pittsburgh, PA; and [2]University of Louisville, Louisville, KY.*

Vinyl chloride (VC), a common environmental pollutant, directly causing liver injury at high exposure levels. Importantly, we have shown that lower concentrations (i.e., < OSHA limits), which do not overtly damage the liver, enhance injury caused by high fat diet (HFD), at least in part, via mitochondrial dysfunction and ER stress. It has been shown that mitochondrial function and ER stress may be interconnected via ER-mitochondria interactions. These contact sites are sensitive to (patho)physiological conditions and maladaptive changes in this interaction have been associated with mitochondrial dysfunction. The purpose of the current study was to investigate the mechanistic impact of VC on ER-mitochondria interactions. C57Bl/6J mice were exposed to VC below the current OSHA standard (<1 ppm), or room air for 6 hrs/d, 5 d/wk for up to 12 wks. Mice were fed HFD, or low-fat control diet (LFD). Some mice received Alda-1 (20 mg/kg i.p., 3×/wk) for the last 3 weeks of diet/VC. Plasma and liver samples were collected for determination of injury and mitochondria were isolated for analysis of mitochondrial (dys)function. VC exposure exacerbated liver injury caused by HFD, reflected in increased transaminases, oxidative stress, and ER stress. VC exposure also dysregulated energy homeostasis and impaired mitochondrial function - even in the absence of HFD. Evidence for impaired mitochondrial function included dramatic structural changes to the mitochondria, impaired hepatic mitochondrial electron transport chain function and a decrease in maximum mitochondrial respiratory capacity, while fatty acid oxidation and mitochondrial DNA content were unaffected. VC also changed hepatic protein levels of several mitochondrial associated ER membrane (MAMs) proteins, which are involved in mitochondrial function, and quality control of ER-mitochondrial crosstalk, such as regulation of ER-mitochondrial calcium flux. Interestingly, mitochondrial dysfunction and changes to ER-mitochondria interactions, caused by VC and HFD, were diminished by ALDH2 allosteric activator, Alda-1. These results suggest a 'targeted' attack of mitochondrial function by VC, rather than overall nonspecific mitotoxicity. Taken together, VC dysregulates mitochondrial function/dynamics, ER stress and their interaction. These stress responses therefore play a causative role in VC-mediated liver toxicity and sensitization to other stressors (e.g. HFD). Importantly, these data raise concerns about potential overlap between diet and VC and emphasize that current safety restrictions may be insufficient to account for other factors that can influence hepatotoxicity in humans.

1931 Hepatotoxic Response in 2D and 3D Co-culture Models Differs from Hepatocyte-Alone Models

A. Stern, K. Marino, T. Beames, A. Stefanowicz, M. Black, P. McMullen, S. Slattery, and J. Hartman. *ScitoVation, Morrisville, NC.*

It has become more widely accepted in both the regulatory and commercial fields that moving away from in-life rodent studies and toward testing species-relevant cells *in vitro* will provide alternative safety assessment strategies that are budget-conscious and alleviate ethical considerations. The liver has been a major focus of these efforts, yet there are currently no *in vitro* alternatives for hepatotoxicity testing accepted by regulators. An ideal *in vitro* liver model for hepatotoxicity testing would include hepatocytes and the non-parenchymal cells (NPCs) (ie. hepatic stellate cells, Kupffer cells, and liver sinusoidal endothelial cells), and would support hepatocyte viability, phenotypic maintenance, and metabolic competence for an extended time in culture to allow for repeated exposures and long-term dosing. The current studies have focused on developing organotypic two-dimensional 96-well plate-based and three-dimensional alginate bead-based culture systems that include primary rat hepatocytes and NPCs and can support hepatocyte viability *in vitro* out to eight days in 2D and 28 days in 3D. Using several canonical hepatotoxicants, we have compared 2D and 3D hepatocyte-alone (mono-) and hepatocyte and NPC (co-) culture systems to determine the robustness of these models. After treatment with acetaminophen (APAP; 5mM, 10mM, 20mM) for 3 consecutive days, APAP-induced cytotoxicity was significantly mitigated in the co-culture model, compared to the mono-culture model. In addition, APAP-induced CYP expression was lower in the co-culture model compared to mono-culture. Transcriptomic analysis of 2D mono- and co-culture models revealed that co-culture response to phenobarbital (10uM) is more representative (32% increase in similarity of the ontology enrichment) of *in vivo* responses (using OPEN TG_GATEs *in vivo* data, 300mg/kg, 24h). Similar to 2D models, after 10 days of repeat dosing with phenobarbital (25uM-400uM) relative cytotoxicity is diminished in 3D co-culture models compared to mono-culture. These studies have demonstrated that the organotypic model can recapitulate rodent *in vivo* liver phenotypes observed in response to canonical hepatotoxicants and suggest that the co-culture model could be useful for testing the effects of compounds *in vitro* as an early stage alternative to in-life studies.

1932 Co-administration of the Cannabidiol-Rich Cannabis Extract and Acetaminophen Leads to Severe Liver Injury in Mice

L. Ewing[1], C. Skinner[1,2], C. M. Quick[1], E. Yee[1], M. Clemens[1], S. Kennon-McGill[1], M. McGill[1], L. Walker[3], M. ElSohly[3], B. J. Gurley[3], and I. Koturbash[1,2]. *[1]University of Arkansas for Medical Sciences, Little Rock, AR; [2]Center for Dietary Supplements Research, Little Rock, AR; and [3]University of Mississippi, Oxford, MS.*

The goal of this study was to investigate the potential for a cannabidiol-rich cannabis extract (CRCE) to interact with the most common over-the-counter drug and the major known cause of drug-induced liver injury – acetaminophen (APAP) – in aged female CD-1 and young C57BL6/J mice. Gavaging with 116 mg/kg of cannabidiol (CBD) [mouse equivalent dose (MED) of 10 mg/kg of CBD] in CRCE delivered with sesame oil for three consecutive days followed by i.p. acetaminophen (APAP) administration (400 mg/kg) on day 4 resulted in overt toxicity with 37.5% mortality in CD-1 mice. No mortality was observed in CD-1 mice treated with 290 mg/kg of CBD+APAP (MED of 25 mg/kg of CBD) or APAP alone. In C57BL/6J mice, 8% mortality was observed in 290 mg/kg dose. Following CRCE/APAP co-administration, microscopic examination revealed a sinusoidal obstruction syndrome-like liver injury in CD-1 mice and pan-necrosis in both CD-1 and C57BL6/J mice. The severity of both correlated with the degree of alterations in physiological and clinical biochemistry end points. Mechanistically, glutathione depletion and oxidative stress were observed in the APAP-only and co-administration groups, but co-administration resulted in much greater activation of c-Jun N-terminal kinase (JNK) in both mouse strains. These findings highlight the potential for CBD/drug interactions, and warrant further research needed to understand safety profile of CBD.

1933 Temporal Course of JNK Activation after an APAP Overdose

A. Ramachandran, D. Umbaugh, and H. Jaeschke. *University of Kansas Medical Center, Kansas City, KS.*

Mitochondrial oxidant stress, activation of c-Jun N-terminal kinase (JNK) and its translocation to the mitochondria are recognized to be important early steps in acetaminophen (APAP)-induced hepatotoxicity. APAP-induced hepatocyte necrosis is initiated in cells around the central vein and radiates outward, with surviving cells at the border of the necrotic area initiating a regenerative response to ultimately re-populate areas of necrosis. While early JNK activation and its role in amplification of APAP induced mitochondrial damage is well characterized, its relevance in the later events, is not well understood. To examine activation, translocation and persistence of JNK on mitochondria after an APAP overdose, C57BL/6J mice were treated with 300mg/kg APAP followed by sacrifice at 2, 6, 12 or 24h later and liver injury assessed by measurement of plasma ALT levels and liver histology. Liver mitochondria and cytosol were separated by subcellular fractionation, followed by western blotting for total as well as activated phospho-JNK. Robust JNK activation in the cytosol and translocation to mitochondria was evident within 2h after APAP, which persists until 6h. However, by 12 and 24h, phospho-JNK was not detectable in either cytosol or mitochondria, which had only minimal amounts of inactive JNK protein. The spatiotemporal changes in activated phospho-JNK levels were then examined in liver sections and intense JNK activation was evident in centrilobular cells within 2h after APAP overdose, which persisted in cells surrounding the necrotic area by 6h. However, phospho-JNK expression had disappeared by 12 and 24h after APAP at which time we have earlier shown that mitochondrial biogenesis is initiated in cells bordering areas of necrosis. To explore mechanisms behind the transient nature of JNK activation, the temporal expression of mitogen-activated protein kinase phosphatase-1 (MKP-1), which is a negative regulator of JNK and has been implicated in APAP hepatotoxicity was examined. MKP1 protein levels were found to be elevated beginning at 6h and peaking at 12h after APAP, which paralleled the decrease in activated JNK indicating that dephosphorylation of JNK by MKP1 could be contributing to the transient JNK activation. In conclusion, these results suggest that the transient nature of JNK activation is probably relevant to progression of the necrotic area after APAP and delayed activation of MKP-1 helps in modulating this process.

1934 Gene Expression Regulation by mTOR Complexes I and II in the Mouse Liver

A. A. Poluyanoff, J. McGaunn, V. R. Salemme, A. Khalil, and A. Suvorov. *University of Massachusetts Amherst, Amherst, MA.*

The mechanistic target of rapamycin (mTOR) is a key serine/threonine protein kinase that functions in complexes mTORC1 and mTORC2. mTORC1, originally discovered due to its sensitivity towards the mTOR inhibitor rapamycin, responds to extracellular growth factor signaling, nutrient abundance, and variety of stress signals. Downstream effects of mTORC1 signaling consist in the regulation of the balance between anabolism and catabolism, including regulation of autophagy, mitochondrial metabolic function, protein synthesis, and ribosome biogenesis. mTORC2, initially discovered as a rapamycin-insensitive complex of mTOR, responds to insulin, growth factor signaling, and inflammatory signaling such as tumor necrosis factor-alpha, with its downstream effectors being Akt, a key serine/threonine kinase that functions in cell division, the NFkB pathway, and cytoskeletal reorganization and protein synthesis. Ability of mTOR pathway to integrate variety of stress (ROS, UPR, hypoxia) and nutrient signals (amino-acids, glucose, lipids, insulin) and convert them into downstream regulation of metabolism makes it central to the regulation of liver physiology. Little is known however about the role of mTOR signaling in liver response to toxic exposures. One knowledge gap that hiders this progress consists in non-complete understanding of unique and overlapping functions of the two mTOR complexes. In this study, we analyzed changes in gene expression in mouse models with liver-specific suppressed mTORC1 or mTORC2 complexes using RNA-seq approach. These models were generated by breading transgenic animals with Cre recombinase controlled by the Alb promotor and animals with floxed Raptor (component of mTORC1) or Rictor (component of mTORC2) respectively. Bioinformatic analysis of gene expression data counterintuitively demonstrated that functions positively regulated by mTOR complexes are activated by suppression of these respective complexes. That finding suggests presence of redundant mechanisms that likely overcompensate suppression of mTOR complexes. We have also found that in both KO models different pathways of lipid metabolism and protein biosynthesis and TNF-a signaling via NFkB were enriched. While mitotic cycle and xenobiotic metabolism were enriched in mTORC1 KO model only.

1935 Correlation of Physiochemical Properties of CC001 and Its Metabolites with Lysosome Accumulation in Rats

G. M. Yanochko, R. Guzman, C. Pourvahidi, K. Noda, Y. Tang, D. Dalvie, L. Alvarado, K. Ghoreishi, and J. R. Piccotti. *Celgene Corporation, San Diego, CA.*

Lysosomal sequestration is a well-known phenomenon of basic, lipophilic compounds. In an exploratory toxicity study, male Sprague Dawley rats (CRL:CD(SD)) dosed with CC001 at 50, 150, and 500 mg/kg/day, for 7 days had bile duct hyperplasia, increased macrophage vacuolation in liver and lymphoid tissue, and increased LAMP-2 staining in hepatocytes. Evaluation of tissues by electron microscopy showed evidence of phospholipidosis, as evidenced by concentric lamellar bodies, in bile duct epithelial cells but not in Kupffer cells or hepatocytes in the liver. These findings were absent in dogs and cynomolgus monkeys with studies of CC001 at equivalent or higher exposures. We initially hypothesized that a rodent-specific metabolite was responsible for the findings in the rat exploratory study, however, no apparent differences in parent:metabolite ratios or tissue specific concentrations of parent or metabolites was observed across species. We used *in vitro* cultures of the rat hepatoma cell line H4IIe as well as primary rat and dog hepatocytes to determine if CC001 or two of its metabolites, CC001a and CC001b, could disrupt lysosomes and induce vacuolation *in vitro*. Cells were incubated with CC001, CC001a, CC001b or the lysosomotropic compound chloroquine for up to 24 hours and disruption of lysosomes was measured by fluorescence microscopy of lysotracker red (LTR, Lysotracker Red DND-99) staining. We found that both the parent molecule, CC001, and the CC001b metabolite dose-dependently increased LTR labeling of rat H4IIe cells and rat hepatocytes. The extent of LTR increase in both H4IIe cells and hepatocytes corresponded to the physicochemical properties of the compounds: CC001a (cLogP = 4.31, pKa = 1.8, 8.7) < CC001 (cLogP = 4.5, pKa = 3.0, 4.7, 7.0) < CC001b (cLogP = 4.76, pKa = 9.2). Preliminary data suggests differential sensitivity of dog hepatocytes to CC001 and CC001b induced lysosomal disruption.

1936 Hepatocyte Exposure to Acetaminophen Induces DNA Damage, Epigenetic Changes, and Senescence

S. Arami, S. Rezaei, M. Moghaddam, P. Sajjadi, and G. Acquaah-Mensah. *Massachusetts College of Pharmacy and Health Sciences, Worcester, MA.*

Liver cells exposed to high levels of acetaminophen (APAP) accumulate by-products of metabolic pathways. Accumulation of reactive species in hepatocytes induces oxidative stress and alters genetic stability for hepatocytes. This leads to gene expression changes, as hepatocytes cope with their newly-imposed environ due to APAP exposure. In this study, gene expression data from non-malignant hepatocytes and a human liver cancer cell line (HepG2) exposed to between 2 and 10 mM APAP were interrogated for further insights. All microarray data were obtained from the Gene Expression Omnibus: non-malignant hepatocytes from *Homo sapiens* (GSE13430), *Rattus norvegicus* (GSE40336), and *Mus musculus* (GSE18614) as well as HepG2 cells (GSE53216). The Bioconductor *GEOquery* and *siggenes* packages were used in the R programming environment for processing data and for hypothesis testing, respectively. Furthermore, over-representation and Gene Set Enrichment analyses (GSEA) were performed. In both rats and humans, 5mM APAP over 24 hours increased the expressions of genes including those associated with *DNA Damage- /Telomere Stress-Induced Senescence*, and epigenetics-relevant processes such as *DNA methylation*, *SIRT1 negatively regulates rRNA expression*, and *PRC2 methylates histones and DNA*. Others include *Formation of the beta-catenin:TCF transactivating complex*, and *ERCC6 (CSB) and EHMT2 (G9a) positively regulate rRNA expression*. In mice, exposure to 2 mM of APAP over 24 hours, led to changes in expression of 214 genes, affecting 19 cellular pathways similar to those observed in rats and humans at 5 mM. Similar pathways were over-represented in up-regulated genes in HepG2 cells following 10 mM APAP exposure for 24 hours except that *p53-Dependent G1 DNA Damage Response* and *p53-Dependent G1/S DNA damage checkpoint* were also affected. GSEA results show a *DNA Repair* gene set is enriched in control hepatocytes, compared to 5 mM APAP-exposed ones, while *DNA Damage- /Telomere Stress-Induced Senescence* and *Oxidative Stress-Induced Senescence* gene sets are enriched in the 5 mM APAP-exposed ones compared to control. Furthermore, the gene set capturing *Methylation of Histones and DNA by PRC2* is enriched in 5mM APAP-exposed hepatocytes. Thus, hepatocyte APAP exposure for 24 hours likely increases DNA damage, while suppressing DNA repair, leading to epigenetic changes and senescence.

1937 The Involvement of Ryanodine Receptors in Halothane-Induced Liver Injury in Mice

R. Jia, S. Oda, and T. Yokoi. *Nagoya University Graduate School of Medicine, Nagoya, Japan.*

Drug-induced liver injury (DILI) is a major problem in drug development and clinical drug therapy. However, it remains difficult to predict DILI in humans due in part to the lack of suitable animal models and knowledge of susceptibility factors that predispose individuals to DILI. Halothane (HAL), an inhaled anesthetic, induces severe and idiosyncratic liver injury. It has been known that disordered hepatic calcium homeostasis is an early feature of HAL-induced liver injury in guinea pigs. Even though some underlying mechanisms in HAL-induced liver injury have been understood, there are no reports of involvement of ryanodine receptors (RYR) that mediates calcium release. To investigate the mechanism of HAL-induced liver injury, ryanodine (RYA, 50 ug/kg, i.p.), a RYR agonist, which was administered 1 h prior to HAL (15 mmol/kg, i.p.) with BALB/cCrSlc female mice significantly elevated plasma alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels, while resulted in severe hepatic inflammation and necrosis by histological analysis at 24 h compared with HAL-administered group. In contrast, administration of mice with dantrolene sodium (DAN, an inhibitor of RYR) showed a dose-dependent manner to suppress HAL-induced elevation of the plasma ALT and AST levels significantly, as well as alleviated the liver damage. Among the immune and inflammatory factors, the hepatic mRNA levels of TGF-β1, S100A8, macrophage inflammatory pryrotein-2, vascular cell adhesion molecule 1 were significantly increased in RYA and HAL co-administered group, but decreased in DAN and HAL co-administered group compared with HAL-administered group. In addition, hepatic mRNA expression levels of apoptosis markers including Bcl2-associated X, Bcl-2-interacting mediator and tribbles-related protein 3 were significantly decreased in RYA and HAL co-administered group compared with HAL-administered group. These results suggest that RYA has an enhanced effect and DAN has a protective effect on HAL-induced liver injury. In conclusion, we found a new insight into the effect of RYR which might be as a novel factor involved in the analysis of the mechanism on HAL-induced liver injury.

1938 Disturbed Microsomal TG Trafficking Contributes to Hepatic Fat Accumulation in Different Mouse Fatty Liver Models

Y. Lu. *Marshall University, Huntington, WV.*

In liver endoplasmic reticulum (ER), newly synthesized triglyceride (TG) is transferred by microsomal triglyceride transfer protein (MTTP) to apolipoprotein B (apoB), which is matured in Golgi bodies to very low density lipoprotein (VLDL) and secreted into blood. If the synthesized TG does not bind to apoB to be secreted out of liver, the TG might be accumulated in liver forming fatty liver. In *ob/ob* mice, as expected, we observed an elevated TG contents in liver. Likewise, hepatic expression of MTTP and a lipid droplet-associated protein (Plin2) was increased dramatically. In contrast to liver TG and Plin2, liver apoB expression was decreased, but serum apoB and TG were not increased in *ob/ob* mice, suggesting that the decreased liver apoB in *ob/ob mice* is not due to a elevated apoB secretion. The observation that liver MTTP was increased but apoB was decreased in *ob/ob* mice with fatty liver leads us to further test the role of microsomal TG trafficking in another fatty liver model-binge alcohol-induced fatty liver. Mice were gavaged 5 g/kg of ethanol. Six hours later, like what we observed in *ob/ob* mice, liver TG and Plin2 were increased, liver apoB was also decreased. However, unlike *ob/ob* mice, binge alcohol-treated mice did not alter liver MTTP expression. Interestingly, in binge alcohol model serum apoB and TG were decreased, which was not observed in *ob/ob* mice. These results indicate that decreased liver apoB and increased Plin2 are essential for fatty liver in both *ob/ob* model and binge alcohol model. Previously we reported that peroxisome proliferator-activated receptor α (PPARα) deficiency promotes alcoholic fatty liver in *cyp2a5*$^{-/-}$ mice i.e. fatty liver was more severe in PPARα and CYP2A5 double knockout (P-A-) mice than in *cyp2a5*$^{-/-}$ mice still expressing PPARα (P+A-). Here we found that similar to what we observed in chronic alcohol model, binge alcohol-induced liver TG accumulation was higher in P-A- mice than in P+A- mice. Consistently, hepatic Plin2 expression was higher in P-A- mice than in P+A- mice. However, unlike P+A- mice, P-A- mice did not show a decreased liver apoB after a binge alcohol gavage. Surprisingly, liver MTTP was not detectable in control and alcohol treated P-A- mice, suggesting that PPARα regulates liver MTTP expression, and downregulated MTTP may play a pivotal role in the enhanced fatty liver in P-A- mice. To summarize, disturbance in microsomal TG trafficking (either MTTP or apoB) contribute to the development of fatty liver.

1939 Predictive and Mechanistic *In Vitro* Assays for Identifying DILI Potential

H. Kohara[1], P. Bajaj[2], T. Yukawa[2], H. Hara[1], K. Harada[1], K. Miyamoto[1], S. Igaki[1], M. Wagoner[2], R. Naven[3], M. Miyamoto[1], and T. Shinozawa[1]. *[1]Takeda Pharmaceutical Company Limited, Fujisawa, Japan; [2]Takeda Pharmaceutical Company Limited, Cambridge, MA; and [3]Takeda Pharmaceutical Company Limited, San Diego, CA.* Sponsor: T. Shinozawa, Japanese Society of Toxicology

Drug-induced liver injury (DILI) is one of the highest causes of drug attrition. *In vitro* cytotoxicity assays and several mechanistic assays with multiple endpoints were proposed as potential solutions to improve predictability of DILI in early phase of drug development. In this study, we assessed the utility of four *in vitro* cell-based assays, HepG2- and 3D human liver microtissue (hLiMT)-based ATP-driven cytotoxicity assay, HepaRG-based GSH consumption assay and liver humanized mice-derived human hepatocytes-based bile acid (BA) transport inhibition assay either alone or in combination for DILI risk assessment. We then compared the assay results with clinical information on DILI and previously published physicochemical property-based DILI risk classification (Biopharmaceutical Drug Disposition and Classification System:BDDCS;Benet LZ et al., AAPSJ, 2011) which classify extensively permeable, low aqueous solubility drugs as high risk. Eighty licensed DILI-causing and DILI-negative drugs were evaluated by these 4 assays. Previously published results were used for hLiMT-based cytotoxicity assay (Proctor WR et al., Arch Toxicol. 2017). The results showed that *in vitro* cell-based assays in combination were able to predict DILI with sensitivity range of 53.7-61.1%; specificity range of 76.9-84.0%; accuracy range of 63.3-66.3%. All the false positive drugs in *in vitro* assays except one drug in BA transport inhibition assay showed the therapeutic C_{max} values lower than 1 μM and sufficiently high margins. Notably, *in vitro* assays and BDDCS class 2 (high risk) detected different DILI-causing drugs as positive with overwrap, suggesting that potential DILI risk caused by extensive permeability and low solubility could not be fully captured by *in vitro* assays tested. Our data indicated that *in vitro* cell-based assays and/or physicochemical property-based assessment could contribute to drug candidate prioritization in early phase of drug development, and correction of assay results with predicted human exposure might be effective to improve predictive power when available.

1940 Expanded Primary Human Liver Sinusoidal Endothelial Cells as a Tool for Complex Hepatotoxicity Studies

A. Noerenberg, T. Evenburg, J. Boldt, and T. Johannssen. *Upcyte Technologies GmbH, Hamburg, Germany.* Sponsor: P. Hewitt

Liver sinusoidal endothelial cells (LSECs) are highly specialized endothelial cells lining the walls of hepatic sinusoids. Their key roles include liver regeneration, the transfer of substrates between blood and liver parenchyma, rapid internalization of blood-borne macromolecules as well as immune tolerance. Despite their substantial contribution to liver homeostasis, LSECs are often overlooked during hepatotoxicity assays due to insufficient cell yields after isolation and a restricted proliferation capacity *in vitro*. To address these issues, we expanded primary LSECs derived from 3 donors by lentiviral transduction with proliferation inducing genes. Transduced LSECs performed 28-45 population doublings in a donor-dependent manner until senescence occurred. Generated upcyte LSECs expressed typical endothelial cell markers (CD31, von Willebrand factor) and showed marked binding of UEA-1 (Ulex Europaeus Agglutinin I). In addition, we found expression of several LSECassociated receptors including MMR (mannose receptor), LYVE-1 (lymphatic vessel endothelial hyaluronan receptor 1) and FCGR2B (inhibitory receptor for the Fc region of immunoglobulin gamma). Expanded LSECs further revealed marked uptake of macromolecule ligands (ovalbumin, acetylated low density lipoprotein) and were capable of tube formation when cultured in Matrigel. Since LSECs are involved in drug-induced liver injury, we challenged the cells with several hepatotoxic model compounds. We further developed a co-culture medium which allowed us to analyze the interplay with hepatocytes. Interestingly, upcyte LSECs were more susceptible to e.g. acetaminophen and imipramine-induced toxicity when compared to upcyte hepatocytes, indicating that these cells constitute a useful tool to complement hepatotoxicity evaluation. Taken together, our data suggest that upcyte LSECs combine many characteristics of primary LSECs with the advantage of an extended lifespan, facilitating their use in hepatotoxicity assays under reproducible and standardized conditions. Future applications may include e.g. *in vitro* uptake assays of ADCs (antibody drug conjugates) or modulation of T cell activation in response to specific antigens.

1941 Immune-Mediated Hepatotoxicity: Novel *In Vitro* Model to Advance Drug Safety Testing

F. Tasnim[1], X. Huang[1], Y. Soong[1], and H. Yu[1,2,3]. *[1]Institute of Bioengineering and Nanotechnology, Singapore, Singapore; [2]Southern Medical University, Guangzhou, China; and [3]National University of Singapore, Singapore, Singapore.* Sponsor: F. Tasnim, American Society for Clinical Investigation American Society for Biochemistry and Molecular Biology

Current *in vitro* liver models could greatly benefit from the incorporation of human liver macrophages - Kupffer cells (hKCs) due to their crucial role in the response of the liver to injury caused by drugs and other xenobiotics. Inclusion of hKCs have been limited due to challenges associated with the cell source: tissue availability, cost, donor variability and inability to expand the cells *in vitro*. In order to circumvent these challenges, we recapitulated *in vivo* ontogeny of hKCs to generate human iPSC - derived KCs (iKCs) and incorporated them in a human inflammatory *in vitro* liver model (HINVIL) with human iPSC-derived hepatocytes (iHeps). HINVIL was characterized by assessing performance of iHeps and iKCs in the model using marker expression (qPCR/FACs), cytokine production and phagocytosis assays. HINVIL was exposed to several inflammation-associated drugs including Acetaminophen, Trovafloxacin and Chlorpromazine. iKCs in HINVIL expressed macrophage markers CD32, CD68, CD11, CD14, CD163 at 0.3-5 folds of primary hKCs and KC-specific markers CLEC-4F, ID1 and ID3. iKCs produced cytokines IL-6 and TNFα and phagocytosed at levels similar to primary hKCs. iHeps in HINVIL expressed key hepatic markers (albumin and α1-antitrypsin) and key metabolizing cytochrome P450 (CYP) enzymes at 2.4-10.8 folds higher levels compared to iHeps mono-culture. Importantly, HINVIL could recapitulate *in vivo* like drug sensitivity by being able to detect hepatotoxicity at close to physiological concentrations of the tested drugs. In contrast, mono-culture of hepatocytes without the presence of iKCs did not show any improvement in the sensitivity of detecting these drugs. Furthermore, HINVIL could capture changes in cytokine levels (particularly decrease in IL-6 and increase in TNFα) produced by KCs in response to these drugs and consequent effects on important hepatic CYPs such as CYP3A4. Altogether, HINVIL comprises of renewable, mature and functional cells and represents a novel system for detecting immune-mediated hepatotoxicity.

1942 Oxidation of Fatty Acids Induced by PPAR-α Is Counteracted by PPAR-γ Activation in Mice with Hepatic Steatosis

J. P. Fyolek, X. Li, Z. Wang, and J. E. Klaunig. *Indiana University-Bloomington, Bloomington, IN.*

Peroxisome proliferator activated receptors (PPARs) have been shown to modulate many important pathways related to lipid metabolism in the liver. We have previously demonstrated that oral administration of PFOA in mice activates PPAR-α. We have also shown that the antibacterial compound triclosan (TCS) activates both PPAR-α and PPAR-γ. We examined these two compounds for their effect in our liver dietary steatosis model in mice. A HFD was administered *ad libitum* to male C57BL/6J mice for 32 weeks. After 16 weeks, when hepatic steatosis is established, the mice were treated with 1 mg/kg/day PFOA or 100 mg/kg/day TCS via diet for 2, 8, and 16 weeks. Histopathological examination revealed a reduction in the size and number of hepatic lipid vesicles of PFOA-treated mice in the HFD groups at all time points, but no change was observed in TCS-treated mice. This observation is supported by a significant reduction in hepatic triglycerides across all time points in HFD groups treated with PFOA, but not with TCS. Acyl-CoA oxidase activity (ACO) and *Cyp4a10* expression, as a measure of PPAR-α activity, were significantly increased in both PFOA and TCS-treated groups at all timepoints. However, ACO activity in HFD-fed mice was approximately twice as high when treated with PFOA compared to TCS despite having similar activity in mice fed the control diet. Total hepatic RNA was isolated for RNA sequencing and subsequent pathway analysis. Ingenuity Pathway Analysis revealed that in HFD groups both PFOA and TCS enriched many of the same pathways related to lipid metabolism including "oxidation of lipid" and "oxidation of fatty acid." The PPAR-γ pathway was significantly enriched as an upstream regulator of HFD-fed mice in the TCS group, but not the PFOA group. Across all time points mRNA expression of *Pparγ* was significantly increased in all TCS groups but not PFOA groups. Pathways related to fatty acid transport including "hydrolysis of lipid" and "activation of fatty acid" were significantly enriched when treated with PFOA but not TCS in the HFD groups. This data indicates that fatty acid oxidation induced by PPAR-α activation is blunted by PPAR-γ activity due to dysregulation of fatty acid transport mechanisms. Although PPAR-α activation primes liver machinery for fatty acid metabolism, simultaneous activation of PPAR-γ prevents the release of free fatty acids from the adipose tissue and are not available for transport to the mitochondria for oxidation.

1943 Microphysiological System for Studying Fatty Liver Disease and Its Impact on Drug-Induced Liver Injury

T. Kostrzewski[1], A. Miedzik[1], S. Regan[2], A. Srivvastava[2], D. Williams[2], and D. Hughes[1]. *[1]CN Bio Innovations, Welwyn Garden City, United Kingdom; and [2]AstraZeneca, Cambridge, United Kingdom.* Sponsor: P. Newham

Non-Alcoholic Fatty Liver Disease (NAFLD) is a growing concern worldwide and is set to become the most predominant cause of chronic liver disease. Additionally, there is a growing awareness of the potential risk factors for drug induced liver injury (DILI) due to the underlying metabolic condition. DILI in NAFLD patients can be exacerbated in two distinct ways; some drugs seem to aggravate pre-existing NAFLD, whereas more frequently others can induce acute hepatitis. However, the mechanisms by which these processes occur are poorly understood and adverse drug responses due to fatty liver are becoming more common with the ever-increasing obesity epidemic. Therefore, we have developed an advanced *in vitro* model to explore the relationships and mechanisms that link DILI and NAFLD. Using a microphysiological system (MPS), we have developed a fully human perfused *in vitro* NAFLD model, utilising primary human hepatocytes cultured in 3D to mimic the liver microarchitecture. Cells are cultured with high concentrations of free fatty acids for up to four weeks to induce intracellular triglyceride (fat) accumulation and mimic hepatic steatosis. Fat loaded cells can then be dosed with compounds of interest, potentially for extended periods of time to assess the effects of acute or chronic dosing. Fat loading of hepatocytes did not induce cell death or apoptosis, but impacted significantly on their metabolic capacity, reducing CYP3A4 (>2 fold) and CYP2C9 activity, whilst increasing CYP2E1 (>2 fold) and CYP1A2 activity (1.5-fold). We therefore explored if fat loaded hepatocytes were more sensitive to DILI with a range of compounds identified clinically to have exacerbated DILI in the presence of NAFLD. We observed both ticlopidine and acetaminophen to cause increased LDH release, decreased cell viability and decreased albumin production in fat loaded cells, compared to healthy/lean controls when compounds are dosed at or around IC:50 concentrations. We demonstrate the MPS *in vitro* NAFLD model is ideally suited to exploring the molecular mechanisms that underlie DILI and its association with hepatic steatosis. It will be a highly useful tool for analysing the toxicity profiles of novel compounds and how they may behave in diverse patient subsets.

1944 Gender Differences in Diet-Induced Nonalcoholic Steatohepatitis (NASH) in Cyp2b-Null Mice

M. M. Heintz, R. McRee, R. Kumar, and W. S. Baldwin. *Clemson University, Clemson, SC.*

Nonalcoholic fatty liver disease (NAFLD) is the most common liver disease; however, it is the progression to nonalcoholic steatohepatitis (NASH) that is associated with most adverse outcomes. CYP2B metabolizes multiple xeno- and endobiotics, and male Cyp2b-null mice are diet-induced obese (DIO) with increases in NAFLD but little hepatic inflammation. However, this DIO-study was only performed for 10-weeks and recent research indicates that C57Bl/6 mice are recalcitrant to fibrosis and NASH development for up to 22-weeks. Therefore, to properly assess the role of Cyp2b in fatty liver disease progression from NAFLD to NASH, we treated wildtype (WT) and Cyp2b-null mice with a normal diet (ND) or choline-deficient, L-amino acid-defined high fat diet (CDAHFD) for 8 weeks and determined metabolic and molecular changes. CDAHFD-fed WT female mice gained more weight and had greater liver (11%) and white adipose tissue (44%) mass than their Cyp2b-null counterparts, while males experienced diet-induced weight loss regardless of genotype. In both genders, hierarchical clustering of RNA-seq data demonstrates several genes involved in lipid metabolism, fibrosis, and inflammation responded differently in CDAHFD-fed Cyp2b-null mice compared to WT mice. Serum biomarkers of liver injury increased in both CDAHFD-fed female and male mice; however, CDAHFD-fed Cyp2b-null females exhibited significantly lower serum alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase concentrations compared to WT mice, indicating the loss of Cyp2b protected mice from liver injury in females. In contrast, males showed few differences in serum parameters related to genotype. Oil Red O staining and direct triglycerides measurements confirmed that CDAHFD-fed Cyp2b-null females were protected from fatty liver disease. CDAHFD-fed Cyp2b-null mice showed equivocal changes in fibrosis with some markers suggesting less inflammation probably due to glucocorticoid-mediated repression of immune responses. In contrast, CDAHFD-fed Cyp2b-null males had higher triglyceride levels. Results indicate that female Cyp2b-null mice are less susceptible to NASH than WT mice, while male Cyp2b-null mice are more susceptible to NAFLD with no changes in NASH development. Overall, this study indicates a minor role for Cyp2b in fatty liver disease progression that differs based on gender, with males being more susceptible to chemical inhibition of Cyp2b than females, who may be protected.

1945 Use of 2D and 3D *In Vitro* Models to De-Risk Potential for Liver Toxicity by BACEi BU

D. Simic[1], L. Shanno[1], N. Bogdan[1], F. Van Goethem[2], M. Steemans[2], L. Lammens[2], M. Singer[1], J. Snoeys[2], and M. Otieno[1]. *[1]Janssen Research & Development, Spring House, PA; and [2]Janssen Research & Development, Beerse, Belgium.*

JNJ-54861911 (JNJ-1911; Atabecestat) is a BACE inhibitor that caused Drug Induced Liver Injury (DILI) in the clinic. Resulting increases in liver enzymes (ALT) halted the program from further development. In order to avoid related issues with the backup compounds, we set off to understand the mechanism of JNJ-1911 induced DILI. This included generating the hypothesis, testing the hypothesis and designing model(s) to screen backup compounds. We hypothesized that oxidative stress induced by parent and/or reactive metabolites is a key contributor toward JNJ-1911 mediated DILI. To test this hypothesis, three separate *in vitro* methods were implemented: 1) Emulate's liver-on-chip, 2) Liver spheroids, and 3) Bio IVT HepatoPac. All models were treated with JNJ-1911 with or without glutathione inhibitor, Buthionine Sulfoximine (BSO). In addition, liver-on-chip and HepatoPac cultures were treated with competitor BACEi compounds with reported ALT increases (Lily LY2886721; JNJ-334) or no DILI (Merck Verubecestat; JNJ-548). Using APAP and aspirin as positive and negative controls respectively, we show that depletion of glutathione results in reduction of ATP and hepatic cell viability when treated with Atabacestat and LY2886721, but not Verubecestat, further suggesting a role of oxidative stress/reactive metabolite in initiation of DILI.

1946 Molecular Markers of Non-Alcoholic Fatty Liver Disease Variability in a Collaborative Cross Mouse Population

A. de Conti[1], V. Tryndyak[1], R. A. Willett[1], B. Borowa-Mazgaj[1], A. Watson[1], F. A. Beland[1], I. Rusyn[2], and I. I. Pogribny[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]Texas A&M University, College Station, TX.*

Nonalcoholic fatty liver disease (NAFLD) is a fast-rising and the most prevalent form of chronic liver diseases in the United States. Interindividual variability and sexual dimorphisms in the development of NAFLD are still poorly understood. In the present study, 24 strains of male and female Collaborative Cross (CC) mice, a state-of-the-art mouse population model, were fed a high-fat and high-sucrose (HF/HS) diet or an ingredient-matched low-fat and reduced sucrose control diet for 12 weeks to investigate interindividual- and sex-specific variations in the development of NAFLD. The severity of liver steatosis in HF/HS diet-fed mice varied between sexes and individual strains, with a greater magnitude of hepatic steatosis found in male mice. This was evidenced by facts that (*i*) 68% of male strains showed a significant increase in fat liver accumulation as compared to 58% of female strains, and (*ii*) the inter-strain magnitude of steatosis was 66% in male mice, ranging from 3% to 69%, versus 27% in female mice, ranging from 4% to 31%. These changes were accompanied by an elevation of serum NAFLD diagnostic markers, including increases in serum total cholesterol, low-density lipoproteins, high-density lipoproteins, phospholipids, and glucose levels. The development of NAFLD was accompanied by over-expression of *Pparg, Mogat1, Cd36, Acaab1, Fabp2,* and *Gdf15,* and critical fatty acid uptake and *de novo* lipogenesis genes in male and female mice, among which the expression of *Pparg, Mogat1,* and *Cd36* was positively correlated with liver triglycerides in male mice, and *Mogat1* and *Cd36* expression was positively correlated with liver triglycerides in female mice. There was also an association between susceptibility to NAFLD and histone H4K16 deacetylation. In summary, our results indicate the value of the genetically diverse CC mice in combination with HF/HS diet-induced alterations to study the pathogenesis of NAFLD. This combination demonstrates the strength of our approach in the identification of molecular determinants of NAFLD pathogenesis and progression at the population level.

1947 Effects of Common E-cigarette Compounds in a Mouse Hepatocyte Model and Glutathione as a Potential Modulator of Susceptibility

M. Anderson[1], D. Botta[1], C. White[1], T. Gordon[2], L. Chen[2], and T. Kavanagh[1]. *[1]University of Washington, Seattle, WA; and [2]New York University, New York, NY.*

In 2017/2018, 2.9% of adults reported having used an e-cigarette at some point. More concerning is that 20.8% and 4.9% of high school and middle school students, respectively, also reported using e-cigarettes at least once. However, comparatively little research has been done on the potential hazards and effects of e-cigarettes. Four specific chemicals have been commonly associated with vaping: the pyrolysis products formaldehyde and acetaldehyde; and the flavoring agents cinnamaldehyde and diacetyl. In addition to assessing cytotoxicity caused by these agents, we are investigating whether the antioxidant glutathione (GSH) modulates susceptibility. *In vitro* experiments were carried using two immortalized mouse liver cell lines (wild-type cells, and GSH deficient Gclm null/β-galactosidase knock-in cells). Cell viability at multiple doses of each compound was measured using the alamarBlue assay after 24 hr. DDAOG, a β-galactosidase substrate, was used as a proxy for Gclm promoter activity, also at 24 hr. Formaldehyde, cinnamaldehyde, and diacetyl all resulted in an initial increase in viability at low doses followed by a subsequent dose-dependent decrease in viability by 2-way ANOVA. However, after correcting for multiple comparisons, only formaldehyde and cinnamaldehyde treatments caused decreases in cell viability. Interestingly, cinnamaldehyde treatment caused a dramatic decrease in viability in Gclm null cells at 250 μM, followed by a resurgence in survival until the 750 μM dose. Acetaldehyde showed very little effect on cell viability. β-galactosidase activity in GSH-deficient cells suggested an increase in Gclm promoter activity at lower, relatively non-toxic doses for all 4 compounds, providing preliminary evidence that they cause oxidative stress. Investigation of oxidative damage, GSH redox and transcriptional responses are ongoing. *Supported by NIH grants R01CA239253 and P30ES007033.*

1948 ratHepatoPearls: Encapsulated Rat Hepatocyte Spheroids for Better *In Vitro In Vivo* Correlation (IVIVC)

I. Bivas, A. Vercoutère, Z. Hamidouche, T. Baudequin, and N. Dianat. *Cyprio, Paris, France.* Sponsor: S. Ferguson

Through the development of HepatoPearls®, Cyprio validated an *in vitro* 3D liver model based on spheroids of primary human hepatocytes encapsulated in alginate pearls. HepatoPearls® show physiologically relevant functions such as CYP450 enzymes and urea and albumin production with high cell viability over 6 weeks. They offer a long-term, highly consistent solution for many applications, in particular in preclinical ADMET studies. HepatoPearls® were therefore developed with human cells to obtain relevant *in vitro* characterizations in line with human trials. However, it can be of primary interest for drug manufacturers to compare *in vitro* 3D animal results with the historical database generated from small animal trials. In addition, 2D cultured rat hepatocytes are known to lose functions and viability even earlier than 2D human cells. Thus, we investigated here the development of rat HepatoPearls® as a 3D liver model to help correlating *in vitro* and *in vivo* results obtained on rodents. Rat primary hepatocytes were encapsulated with Cyprio's BioPearls® technology. Different initial cell densities and culture medium were compared to ensure spheroid formation, cell viability (Live/Dead) and liver functions (CYP P450 activity and bile canaliculus staining) during 4 weeks after encapsulation. With an increase in cell density compared to human HepatoPearls®, homogeneous encapsulation was successfully achieved and spheroid formation was validated. The spheroid stability over time showed important variations depending on the used medium. For optimal composition, rat HepatoPearls® were formed earlier than human ones (day 4 instead of 7) and were stable for 4 weeks with similar viability rate. Metabolic functionality was also confirmed through induction of CYP3A4 activity (up to 13-fold at day 4) and bile canaliculus observations. Interestingly, CYP3A4 basal activity tended to stabilize over the four weeks of study and the rat HepatoPearls® were inducible during all this period with 8.8, 5.5 and 5.7-fold of induction respectively at days 10, 17 & 24 In summary, we report here the first production of encapsulated ratHepatoPearls® with high cell viability and metabolic activity. The ability of providing reliable rat *in vitro* liver model with more than 1-week metabolic stability is a crucial improvement for *IVIVC*. We will investigate further the application of this new *in vitro* rat 3D liver model in hepatotoxicity studies.

1949 Transcriptomic Profiling of Human 3D Liver Spheroids Treated with Three Discontinued BACE Inhibitor Drugs

F. Van Goethem[1], M. Steemans[1], A. De Bondt[1], J. Van Houdt[1], I. Van Den Wyngaert[1], S. Van Tilburg[1], H. Goehlmann[1], M. Otieno[2], J. Snoeys[1], P. Kohonen[3], R. Grafström[3], and A. De Smedt[1]. *[1]Janssen, Beerse, Belgium; [2]Janssen, Springhouse, PA; and [3]Karolinska Institutet, Stockholm, Sweden.*

Janssen recently ended clinical development of the BACE inhibitor Atabecestat since elevations in liver enzymes were detected in patients taking the drug. Dating back several years, Eli Lilly halted clinical development of its BACE inhibitor LY2886721 because of liver abnormalities. Also Merck stopped Verubecestat due to lack of desired pharmacology but without any indications of human liver toxicity. To assess the underlying mechanisms of the clinical drug-induced liver injury (DILI), a mechanistic *in vitro* study was set-up to explore the transcriptomic profiles induced by the 3 BACE inhibitors. In this proof-of-concept approach, 3D human liver spheroids were treated with different concentrations of each BACE inhibitor based on the clinical Cmax and on the cytotoxicity profiles obtained in a range finder study. Differentially expressed genes and pathways were compared after a 1- and 12-day exposure period. After treatment with Atabecestat at 3x and 10x Cmax, a significant deregulation of gene expression and pathway perturbations were observed, while the 2 other BACE inhibitors showed limited to no effect. Differences between the transcriptomic profiles generated at day 1 and 12, illustrated the dynamic nature of the human liver cell responses. The obtained transcriptomic data set was then analyzed using the Predictive Toxicogenomics Space (PTGS) model, a compacting and data fusion-derived tool to predict adverse outcomes and risk of human DILI from *in vitro* hepatocyte experiments. Based on the resulting PTGS-derived DILI scores after the 12-day treatments, the analysis could discriminate between the clinical DILI potential of the 3 BACE inhibitors. It can be concluded that the integrated use of a 3D human *in vitro* liver model, transcriptomic profiling, pharmacokinetic-based exposure calculation and PTGS modeling, can predict clinical DILI risk. The proposed test strategy needs further validation but is considered a promising approach to prioritize new drug candidates early in Discovery and/or select safe back-up compounds.

1950 A Systematic US FDA-Approved Drug High Content Imaging Screen to Uncover Drug Liabilities for Cellular Stress Response Pathway Activation

M. Vlasveld, G. Callegaro, S. Lok, S. van Oost, S. Wink, and B. van de Water. *Universiteit Leiden, Leiden, Netherlands.*

Adverse Drug Reactions (ADRs) account for 5-10% of all hospital admissions. The most common drugs that cause ADRs are cardiovascular drugs, NSAIDs and central nervous system agents. Over the past decades, research has been focusing on individual drugs to understand mechanisms responsible of specific ADRs. In this project, an unprecedented large screen is performed to link the most frequent ADRs to the drug-like chemical space. This can lead to a better prediction of drug safety based on the chemical structure of a compound. Two libraries of in total 1965 drugs including all FDA approved drugs as well as 378 kinase inhibitors were screened with a panel of HepG2 BAC-GFP reporters to quantify cellular stress response activation involving DNA-damage (p21), ER stress (CHOP), oxidative stress (SRXN1) or inflammatory signaling (ICAM1); onset of cell death was followed by staining the samples with annexin V and propidium Iodide. In order to include as many compounds as possible to study the mechanism of toxicity, cells were exposed to 50 µM for all of the compounds. More than 600 compounds did activate at least one of the cellular stress response reporters. We observed an equal distribution pattern of reporter activation between the two libraries for p21-GFP (10% of the compounds from both libraries), CHOP-GFP (20%) and SRXN1-GFP (5%). Inhibition of the inflammatory pathway was predominantly caused by KIs, whereas enhancement of the response was mostly observed after treatment with FDA approved drugs. To validate the effect of the hits on a therapeutic dose level, a secondary screen was performed with dosages in a range of 0.3 - 50 µM. Here, 350 compounds were confirmed to activate the stress response pathway in a dose-dependent way. For some groups of structurally similar compounds, identical biological responses are activated. Our current data allows the classification of different FDA approved drugs and KIs for their dose-response dependent activation of individual stress response pathways. To gain more mechanistic knowledge, the pathway dynamics landscape has been extended by measuring protein-GFP expression for different modulators of the pathways. Furthermore, QSAR methods are being applied to define structural alerts for particular pathway activation.

1951 Hepatic Steatosis Shifts Phase I Metabolism and Increases Susceptibility to Toxicants *In Vitro*

N. N. Tucker[1], G. M. Nelson[2], J. A. Harrill[2], and B. N. Chorley[2]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [2]US EPA, Durham, NC.*

Hepatic steatosis (fatty liver disease) is a pathological condition that can alter xenobiotic metabolism, and thereby, alter susceptibility to environmental toxicants. Here we used a metabolically competent human liver-derived cell line - HepaRG - to model steatosis for *in vitro* toxicity assessment. Cells were exposed to vendor-provided completed-media with added 1% BSA-complexed oleate and palmitate fatty acids to induce a steatotic state. An optimum free fatty acid (FFA) ratio of 1:2 oleate to palmitate fatty acid, total FFA concentration of 1 mM, and a 7-day FFA incubation time were identified experimentally and chosen to achieve measurable lipid accumulation with minimal toxicity. The hepatotoxic piscicide rotenone was selected to assess chemical toxicity in our steatotic model. Cell viability was measured 24h after exposure using Cell Titer Glow, an intracellular ATP, assay. The IC50's for rotenone were altered with lipid loading, shifting a naïve IC50 from 0.64 µM to 0.46 µM in a steatotic model. The altered cell viability becomes increasingly significant, as seen using a two-tailed students t-test where $p<0.05$, with increasing concentrations of rotenone. There was a reduction in expression of several cytochrome P450 (CYP) genes in the HepaRG cells in a steatotic state when measured by qPCR. For example, CYP3A4, the most active P450 enzyme in rotenone metabolism, expression was reduced. P450 activity is a major factor in limiting rotenone toxicity as rotenone metabolites are less active than the parent compound. These results suggest that our *in vitro* HepaRG steatosis model can be a useful tool for evaluating *in vivo* hepatic steatosis as a risk factor in chemical toxicity. Future addition of high content analysis of oxidative stress and mitochondrial dysfunction in the model may enhance its predictive capability for human hepatotoxicity susceptibility screening. *This abstract does not necessarily reflect the policy of the US EPA.*

1952 *In Vivo* Effects of Endogenous AhR Ligands within the Intestine-Liver Axis

K. A. Fader[1,2], R. Nault[1,2], R. R. Fling[1,2], and T. Zacharewski[1,2]. *[1]Michigan State University, East Lansing, MI; and [2]Michigan State University Institute for Integrative Toxicology, East Lansing, MI.*

Anthropogenic aryl hydrocarbon receptor (AhR) ligands such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) cause the dose-dependent progression of steatosis to steatohepatitis with fibrosis in mice. Several endogenous ligands of the AhR have also been identified, however their *in vivo* hepatic effects remain unexplored. In these studies, male C57BL/6 mice were orally gavaged with the endogenous tryptophan metabolites - kynurenine (KYN; 0, 10, or 50 mg/kg dissolved in acidified water) or 6-formylindolo[3,2-b]carbazole (FICZ; 0, 1, or 4 mg/kg dissolved in sesame oil). Liver and intestinal epithelium samples were collected 2, 4, and 24 hours (h) following treatment. KYN did not alter body weight, relative liver weight (RLW), or hepatic histopathology. Although the expression of classic AhR battery genes was unchanged in the liver, *Cyp1a1* and *Cyp1a2* were induced in the jejunal epithelium 4.8- and 4.0-fold, respectively, at 50 mg/kg KYN. In contrast, FICZ induced hepatic expression of *Cyp1a1* (4180.7-fold), *Cyp1a2* (9.7-fold), and *Cyp1b1* (19.9-fold) at ≥ 1 mg/kg. At 24h, *Cyp1a1* and *Cyp1b1* expression returned to near basal levels, while *Cyp1a2* induction persisted throughout the study. Similarly, RLW was increased ~20% at 2 and 4h, but not at 24h. Dose-dependent increases in serum ALT levels at 2h suggest FICZ induced liver damage, while hepatic induction of the *Cd36* fatty acid transporter may promote lipid accumulation. Overall, the early hepatic effects elicited by 1 mg/kg FICZ are qualitatively and quantitatively similar to those elicited by TCDD, but lack the persistence reported with poorly metabolizable ligands. These studies demonstrate that some labile endogenous, dietary, and/or microbial ligands elicit effects that may contribute to the AhR–mediated progression of steatosis to steatohepatitis with fibrosis. *Funded by the National Institutes of Health ES029541.*

1953 Advanced Glycation End Products Induce Lipid Accumulation through Hepatic Lipid Uptake and *De Novo* Lipogenesis Pathway in Hepatocyte

Y. Jeong, and K. Lee. *Korea University College of Life Sciences and Biotechnology, Seoul, Korea, Republic of.*

Nonalcoholic fatty liver disease (NAFLD) is known as chronic liver disease and the most prevalent liver disease, worldwide. Metabolic syndrome, type 2 diabetes, and insulin resistance are main causes of NAFLD, which is the first step of the development of cirrhosis. Five different advanced glycation end-products (AGE1 to AGE5) were prepared by a non-enzymatic reaction between the reducing sugars, such as glucose, glyceraldehyde, glycolaldehyde, methylglyoxal, and glyoxal, respectively and the protein, bovine serum albumin in this study. The formation of AGEs was widely detected in food and was generally known that induced chronic renal disease, type 2 diabetes and its complications. Although there is high relevance between causes of NAFLD and AGEs, the study that impact of AGEs on fat accumulation is insufficient. This study investigated that the AGEs augmented lipid accumulation that resulted from *de novo* lipogenesis and hepatic lipid uptake pathway in HepG2 cells. The mixture of oleic acid and palmitic acid was used as positive control. Increased Nile red binding, indicator marker of lipid accumulation, was observed after treated AGEs. The mRNA and protein expression of lipid synthesis markers such as PPARγ, FASN, and FAPB were up-regulated in AGEs treated cells. Furthermore, the AGEs regulated the mRNA and protein expression lipolysis marker such as CPT-1, and CD36. These findings suggest that AGEs may induce NAFLD and chronic liver injury through an imbalance between lipid acquisition and disposal.

1954 Using Transcriptomics Combined with 3D Microtissues to Predict DILI

F. Haniel, A. Lavado, J. Eakins, A. Raza, S. Ryder, C. Bauch, and P. Walker. *Cyprotex Discovery Limited, Alderley Edge, United Kingdom.* Sponsor: C. Strock

Drug-induced liver injury (DILI) is a central problem in drug development programs that typically results in late stage clinical trial failures, precautionary warnings and the post-marketing withdrawal of drugs. A variety of *in vitro* approaches have been used in an effort to improve prediction of DILI. Transcriptomics has been shown to play an important role in the understanding of cellular pathways and their alterations in stress situations, whilst also outlining the transcriptional alterations that occur as a result of chemical exposure. Moreover, toxicity assays utilising the combined approaches of

High-Content Analysis (HCA) and phenotypically relevant three-dimensional (3D) microtissue cultures allows deeper interrogation of the most important features contributing to liver toxicity (mitochondrial function, GSH, oxidative stress, cytotoxicity). Mechanistic understanding of DILI can be gained by combining the most predictive and physiologically relevant *in vitro* models with analysis through high-throughput RNA sequencing to deliver more comprehensive toxicity profiles. The screening of twenty-eight drugs with and without clinical DILI was assessed across eight doses in a long-term (14 days) HepaRG 3D model utilising high-throughput (HTS) RNA-seq and multiplexed high content screening (HCS) with mitochondrial membrane potential, GSH, oxidative stress and cellular ATP endpoints. The transcription profiles obtained allowed grouping of DILI positive and negative compounds into functional clusters by PCA (principal component analysis) and t-SNE analysis. A Large impact of gene expression, in a dose-dependent manner, was observed for DILI compounds and the degree of gene expression (DGE) was DILI rank dependent. Multi-parametric HCS in 3D microtissues allowed the identification of DILI compounds with 81 % of sensitivity, 86% specificity and 82 % of accuracy. In summary, predictive toxicogenomics where more comprehensive profiles can be drawn and combined with established mutiplexed *in vitro* assays, using human 3D hepatotoxic models, deliver early and late stage event identification in the hepatotoxic process. Such combination provides insights in the mechanisms implicated in drug toxicity, with heightened predictive understanding of DILI.

PS 1955 Novel Insight into the Dysmetabolic Effects of Olanzapine

R. Pathak[1], R. H. Isaacson[2], J. I. Beier[1], J. Li[1], R. D. Schnegelberger[1], T. Sato[1], A. Kumar[1], S. J. Mullett[1], M. Reynolds[1], N. K. Khoo[1], B. A. Freeman[1], Z. Freyberg[1], S. G. Wendell[1], S. Shiva[1], and G. E. Arteel[1]. *[1]University of Pittsburgh, Pittsburgh, PA; and [2]University of Louisville, Louisville, KY.*

Olanzapine (OLZ), a second-generation antipsychotic, is effective in the treatment of schizophrenia and other mood disorders. However, these beneficial effects of OLZ are limited by its associated side effects, such as weight gain, metabolic syndrome and increased risk of cardiovascular disease. These effects are compounded by the fact that obesity is exceedingly prevalent in the psychiatric population. Most studies thus far have focused on the central effects of OLZ on dysmetabolism, but peripheral effects on key metabolic organs (e.g., liver) may also have important implications. Previous work by this group suggested that OLZ exposure *in vivo* directly alters hepatic metabolism, which contributed to organism-level dysmetabolism. The goal of the current study was to build on these findings both *in vitro* and in an animal model of obesity-induced dysmetabolism. 8-week old female C57BL/6 mice were fed either a high-fat or low-fat control diet (HFD and LFD). Mice also received either OLZ (8 mg/kg/d) or vehicle by osmotic minipump for 4 weeks. AML12 cells were exposed to OLZ (25 μM) for up to 24 h. The impact of OLZ exposure on metabolism was tracked by metabolic flux analysis (Seahorse) and via metabolomics analysis of cell lysate. OLZ alone increased mouse body weight, without a commensurate increase in food consumption. OLZ also caused hepatic steatosis and injury. Combining OLZ and HFD caused further dysregulation of glucose and lipid metabolism. Liver damage from concurrent HFD and olanzapine was worse than liver damage from HFD or OLZ alone. OLZ exposure directly inhibited oxidative phosphorylation in AML-12 cells, which was paralleled by a commensurate increase in lactate levels. As observed *in vivo*, OLZ also increased glutamine levels in AML-12 cells, which was coupled with an increase in mTOR phosphorylation. All of these effects *in vitro* reflect changes observed after *in vivo* exposure, in the presence and absence of an obesogenic diet. Taken together, these data suggest that OLZ directly impacts hepatic metabolism and exacerbates dysmetabolism. Importantly, directly targeting peripheral effects of OLZ may spare beneficial effects of OLZ in the central nervous system.

PS 1956 Hepatocytes Proliferation Studies with Primary Rat Hepatocytes and Primary Human Hepatocytes

H. Gehrke[1], K. Roedig[1], H. Ritthammer[1], S. Baumgartner[1], E. Hoerterer[2], V. Amirian[2], E. Schmidt[1], and C. Freitag[1]. *[1]Eurofins BioPharma Product Testing Munich GmbH, Planegg, Germany; and [2]BSL Bioservice Munich GmbH, Planegg, Germany.* Sponsor: C. Freitag, EUROTOX

Many chemicals, classified as peroxisome proliferators, are known to increase the number of peroxisomes, which is accompanied by DNA replication and liver growth in rat and mouse hepatocytes. This in consequence can induce hepatocellular tumors. Hence, chemicals which induce the proliferation of peroxisomes have formed a unique class of chemical carcinogens, despite being initially classified as non-genotoxic. It has been shown that certain species differences are apparent in response to peroxisome proliferations. Rats and mice appear to be the most sensitive while humans appear to be relatively insensitive or non-responsive (Lai Dy, 2004). These species differences may be reproduced *in vitro* using primary culture hepatocytes isolated from a variety of species including humans. In response to high interest in hepatocyte testing Eurofins BioPharma Product Testing Munich developed hepatocytes proliferation assay using both primary human and primary rat hepatocyte cells. Primary rat hepatocytes were obtained using the method based on two-step collagenase perfusion developed by Berry and Friend (1969) and modified by Seglen (1976). Primary human hepatocytes were obtained from Sigma Aldrich. The quality of hepatocytes-culture was evaluated; preparations with viabilities below 90% were rejected. Cells were maintained in culture for 4 to 5 days and supplemented with hEGF for positive control. Proliferation of hepatocytes was determined using EdU incorporation into genomic DNA of proliferating cells. EdU-incorporation was than detected using click reaction with azide, conjugated with fluorescent dye: 6-FAM Azide. For the primary rat hepatocytes cells, we noticed an increase of 44.02 ± 14.27% in EdU positive cells in the dose group incubated with 50 ng/mL hEGF (96h treatment) in comparison to the negative control 0.45 ± 0.48%. Human primary hepatocytes showed an increase of 45.47 ± 18.24% in EdU positive cells in the dose group incubated with hEGF (72h treatment) in comparison with negative control 7.67 ± 3.58%. This assay allows for quick and reliable evaluation of the effect of test materials on hepatocytes proliferation. The hepatocyte proliferation assay is a universal method that can be applied for each identified target without extensive developmental work.

PS 1957 Gene Expression Analysis, Quantitative Proteomics, and Chronic Toxicity Studies in Primary Mouse Hepatocyte Spheroids Support the Development of an *In Vitro* Collaborative Cross Platform for the Evaluation of Genetic Susceptibility Factors Associated with DILI

M. Nautiyal[1], S. U. Vorrink[2], R. J. Qasem[1,3], J. K. Fallon[1], K. K. Wolf[4], P. C. Smith[1], M. Ingelman-Sundberg[2], and M. Mosedale[1]. *[1]UNC Eshelman School of Pharmacy, Chapel Hill, NC; [2]Karolinska Institutet, Stockholm, Sweden; [3]King Saud Bin Abdulaziz University for Health Sciences, Riyadh, Saudi Arabia; and [4]LifeNet Health, Research Triangle Park, NC.*

We are developing an *in vitro* platform using primary mouse hepatocytes isolated from the genetically diverse lines of the Collaborative Cross and cultured as 3D spheroids to enable the rapid and cost-effective investigation of gene-by-treatment interactions associated with drug-induced liver injury (DILI). The objective of this study was to compare the spheroid model to native liver and fresh hepatocytes using global gene expression profiling and quantitative targeted proteomics (QTAP) and to demonstrate time and concentration-dependent toxicity responses to DILI drugs. Microarray profiling of the entire transcriptome and QTAP assessing 10 important drug metabolizing enzyme and transporter (DMET) proteins were performed on liver, hepatocytes, and corresponding hepatocyte spheroids cultured for 1, 7, and 14 days post spheroid formation from N=3 male and female C57BL/6 mice. Differences among models were determined by ANOVA with linear contrasts (FDR $p<0.05$ and $|FC|>1.5$). In total, 1073 of 12826 genes (8.4%) measured in spheroids were differentially expressed compared to liver and hepatocytes. However, only 52 genes (0.4%) were differentially expressed in spheroids over time and no changes were observed in mRNAs encoding the 10 important DMET proteins. Correspondingly, the levels of 9 of 10 important DMET proteins measured by QTAP were decreased in spheroids compared to hepatocytes and liver. However, only 1 of the 10 DMET proteins (Cyp2e1) was decreased in spheroids over time. Time and concentration-dependent decreases in ATP and albumin were observed in response to acetaminophen, fialuridine, AMG-009, and tolvaptan with albumin responses to chronic exposures observed for 3 of 4 drugs (all but acetaminophen) at <1 μM concentrations. Collectively, these results demonstrate maintenance of mRNA and DMET protein levels from days 1-14 post spheroid formation and the ability to show responses to DILI drugs at clinically relevant concentrations in chronic toxicity studies using the spheroid model.

1958 Effect of Low- and High-Fat Diet on Lipidomic Blood Changes Induced after *In Vivo* Exposure of Male C57BL/6 Mice to Perflorooctane Sulfonic (PFOS) and Perflourohexane Sulfonic Acid (PFHxS)

L. Ingram[1], M. Pfohl[2], A. Slitt[2], and B. S. Cummings[1]. *[1]University of Georgia, Athens, GA; and [2]University of Rhode Island, Kingston, RI.*

Millions of people are exposed to per- and polyfluoroalkyl substances (PFASs) exposure every day through diet and it is known that there is an association between exposure to these PFOS and hepatic steatosis. However, there is a gap in knowledge about the association between changes in blood lipids and exposure to PFASs, as well as lack of knowledge about the effects of low and high fat diet on both hepatotoxicity and blood lipids. We addressed these gaps by exposing C57BL/6 mice to perfluorooctane sulfonic acid (PFOS) and perfluorohexane sulfonic acid (PFHxS) in low-fat diet (LFD (11% kcal from fat)) and high-fat high carbohydrate diet (HFD (58% kcal from fat)) for 29 weeks. Changes in the blood lipidome were analyzed using both an untargeted shotgun approach (electrospray ionization-mass spectrometry (ESI-MS)), and a targeted quantitative approach (HPLC-ESI-Orbitrap-MS/MS). Blood was isolated from C57BL/6 mice exposed to either PFOS or PFHxS (~0.3mg/kg/day) via low or high fat diet, and lipids were extracted from the blood using the Bligh-Dyer method. The initial untargeted ESI-MS approach demonstrated distinct clustering within the blood lipidome with the most dramatic shifts occurring between LFD and LFD with PFAS (L-PFOS and L-PFHxS) exposure and HFD and HFD with PFAS (H-PFOS and H-PFHxS) exposure. HPLC-ESI-MS/MS analysis revealed a total of 2,918 discriminatory ion features for lipids isolated from mice exposed to LFD, L-PFOS, L-PFHxS, HFD, H-PFOS, and H-PFHxS. Mice exposed to PFOS and PFHxS in the presence of a LFD had higher levels of phosphatidylcholine (PC), as compared to those only exposed to the LFD. 14:0-22:2 PC was enriched in the blood of mice exposed to L-PFHxS and L-PFOS as compared to LFD control mice. Surprisingly, plasmalogens were significantly enriched in mice exposed to H-PFHxS as compared to HFD control mice. These data demonstrate the novel finding that PFAS exposure alters the blood lipidome of mice after *in vivo* exposure, and suggests that the effect of PFAS's on the blood lipidome is diet-dependent. The serum lipidome findings indicate a correlation between dietary consumption and PFAS exposure, which may provide a basis for identification of PFAS related lipid predictors.

1959 Hepatocyte AhR Expression Mediates TCDD-Induced Hyaluronan Accumulation and Extracellular Matrix Degradation during Carbon Tetrachloride-Induced Liver Injury

N. L. Johnson[1], G. N. Cholico[2], K. A. Mitchell[2], and M. T. Pritchard[1]. *[1]University of Kansas Medical Center, Kansas City, KS; and [2]Boise State University, Boise, ID.*

Liver fibrosis occur after relentless injury due to an imbalance between the synthesis and degradation of extracellular matrix (ECM) molecules, such as collagen and hyaluronan (HA). We previously found that aryl hydrocarbon receptor (AhR) activation by 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) exacerbates liver injury, inflammation, and myofibroblast activation during experimental liver fibrosis induced by carbon tetrachloride (CCl_4). This effect of TCDD was abrogated in CCl_4-treated mice with AhR-deficient hepatocytes ($AhR^{\Delta Hep}$), but unexpectedly, the extent of liver fibrosis was not reduced in these mice. Our objective was to determine if increased HA content and/or reduced ECM degradation mediated the robust fibrosis observed in CCl_4/TCDD-treated $AhR^{\Delta Hep}$ mice. Male $AhR^{\Delta Hep}$ and $AhR^{fl/fl}$ mice were treated with 1.0 ml/kg CCl_4 every four days for five weeks, and TCDD (100 ug/kg) was administered during the final week of the experiment. Mice were euthanized at the end of the five-week period. A hyaluronan binding protein assay was used to localize hepatic HA, *in situ* zymography was performed to evaluate gelatinase activity, and RNA sequencing was used to interrogate gene expression. Results indicate that TCDD treatment increased HA content in the CCl_4-injured liver of $AhR^{fl/fl}$ mice but not $AhR^{\Delta Hep}$ mice. Increased HA correlated with increased gene expression for hyaluronan synthase-1 and the HA cell surface receptor, CD44, as well as decreased expression of hyaluronidase (*Hyal2*). *In situ* zymography showed that cotreatment with CCl_4 and TCDD increased gelatinase activity in $AhR^{fl/fl}$ mice. In contrast, there was no increase in gelatinase activity among any treatment groups in $AhR^{\Delta Hep}$ mice, and transcript levels for matrix metalloproteinases-8 and -9 were consistently reduced. These data suggest that hepatocyte AhR signaling mediates the TCDD-induced accumulation of HA in the fibrotic liver, as well as ECM degradation, the latter of which likely underlies the robust fibrosis observed in CCl_4/TCDD-treated $AhR^{\Delta Hep}$ mice. *Supported by P20GM103549 & P30GM118247.*

1960 Cryopreservation of Encapsulated 3D Micro-Livers, HepatoPearls, through Careful Optimization of Freezing and Thawing Processes

I. Bivas, Z. Hamidouche, T. Baudequin, and N. Dianat. *Cyprio, Paris, France.* Sponsor: S. Fergusson

Approval of new drug candidates is a long and costly process. It is unfortunate to fail during or after clinical trials due to undetected toxicity issues during preclinical studies. Indeed, performant cellular models providing reliable risk prediction and allowing for high-throughput *in vitro* screening are still lacking. Previously, Cyprio showed that HepatoPearl®, a 3D spheroid liver model encapsulated in alginate pearls, is a viable and metabolically functional human model for acute and chronic toxicity tests and DMPK studies. It ensures improved CYP450 enzymes activity over a longer lifespan (6 weeks) compared to 2D culture, as well as urea and albumin synthesis and bile efflux. To go further and provide a ready-to-use 3D cellular model for high-throughput screening, we cryopreserved HepatoPearls® to enable long-term in-lab storage. We compared 5 different protocols from faster to slower cooling rates and 2 thawing protocols. HepatoPearls® were cryopreserved accordingly immediately after production then kept in liquid $N_2$for 1 week before thawing, 1-month culture and analysis. We investigated alginate pearls integrity, Cyp3A4 enzymatic activity and induction, urea and albumin synthesis and cell viability in comparison with non-cryopreserved ones. With the fastest cooling rate, we observed 27.4% of altered pearls (respectively 3.6% destroyed and 23.8% damaged) post-thawing. However, with slower and more controlled cooling rates (multi-step processes), impacted pearls decreased to 6.8% (respectively 0.36% and 6.45%). Interestingly, the different thawing processes didn't affect the number of altered capsules, allowing us to validate a protocol similar to the thawing step of standard cryopreserved cells (37°C water bath). The cell functionality assessment showed that HepatoPearls® were still presenting equivalent levels of CYP3A4 expression over one month compared to non-cryopreserved samples. Moreover, spheroid integrity and cell viability remained unaffected. In summary, we validated the development of an efficient cryopreserved model of HepatoPearls® for high throughput *in vitro* hepatotoxicity tests. From a broader perspective, this is a major step towards an off-the-shelf human 3D liver model, physiologically relevant over 1 month and allowing for easy and adaptable study designs. Further developments to cryopreserve encapsulated liver cells from other origins (species and cell sources) are ongoing.

1961 Dose-Dependent Effects of 2,3,7,8-tetrachlorodibenzo-*p*-Dioxin (TCDD) on Acetyl-CoA Metabolism

N. Zacharewski[1,2], R. Nault[2,3], R. R. Fling[2,3], T. R. Zacharewski[2,3], and K. A. Fader[2,3]. *[1]Trinity College, Hartford, CT; [2]Michigan State University, East Lansing, MI; and [3]Michigan State University Institute for Integrative Toxicology, East Lansing, MI.*

Acetyl-CoA is a two-carbon metabolite that plays a central role in carbohydrate, lipid, and protein metabolism. Its primary function is to deliver an acetyl group into the Krebs cycle leading to further oxidation and production of adenosine triphosphate (ATP). 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD), a persistent environmental contaminant, has been shown to cause the development and progression of steatosis to steatohepatitis in mice resembling human non-alcoholic fatty liver disease (NAFLD). TCDD activates the aryl hydrocarbon receptor (AhR), a transcription factor responsible for regulating gene expression. TCDD causes central carbon metabolism reprogramming in mice, however the effects on acetyl-CoA metabolism have not been investigated. In this study, male C57BL/6 mice were orally gavaged every 4 days for 28 days with sesame oil vehicle control or 0.01, 0.03, 0.1, 0.3, 1, 3, 10, and 30 µg/kg TCDD. Hepatic acetyl-CoA levels and gene expression were examined using untargeted liquid chromatography tandem mass spectrometry and RNA-Seq analysis, respectively. At 3, 10, and 30 µg/kg TCDD, hepatic acetyl-CoA levels decreased 1.9-, 28.5-, and 6.4-fold, respectively. TCDD also repressed gene expression associated with β-oxidation, fatty acid biosynthesis, ketone body metabolism, and coenzyme-A metabolism. Decreased protein levels of ATP citrate lyase (ACLY) and short-chain acyl-CoA synthetase 2 (ACSS2) were confirmed, suggesting sources (e.g. citrate and acetate) and utilization (e.g. fatty acid biosynthesis) of acetyl-CoA were repressed. Depletion of acetyl-CoA is consistent with reduced protein acetylation and AMPK activation, indicating a hepatic energy deficiency which may compromise cell proliferation and antioxidant defenses. *Funded by the Superfund Research Program P42ES04911 and the National Institutes of Health ES029541.*

1962 Effects of 10 New Generation PFAS-Containing Aqueous Film Forming Foams (AFFF) and Single PFAS Compounds on Human Liver Cell Viability and Function

K. A. Mauge-Lewis, M. Devito, and S. Fenton. *NIEHS, Durham, NC.*

Per- and polyfluoroalkyl substances (PFAS) are man-made chemicals characterized by their carbon-fluorine bonds, and resistance to heat, water, and oil. PFAS have been used in hundreds of industrial applications and consumer products; a use they are well known for is in aqueous film forming foams (AFFF) to extinguish hydrocarbon fuel-based fires. Due to high stability and bioaccumulation of some PFAS in the AFFF, they have been measured in bodies of water and in human blood worldwide. The purpose of this study was to evaluate the cytotoxicity of 10 AFFFs, thought to be in current use in 2018, in a human hepatocyte/cholangiocyte cell line (HepaRG). Numerous studies have demonstrated that the liver is a particularly sensitive tissue to the adverse effects of PFAS. Metabolically-competent HepaRG liver cells were exposed to the AFFF by blinded allocation for 24 hours at a volume-per-volume concentration range of 0.0008% to 0.8% in media. CellTiter-Glo luminescence assay detected substantial declines in cellular viability at concentrations between 0.1% and 0.4%, and total cell death between concentrations of 0.5% and 0.8% for several AFFF. Several of the individual components that have been determined to be present in each of the AFFF, such as 6:2 fluorotelomer sulfonate (6:2 FTS) and non-ionic surfactants, such as sodium lauryl sulfate (SLS), were identified and evaluated for cytotoxicity. 6:2 FTS had an active range of cytotoxicity at approximately 100 uM to 300 uM. Additionally, although SLS was tested within the relevant range found in AFFF, it did not explain the effect of AFFF. Furthermore, lipid accumulation assays and H2AXP DNA repair assays were utilized for the evaluation of how these AFFF and individual PFAS compounds affect functional processes in exposed, metabolically-competent HepaRG liver cells. The AFFF and single PFAS compounds with the highest EC_{50} and least biological toxicities will be prioritized for testing *in vivo*, in hopes of identifying compounds that may serve as alternatives to the legacy PFAS compounds that are currently used in AFFF solutions.

1963 Fgf15 Overexpression and PPARα Activation as a Combination Therapy for NASH in a Mouse Model

M. F. Stofan, B. Kong, and G. Guo. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Non-alcoholic fatty liver disease (NAFLD) is a progressive disease that is increasing worldwide along with the obesity epidemic. Approximately 25% of the US population have NAFLD with up to 30% of that NAFLD population developing non-alcoholic steatohepatitis (NASH). Currently, there is no FDA approved treatment for NASH. One emerging therapeutic target for NASH is fibroblast-growth factor 19 (FGF19, mouse ortholog FGF15). This hormone is expressed in the small intestine and regulates bile acid synthesis and glucose homeostasis. Additionally, activation of peroxisome proliferator-activated receptor-alpha (PPARα) increases fatty acid oxidation in hepatocytes and decreases triglycerides. Therefore, the overexpression of FGF15 in conjunction with a PPARα agonist, was hypothesized to further reduce the severity of NASH in a mouse model. To investigate, 8 week old wild-type (WT; C57BL/6J) and transgenic *Fgf15* (*Fgf15*Tg) mice were maintained on a control diet (CD) or high-fat diet (HFD) for 6 months. PPARα agonist WY-14643 (CAS #: 50892-23-4) (0.05% w:w) was administered for 6 weeks to HFD groups once NASH was induced at 4 months. HFD feeding increased body weight in both genotypes although *Fgf15*Tg mice were more resistant to weight gain. Glucose tolerance tests (GTTs) showed *Fgf15*Tg mice were more glucose tolerant, suggesting they are more insulin sensitive, while HFD decreased glucose tolerance in both genotypes. Serum levels of cholesterol and activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were decreased in *Fgf15*Tg mice after HFD feeding, suggesting hepatic protection. Activation of PPARα promoted weight loss and decreased serum levels of cholesterol, triglycerides, ALT, and AST. In contrast, alkaline phosphatase (ALP) activity was increased after PPARα activation. Combination treatment resulted in further weight loss, reduced serum levels of cholesterol, triglycerides, ALT, and AST; however, combination treatment did not further improve serum biochemical markers compared to individual treatments. *Funding: R21ES029258, BX002741, T32ES007148.*

1964 The Environmental Contribution to Nonalcoholic Fatty Liver Disease Severity

M. Cave[1,2], M. R. Smith[3], Y. Go[3], K. Uppal[3], N. Smith[4], S. Smith[1], D. P. Jones[3], and N. Chalasani[5]. *[1]University of Louisville, Louisville, KY; [2]Robley Rex VA Medical Center, Louisville, KY; [3]Emory University, Atlanta, GA; [4]IUPUI, Indianapolis, IN; and [5]Indiana University, Indianapolis, IN.*

Nonalcoholic fatty liver disease (NAFLD) is the most common chronic liver disease. This cross-sectional NAFLD study seeks to determine: (*i*) if environmental exposures are associated with the severity of steatosis/fibrosis; and (*ii*) if steatosis/fibrosis share any common metabolic pathways. The precision medicine approach applies high resolution exposomics/metabolomics to well-characterized NALFD patients. Archived de-identified plasma samples/data from 150 consenting adult NAFLD patients were utilized. Imaging biomarkers of steatosis (controlled attenuation parameter, CAP) and (liver stiffness measurement, LSM) were previously determined by Fibroscan®. LC-MS^2 was performed using a High-Field Q-Exactive mass spectrometer with C18 (negative ionization) and HILIC (positive ionization) columns. apLCMS and xMSanalyzer were used for data extraction. Linear regression analysis was performed on log2 transformed and quantile normalized data using R. Statistical significance was set at FDR<0.2. Pathway enrichment analysis was performed using mummichog 2.0. Metabolic features were annotated using xMSannotator and an in-house validated library. 65% of subjects were women and 51% were diabetic. Mean age and BMI were 51.4±12.4 (SD) and 36.0±7.4 kg/m^2. Mean CAP and LSM were 325.8±53.5 dB/m and 12.1±11.3 kPa. 30,800 features were detected by LC-MS^2. Of these, 272 were significantly associated with CAP and 271 with LSM. CAP was positively associated with features putatively assigned to pesticides (bromuconazole and methomyl) and hexabromodibenzofuran. Bromuconazole levels were 5.2-fold higher in the highest *vs.* lowest exposure quintile. LSM was positively associated with nicotine and features putatively assigned to pesticides (metolcarb and nitromethylidenehydrazinylbenzoic acid), a prescription medication (olopatadine) and copper benzoate. Metabolic pathways significantly enriched with CAP were: bile acid, carnitine shuttle, porphyrin, aminosugars and amino acids. Pathways significantly enriched with LSM included: porphyrin, carnitine shuttle, bile acid, C21 steroid hormones and other amino acids. Specific environmental exposures were associated with more severe steatosis and fibrosis in NAFLD patients. Steatosis/fibrosis shared several metabolic pathways. More precision medicine data are required to better understand the environmental contribution to NAFLD.

1965 Combined High Content Imaging in Liver Microtissues and Mitochondrial Toxicity to Predict DILI

P. Walker, A. Raza, J. Eakins, S. Ryder, and C. Bauch. *Cyprotex Discovery Limited, Alderley Edge, United Kingdom.* Sponsor: C. Strock

Drug induced liver injury (DILI) is a leading cause of drug attrition in drug development. A considerable aetiology of DILI is mitochondrial toxicity leading to withdrawal of drugs such as troglitazone and cerivastatin (1). In order to avoid such liabilities, an improvement in preclinical cell based models are vital that can predict the mitochondrial toxicity in early stages of drug development. Such models will reduce the late stage attrition of drug candidate and ultimately lead to safer drugs in the market. The approach of 3D liver models using human isolated hepatocytes and human non-parenchymal cells provides a physiological microtissue with prolonged cytochrome P450 activity up to 3 weeks in culture. The model combined with biochemical assay (ATP) has been shown as a sensitive and specific strategy to predict DILI (2-3). Here, we have optimized the method of producing reproducible liver microtissue (hLiMTs) and combined this with multi-parametric confocal high content imaging (HCI) allowing the determination of mitochondrial dysfunction (mitochondrial mass, mitochondrial membrane potential, mitochondrial specific ROS and cellular ATP). This 3D HCI approach was also combined with a mitochondrial stress test to determine mitochondrial liability using oxygen consumption rate (OCR) and extracellular acidification rate (ECAR). Combining both of these approaches indicated that mitochondrial effects in hLiMTs was implicated in 42% of known DILI compounds from a reference set of 62 compounds. Furthermore by taking all the endpoints into account the overall sensitivity and specificity of this approach was 87% and 100% respectively. This study illustrates the importance of considering mitochondrial liabilities in DILI prediction and in combination with 3D human liver models as a useful approach to de-risk DILI in early drug discovery screens. 1. 1966 An Imaging-Based RNA-Interference Screen Reveals Novel Key Regulators of the Drug-Induced Endoplasmic Reticulum Stress Response

M. Niemeijer, P. Kartal, G. Callegaro, and B. van de Water. *Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands.*

Mechanistic understanding of drug-induced liver injury (DILI) is currently still lacking and therefore hard to predict. Some of these drugs induce endoplasmic reticulum (ER) stress and activate the unfolded protein response. However during chronic ER stress, activation of the UPR will be insufficient and will activate apoptotic pathways mediated by CHOP leading to hepatotoxicity. To improve mechanistic understanding, we aimed to identify novel key regulators of CHOP using a siRNA-screening approach. First, the suitability of the HepG2 CHOP-GFP reporter for evaluating CHOP induction was determined using various ER stress inducers. Secondly, a concentration of 6 µM of tunicamycin was found to be most optimal to study CHOP induction perturbations by siRNA silencing. Using these conditions, we applied an imaging-based RNAi screen of the druggable genome targeting 3457 genes in HepG2 CHOP-GFP cells to identify novel regulators of the tunicamycin-induced ER stress response. CHOP-GFP expression was evaluated after 16 hours of tunicamycin exposure which was altered by 201 genes upon knockdown from which 74 could be confirmed. These potential regulators were further evaluated with other ER stress inducers and their role in induction of other UPR-related genes such as ATF4, XBP1 and BIP. Next, their role in DILI compound-induced ER stress was determined, where potential regulators could affect significantly the UPR activation during DILI compound exposure. As validation, CRISPR/Cas9-mediated knockout showed similar effects on CHOP induction dynamics during ER stress. To evaluate the relevance of 10 selected novel regulators for the human liver during ER stress, we evaluated the transcriptome in both HepG2 and primary human hepatocytes (PHHs) after knockdown and subsequent exposure for 16 hours of tunicamycin. Three potential regulators were confirmed in PHHs which showed upon knockdown perturbation of UPR activation after tunicamycin. Pathway analysis revealed their key role in multiple ER signaling pathways, namely translation, protein degradation, UPR and protein trafficking. Overall, our RNAi screen allowed the identification of novel regulators of the drug-induced ER stress response and will further shape our understanding and prediction of DILI liabilities. *Supported by EU-ToxRisk project (grant agreement No 681002) and IMI MIP-DILI project (grant agreement 115336).*

1967 Differential Hepatic Recovery after Sub-Lethal Microcystin-LR Exposure in Healthy versus Nonalcoholic Steatohepatitis Rats

T. Arman, K. D. Lynch, J. T. Aldan, B. J. Bechtold, and J. D. Clarke. *Washington State University, Spokane, WA.*

Nonalcoholic steatohepatitis (NASH) is a progressive liver disease, and can advance to cirrhosis or hepatocellular carcinoma with continual exposure to exogenous stressors like toxicants or poor diet. Microcystin-LR (MCLR) is a hepatotoxic cyanotoxin known to cause a NASH-like phenotype, and exacerbate preexisting diet-induced NASH. Previous data indicate the liver can recover after MCLR-induced hepatotoxicity in healthy rodents. We hypothesize that MCLR-induced hepatotoxicity in diet-induced NASH will not recover due to continued exogenous stress from the poor diet. Male Sprague-Dawley rats were divided into two groups and fed a control or a high fat/high cholesterol (HFHC) diet for eight weeks. The animals were then subdivided into two treatment groups receiving intraperitoneal injections of 0.9% saline (vehicle) or 30 µg/kg MCLR every other day for two weeks. Sets of animals from each diet/treatment subgroup were euthanized after the MCLR exposure period, and subsequently at two or four weeks of recovery. Diet regimens were maintained for the entirety of the study. MCLR toxicity altered fasting plasma biochemistries in both healthy and NASH groups, which recovered to basal levels after four weeks. At the end of the two-week MCLR exposure period, hepatic apoptosis was evident in both control and NASH groups, as indicated by ~56% decrease in expression of Bcl-2 and up to ~130% and ~184% increase in cleaved caspases 3 and caspase 9, respectively. Protein phosphatase (PP) bound MCLR was observed by western blot after MCLR exposure in both diet groups, but was not observed after two and four weeks of recovery. A low molecular weight form of PP2A (~25 kDa) was observed following MCLR toxicity in both diet groups that persisted through two and four weeks of recovery despite turnover of the PP2A bound MCLR. MCLR-induced liver fibrosis resolved after four weeks of recovery in the healthy group, but persisted in the NASH group. Following four weeks of recovery, the MCLR treated NASH subgroup had less liver steatosis and more liver inflammation compared to the vehicle treated NASH subgroup. These data suggest that despite recovery in plasma biochemistries and resolution of apoptosis, continued stress of a poor diet following MCLR exposure impairs hepatic recovery mechanisms, and resembles a burnt-out NASH phenotype. *Funding: 4R00ES024455.*

1968 Construction of Hepatic Vascular Model and Toxicity Assessment System That Can Predict DILI Compounds

Y. Naito[1], Y. Sorayama[2], H. Kohara[3], S. Kitano[1], S. Irie[1], and M. Matsusaki[2]. *[1]Technical Research Institute, Toppan Printing Co. Ltd., Saitama, Japan; [2]Osaka University, Osaka, Japan; and [3]Takeda Pharmaceutical Company Limited, Kanagawa, Japan.* Sponsor: T. Yokoi

Drug-Induced-Liver-Injury (DILI) is one of the most significant reasons drug development or sales are discontinued. Due to the complicated mechanism of DILI, it still has been far difficult to predict the toxicity before or even after clinical study phase. Researches on predicting such toxicity by using *in vitro* hepatic tissue constructed from human-derived cells have been developed in many groups. But it is also difficult to mimic highly ordered structure like blood vessels, and no hepatic-toxicity assessment system hasn't reached satisfactory level. The purpose of this study is constructing of a hepatic vascular model, and toxicity assessment system by using the model. At first, we constructed a liver-like tissue model consisted from human hepatocytes from xenogeneic host livers (PXB cell), Sinusoidal Endothelial Cell (SEC), and hepatic stellate Cell (LX-2). In this case, we applied our unique 3D culture method. This method can be characterized by mixing cells with collagen in a specific form. By performing immunostaining on the model and observed the morphological features by CLSM, we confirmed the multi-layered structure of blood vessels and hepatic cells. We also evaluated the model in terms of general function of liver, albumin secretion. The models were able to keep albumin secretion at least within 15 days without drastic decreasion. Furthermore, we confirmed the possibility that the model can be used for toxicity assessment by applying typical DILI compound. The model can predict the toxicity of DILI compound as similar to traditional 2D culture. In summary, we constructed a liver-like model having multi-layered structure of blood vessel and hepatocytes. The model kept albumins secretion within 15 days. We showed that the model can function at least as much to 2D culture. In future plan, we will characterize the model by defining unique toxicity assessment ability.

1969 Image-Based Quantification of Bile Canalicular Alteration in HepaRG Cultures for Prediction of Drug-Induced Cholestasis

S. Martin[1], R. Li[2], E. Edwards[3], T. Villani[3], D. Steen[4], and C. Chesne[2]. *[1]Eurosafe, Saint-Grégoire, France; [2]Biopredic International, Saint-Grégoire, France; [3]Visikol Inc., Whitehouse Station, NJ; and [4]Biopredic Inc., Kansas City, KS.*

Hepatic cholestasis involves the abnormal accumulation of bile acids in bile canaliculi (BC) and is implicated as a one of mechanism of drug-induced liver injury. While it has long been suggested that inhibition of bile salt export pumps (BSEP) underlies such abnormal accumulation, more recent studies have found that known drug-induced BSEP inhibition is not the only mechanism of cholestatic DILI. It has been demonstrated that Rho kinase/Myosin Light Chain kinase pathway plays a key role in the alterations. Objective: Our objective was to provide a reliable, quantitative assay that instead more broadly characterizes BC dynamics with the aim of evaluating cholestatic risk more accurately. Through this study, this assay was validated using compounds with known cholestatic risk. HepaRG cells were cultured, treated with or without chlorpromazine and fasudil, and labeled with CDFDA. Images were acquired by fluorescence microscopy and thresholded to enable BC object detection and area quantification. Using automated image analysis, the area of bile canaliculi in treated samples were measured. It was shown that fasudil and chlorpromazine resulted in strong BC dilation and constriction, respectively. Fasudil caused a 44% increase in mean areas measured in HepaRG cells, whereas chlorpromazine induced 41% decrease in mean areas of BC with respect to control cells. Through the combination of a HepaRG *in vitro* model for cholestasis and a quantitative imaging approach to evaluating BC dynamics, this new approach represents a promising screening approach for the prediction of cholestatic liabilities.

1970 Drug-Induced Impairment of Mitochondrial Fatty Acid Oxidation and Steatosis: Assessment of Causal Relationship with 45 Pharmaceuticals

R. Loyant[1], N. Buron[1], M. Porceddu[1], C. Martel[1], J. Allard[2], B. Fromenty[2], and A. Borgne-Sanchez[1]. *[1]Mitologics, Créteil, France; and [2]INSERM Institut NUMECAN, Rennes, France.* Sponsor: Y. Will

Drug-induced liver injury (DILI) represents a major issue for some treated patients and for pharmaceutical companies, being a frequent cause of drug withdrawal from the market. Steatosis (lipid accretion) is one of the diverse liver lesions that can be induced by drugs. While microvesicular steatosis is rare and fatal, macrovacuolar steatosis is relatively common and benign, although it can progress to steatohepatitis and cirrhosis. Both types of steatosis can be secondary to an impairment of fatty acid β-oxidation (mtFAO), although such impairment is stronger in microvesicular steatosis. Importantly, mtFAO can be impaired by direct inhibition of mtFAO enzymes or indirectly via an inhibition of the respiratory chain activity. Of note, an overall causal relationship between steatosis and mtFAO inhibition has not yet been established with a high number of pharmaceuticals. Hence, 32 steatogenic and 13 non-steatogenic drugs were tested for their ability to induce direct or indirect inhibition of mtFAO in mouse liver mitochondria (MiToxView® platform; Porceddu *et al.,* 2018). To this end, we assessed oxygen consumption driven by substrates of complex I (malate/glutamate), complex II (succinate) and mtFAO (palmitoyl-L-carnitine, octanoyl-L-carnitine, or palmitoyl-CoA + L-carnitine), allowing us to specify the mechanism of mtFAO impairment, if any. Our multiparametric assays in isolated liver mitochondria revealed that steatogenic drugs frequently induced mtFAO impairment. Indeed, 25 out of 32 steatogenic drugs (78%) inhibited mtFAO with an EC_{20} lower than 400 µM. For some drugs (e.g. methyldopa and dexamethasone), mtFAO impairment was not related to an inhibition of the respiratory chain, contrary to amiodarone and perhexiline. Inhibition of mtFAO was confirmed in differentiated HepaRG® cells with some steatogenic compounds (e.g. indomethacin and rifampicin). Finally, mtFAO inhibition was observed with only 5 of the 13 non-steatogenic drugs (38%). However, such inhibition was in general weak, excepted for glimepiride. Porceddu M, Buron N, Rustin P, Fromenty B, and Borgne-Sanchez A. *In vitro* assessment of mitochondrial toxicity to predict drug-induced liver injury. 1971 Transcriptomic Profiling of the Inter-Individual Variability of Drug-Induced Cellular Stress Response Activation Using a Large Panel of Primary Human Hepatocytes

M. Niemeijer[1], S. Huppelschoten[1], A. Baze[2], C. Parmentier[2], R. S. Paules[3], L. Richert[2], and B. van de Water[1]. *[1]Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands; [2]KaLy-Cell, Plobsheim, France; and [3]NIEHS, Research Triangle Park, NC.*

Drug-induced liver injury (DILI) remains a major concern for the clinic and pharmaceutical companies. Given the diversity of DILI outcomes, it is crucial to improve its prediction at an early phase in drug development by integrating mechanistic understanding. Many hepatotoxicants are known to induce adaptive stress responses, a cellular mechanism to overcome stress. Since some patients are more prone to develop DILI, it is key to map the inter-individual variability in activation of these stress responses. Therefore, we profiled the transcriptome of a panel of 50 cryo-preserved primary human hepatocytes derived from different individuals exposed for 8 or 24 h to a broad concentration range of tunicamycin for unfolded protein response (UPR), diethyl maleate for oxidative stress response, cisplatin for DNA damage response and TNFα for NF-κB signaling. Transcriptomic profiles were related to LDH leakage as a measure for cytotoxicity. The variance in the concentration-dependent stress response activation among individuals could be captured, where the average of point-of-departures (PoD) for UPR-related genes resulted in a maximum difference of 866 fold. For each stress response, hepatocytes were classified based on a sensitivity score using maximum fold change and PoD for pathway-related genes. Correlation of the sensitivity scores and their background such as disease status was identified. To eliminate that the de-differentiation rate is not the driver of the found variability in stress response activation, the transcriptome in liver tissue, suspension and 24 hour plated for a selection of hepatocytes was profiled. Next, the three most sensitive or insensitive hepatocytes for UPR or oxidative stress response were exposed to various DILI compounds. Here, sensitive hepatocytes showed higher upregulation of pathway-related genes for most of the DILI compounds compared to insensitive hepatocytes. In conclusion, profiling of the inter-individual variance in drug-induced stress response activation will aid in the improved understanding of the variance in susceptibility towards DILI among patients. *Supported by EU-ToxRisk project (grant agreement No 681002) and IMI MIP-DILI project (grant agreement 115336).*

1972 Fibroblast Growth Factor 15 (FGF15) Suppresses NASH Development in Mice

M. J. Campbell, B. Kong, and G. L. Guo. *Rutgers, The State University of New Jersey, New Brunswick, NJ.*

Non-Alcoholic Steatohepatitis (NASH) is a severe progression of Non-Alcoholic Fatty Liver Disease (NAFLD) in which liver steatosis, inflammation and hepatocyte damage occurs. NASH is a prevalent public health concern on the rise with reports of 12% of individuals being affected with this disease in the United States. There are currently no treatments. Farnesoid X receptor (FXR), a nuclear receptor that is critical in regulating glucose and lipid metabolism homeostasis, is activated by bile acids. Previous research has found that FXR protects the liver from NASH progression. An intestinal FXR downstream target gene is fibroblast growth factor (FGF) 15/19. The role of FGF15 in NASH development is unclear. This current research determines the effect of intestinal FGF15 deficiency on NASH development using the conditional knockout (CKO) of intestinal *Fgf15* in a high fat diet (HFD)-induced NASH model in mice. Male *Fgf15* CKO mice were fed either control chow or high fat diet, and sacrificed at 1, 3, and 6 months for assessment of NASH progression. Results suggest that FGF15 decreases bile acid synthesis, hepatic inflammation, and liver fibrosis. In conclusion, FGF15 serves a vital player in gut-liver cross talk, most likely protecting the liver from NASH-related excess bile acid injury. As the NASH global prevalence increases, therapeutic research for possible drug targets is of utmost importance. *Supported by ASPET SURF, NIHR25ES020721 and R01GM104037.*

1973 Acute TCDD Exposure Produces NAFLD-Like Pathology and Gene Expression in Mice with Chronic Liver Injury

G. N. Cholico, K. A. Cornell, and K. A. Mitchell. *Boise State University, Boise, ID.*

Non-alcoholic fatty liver disease (NAFLD) consists of a spectrum of diseases divided histologically into two subgroups: nonalcoholic fatty liver (NAFL), which refers to steatosis without inflammation, and non-alcoholic steatohepatitis (NASH), which includes steatosis and necroinflammation with or without fibrosis. Patients in both subgroups are at risk for developing progressive fibrosis, which can lead to cirrhosis and hepatocellular carcinoma. NAFLD development and progression are influenced by metabolic disarrangements, such as obesity, type 2 diabetes, metabolic syndrome and insulin resistance. Increasing evidence indicates that exposure to environmental toxicants may also be a significant risk factor for NAFLD and NASH. We have previously shown that activation of the aryl hydrocarbon receptor (AhR) by 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) exacerbates liver necrosis, inflammation, myofibroblast activation, and fibrogenesis in a mouse model of chronic liver injury elicited by carbon tetrachloride (CCl_4) administration. In the present study, we expanded these findings to test the hypothesis that acute TCDD exposure produces a NAFLD/NASH-like condition in mice with CCl_4-induced liver injury. Mice were treated with 1.0 ml/kg CCl_4 every four days for five weeks to elicit chronic liver injury, and TCDD (100 µg/kg) was administered during the final week of the experiment. Histological analysis revealed that TCDD treatment elicited hepatic steatosis, necroinflammation, and fibrosis in CCl_4-treated mice. This collection of pathological endpoints was not observed in mice treated with CCl_4 or TCDD alone, and it was not observed in CCl_4/TCDD treated mice with AhR-deficient hepatocytes. RNA-sequencing analysis revealed that co-treatment with CCl_4 and TCDD produced a NAFLD-like gene expression profile in the liver that was dependent on hepatocyte AhR signaling. For example, TCDD treatment increased the expression of genes that promote triglyceride accumulation, and transcriptionally inactivated genes related to glycolysis, gluconeogenesis, glycogen synthesis, as well as insulin signaling. Based on these findings, we conclude that exposure to TCDD may provide the "second hit" required to produce a NAFLD/NASH phenotype in a previously injured liver, and this appears to be mediated by AhR-mediated signaling in hepatocytes.

1974 Time to Treatment after Plating Impacts PFAS Induction of Gene Expression in Cryopreserved Human Hepatocytes

L. C. Ford, E. Marques, W. Wei, M. Pfohl, J. Agudelo, and A. Slitt. *University of Rhode Island, Kingston, RI.*

Per- and polyfluoroalkyl substances are man-made compounds that are ubiquitous in the environment. These compounds originate from the use of aqueous film forming foams (AFFF), non-stick, water-resistant household and personal items. Perfluorooctane sulfonate (PFOS), and perfluorooctanoic acid (PFOA), and perfluorohexane sulfonate (PFHxS) have all been linked to liver damage. PFASs have limited passive permeability and are known substrates for membrane transporters. Organic Anion Transporting Polypeptides (OATPs) and Organic Anion Transporters (OATs) to enter cells, especially hepatocytes and renal proximal tubules. It has been described that OATP expression decreases in 2-D cultured human hepatocytes the longer they remain in culture. Thus, plating time, which can impact OATP expression, could be a significant variable in predicting the relative potency of PFASs, especially for emerging PFASs that are poorly understood. Thus, the goal of this study was to observe whether treating sooner after plating the cryopreserved hepatocytes would induce a more robust transcriptional response compared to the typical 24-hour time point. It was hypothesized that if OATP and OAT transporter expression is higher at an earlier time point after plating (4 hours), then it would result in more uptake of PFAS into the hepatocytes, greater PFAS effects compared to the traditional 24hour time point. Cryostax 5-donor pool of cryopreserved human hepatocytes (HH) were cultured following the manufacturer's protocols. 4-hours after plating, the hepatocytes were treated with PFOS, PFOA, and PFHxS at a series of concentrations (10 nM, 0.025 µM, 0.25 µM, 2.5 µM, 25 µM). 24-hours after plating, a second set of human hepatocytes were treated with the same compounds at the same concentrations. After the 48-hour treatments, the cells were lysed and the gene targets were observed using a QuantiGene 2.0 Bioplex assay, and analyzed on a Bio-Rad Bio-Plex 200 platform. Preliminary results from this study indicate that for many prototypical PFAS targets, (i.e. Cyp4a14), the earlier time to treatment after plating caused a robust upregulation of gene expression at lower concentrations, whereas other pathways (i.e. oxidative stress) were more responsive to treatment at 24 hours after plating. This information may suggest that PFAS potency in hepatocytes may be dictated by factors, such as uptake transporters or other receptor-mediated mechanisms that get modulated by time to treatment after plating, thus demonstrating the importance of time plating for PFAS screening with HH.

1975 Predictive Identification of Drug-Induced Damaged Site in Urinary Organs by Comprehensive Urine Examinations in Comparison with Histopathology in Rats

S. Tsuji, Y. Kurihara, A. Izaki, M. Sugiura, M. Wakamatsu, H. Yamada, and M. Sasaki. *Taisho Pharmaceutical Co. Ltd., Saitama-shi, Japan.*

Urine contains many kinds of cells derived from urinary organs and biological substances. Examination of urine is useful to investigate conditions of urinary organs in the non-invasive way. Male Sprague-Dawley rats were intraperitoneally injected once with cisplatin (CDDP), 2-bromoethylamine (BEA), and cyclophosphamide (CP) which are known to cause proximal tubule, renal papillary, and urinary bladder injuries, respectively, in order to reveal characteristic changes in urinalysis data when different areas in urinary organs are injured. Urinalyses (urine volume, specific gravity, urine color, urine sediment, test paper, and urine chemistry) were performed prior to dosing and 1 to 4 days after dosing, and histopathological examinations on the kidney, ureter, and urinary bladder sampled at necropsy at 4 days after dosing were conducted. CDDP induced increased number of epithelial cells and casts and high excretion levels of glucose, albumin and N-acetyl-β-d-glucosaminidase (NAG) from 2 days after dosing, and these changes were consistent with necrosis in proximal tubules noted in histopathology. BEA induced increased number of epithelial cells, casts, and red blood cells, and high excretion levels of albumin and NAG from the following day of dosing. These changes were consistent with histopathological findings such as necrosis in renal papilla and tubular cast. CP induced ulcer and hemorrhage in the transitional cells of the urinary bladder histopathologically, and increased number of epithelial cells, white and red blood cells in red colored urine and increased excretion level of album in urinalyses from the following day of dosing. There were no histopathological changes in the kidney, and urine glucose and NAG levels were not changed in urinalyses in CP treatment rats. These results suggest that comprehensive evaluation of urinalyses items can be useful for predictive identification of drug-induced damaged site through urinary organs in the non-invasive way.

1976 Development of Human iPSC Derived Cells for Nephrotoxicity Testing

V. Chandrasekaran, C. Murphy, R. Paskel, A. Wilmes, and P. Jennings. *Vrije Universiteit Amsterdam, Amsterdam, Netherlands.* Sponsor: N. Kramer

The prevalence of kidney disease is increasing at an alarming rate. This increase has several aspects, including lack of early detection, metabolic diseases and aging populations. However, it is likely that environmental pollution and pharmaceuticals also have a major role. While animal models provide some prediction value, they are not well suited to cellular mechanistic studies. Also, species differences often play a major role in pharmaco/toxico kinetics and dynamics. Furthermore, humans are genetically diverse, with increasingly identified polymorphisms and gene copy number variations in xenobiotic handling genes (i.e. metabolism and transport). In the kidney, proximal tubular epithelial cells are constitutive transporters that transport substances from the lumen and thus play an essential role in the whole-body homeostasis. Many xenobiotics are also transported here and can reach the cytosolic concentrations not seen in other tissues which may cause injury leading to acute and chronic renal disease. In this study we explore the possibility of differentiating induced pluripotent stem cells (iPSC) into renal proximal tubular like (PTL) phenotypes and their utilization in high throughput screening of drugs and chemicals by testing their sensitivity to the known toxicants. iPSCs were treated with different small molecules (CHIR, TTNBP) and specific growth factors over two weeks transitioning through the intermediate mesoderm, renal vesicles and finally to cells resembling transporting epithelial cells. Temporal development of the tissues was characterized by assessing the expression of pluripotency markers, renal developmental markers and maturation markers via immunofluorescence, RNA sequencing and western blot analysis. The final PTL cells exhibit a polarized phenotype, barrier formation with the expression of tight junction proteins such as occludin and ZO3 and the proximal tubule specific marker, megalin. Cells also showed typical proximal tubular hormonal response such as sensitivity to parathyroid hormone and lack of sensitivity to vasopressin. These cells have also been successfully used for testing pharmaceutical activity and chemical-induced toxicity in transcriptomic and high content imaging assays. In conclusion, the protocols developed here represent a promising tool to explore individual genetic susceptibilities to potential nephrotoxins. *The project was funded by a Marie Sklodowska-Curie Action - Innovative Training Network, entitled in3, under grant no. 721975.*

1977 Dissecting Drug-Induced Toxic Effects on Cell Viability and Metabolic Activity in Proximal Tubule Cells

C. A. Hoogstraten, J. A. Smeitink, F. G. Russel, and T. J. Schirris. *Radboudumc, Nijmegen, Netherlands.*

Acute kidney injury (AKI) is a major disease burden, affecting twenty percent of hospitalized adults worldwide. Mortality rates are over fifty percent in severe cases and less severe manifestations are associated with chronic kidney disease. Twenty-five percent of AKI cases are drug-induced, emphasizing the importance of renal toxicity assessment. The 'gold standard' MTT assay is widely used as a measure of cell viability, but depends on cellular metabolic activity. Mitochondrial dysfunction is expected to play a major role in nephrotoxicity, thus MTT may not be the most optimal assay to assess cytotoxicity of nephrotoxic drugs. We aimed to compare MTT with a fluorescent microscopy approach to measure cell viability. Mature conditionally immortalized proximal tubule epithelial cells (ciPTEC) were exposed to nephrotoxic compounds, including cisplatin, tenofovir, sanguinarine, NSC-95397 at a 0.001-1000 µM range. After 24 hours, cell viability was assessed by MTT or nuclear staining, which was microscopically investigated using a mixture of hoechst, YO-PRO-1 and propidium iodide to detect all, apoptotic and necrotic cells, respectively. Differences were compared with one-way ANOVA and Dunnett's *post hoc*. MTT-based cell viability was reduced by 99.1 ± 0.5% (mean ± SEM, $p<0.0001$) after cisplatin exposure, whereas the microscopic approach only detected a 32 ± 4% ($p<0.0001$) decrease in viability, defined as increased number of apoptotic and necrotic cells. Similarly, tenofovir decreased viability with 68 ± 6% (MTT, $p<0.0001$) and 58 ± 9% (nuclear staining, $p<0.0001$). Sanguinarine and NSC-95397 showed residual viability of 1.4 ± 0.1% ($p<0.0001$) and 2.2 ± 0.2% ($p<0.0001$) using MTT, respectively. However, microscopically both compounds demonstrated a residual viability of 20 ± 10% ($p<0.0001$) and 18 ± 8% ($p=0.0012$), respectively. Currently, time-dependency of enhanced viability reduction by MTT compared to nuclear staining is investigated. This study shows that, compared to our fluorescent microscopy approach, the 'gold standard' MTT assay, does not solely assess cellular toxicity but rather provides a composite readout of cell death and decreased metabolic rate. A nuclear staining approach is thus preferable when assessing cytotoxicity of metabolically active compounds.

1978 Elevated Glucose Concentration Decreases the Expression of Lysosomal Proteins in Human Proximal Tubular Cells

S. Shrestha, R. Guyer, S. Somji, D. Sens, and S. H. Garrett. *University of North Dakota, Grand Forks, ND.*

Hyperglycemia is one of the major health concern in many parts of the world. One of the serious complications of high glucose levels is diabetic nephropathy (DN) which is the leading cause of end stage renal disease, characterized initially by the appearance of microalbuminuria, followed by progression to overt proteinuria and an overall decline in renal function. In order to determine the molecular changes involved in the development of diabetic nephropathy, human proximal tubular cells were cultured in the presence of 7.5, 11 and 16 mM glucose for three passages, and microarray analysis was performed to determine the differential gene expression in the HPT cells. The preliminary data obtained showed a significant downregulation in expression of mTOR as well as some of its associated genes. In addition, there was also a decrease in expression of genes associated with the lysosome. The results of the microarray analysis was confirmed using RT-qPCR, Western blot analysis and confocal microscopy. The results validated the microarray analysis, which showed decrease in the mRNA as well as protein expression of the genes CCLN7, NPC2, LIPA, RRAGD, SQSTM1, mTOR, LAMP1, EIF4EBP1, RPTOR and RICTOR as the concentration of glucose increased. Co-localization of lysosomal marker, LAMP1 and mTOR gene showed lower expression of mTOR as the glucose concentration increased, suggesting decrease in mTOR activity. Although the mechanism by which glucose affects the expression of genes associated with the lysosome is not well known, our results suggest that high levels of glucose may lead to decrease in mTOR activity causing the cells to enter an anabolic state resulting in the downregulation of lysosomal genes.

1979 Transcriptomic Characterization of Renal Pathomechanisms in the ZSF1 Rat Model of Diabetic Nephropathy and Comparison to Toxin-Induced Chronic Kidney Disease

B. J. Petzuch[1], G. Callegaro[2], S. J. Kunnen[2], E. Hartmann[1], and H. C. Ellinger-Ziegelbauer[1]. *[1]Bayer AG, Wuppertal, Germany; and [2]Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands.*

Incidence of chronic kidney injury (CKI) is growing, but early diagnostics and treatment remain insufficient. Many causes of CKI have been identified, examples being nephrotoxins like aristolochic acid (AA) and metabolic diseases. Transcriptomic analyses in the context of CKI should improve our understanding of insult-specific (nephrotoxin vs. disease-associated) or common mechanisms. We therefore compare the renal gene expression in four rat models of CKI: (1) ZSF1 obese rats as a genetically induced model of diabetic nephropathy (DN), (2) L-NAME treated Renin-2 transgenic rats as a model of hypertension, (3) Wistar rats treated with nephrotoxic serum as a model for glomerulonephritis (Pavkovic et al 2014)., and (4) Big Blue rats treated with AA (Su et al 2011). All animals were compared to respective controls. ZSF1 gene expression profiles were furthermore compared to human DN (Woroniecka et al 2011) to assess its translational value. Renal damage was assessed by histopathology and proteinuria. RNA was subjected to Microarray (Affymetrix) hybridization followed by initial analysis using Genedata software. Upstream predictions were derived using Ingenuity pathway Analysis (IPA, Qiagen). In addition, co-expression signatures were determined with the Weighted Gene Co-expression Network Analysis (WGCNA) generated with the TXG-MAPr App, provided in the frame of IMI2 projects eTRANSAFE and TransQST. Kidney injury was confirmed by increased proteinuria and histological observations. On the transcriptome level, damage is mostly associated with similar deregulations across the different CKI models when pathways like fibrosis, inflammation, ROS responses and renal function are analyzed. This is supported by IPA upstream predictions. On the other hand, differences between the CKI models can be observed for other functions, like decreased oxidative phosphorylation specifically in ZSF1 rats. This is supported by WGCNA, which also predicts differences in gene co-expression networks. Comparison to human DN strengthens the translational value of the ZSF1 model. Our results highlight disease-specific and common pathomechanisms in rat models of CKI and the translational value of those models for mechanistic studies and biomarker research.

1980 Sulforaphane Prevents Type 2 Diabetes-Induced Nephropathy via AMPK-Mediated Activation of Lipid Metabolic Pathways and NRF2 Anti-Oxidative Function

Z. Li, H. Guo, T. Ma, S. Zhou, Z. Zhang, L. Miao, and L. Cai. *University of Louisville, Louisville, KY.*

Sulforaphane (SFN) prevents diabetic nephropathy (DN) in type 2 diabetes (T2D) by up-regulating nuclear factor (erythroid-derived 2)-like 2 (NRF2). AMP-activated protein kinase (AMPK) can attenuate the pathogenesis of DN by improving renal lipotoxicity, which is also found associated with the activation of NRF2-mediated antioxidants. Therefore, we investigated whether AMPKα2, the central subunit of AMPK in energy metabolism, is required for SFN protection against DN in T2D, and whether potential crosstalk occurs between AMPKα2 and NRF2 in this context. AMPKα2 knockout (Ampkα2-/-) mice and wild type (WT) (C57BL/6J) mice were fed a high-fat diet (HFD) to induce insulin resistance, followed by streptozotocin (STZ) injection to induce hyperglycemia (T2D model mice). Both T2D and control mice were treated with SFN or vehicle for three months. At the end of the three-month treatment period, five mice from each group were sacrificed (three-month (3M) time point). The remaining mice were only fed either a HFD or normal diet (ND) for three more months and the study was terminated at six months (six-month (6M) time point). Renal function was assessed by measurement of 24h urine albumin before sacrifice at 3M and 6M. SFN significantly attenuated T2D-induced renal dysfunction and pathology accompanied with biochemical changes including proteinuria, renal hypertrophy, renal oxidative damage, inflammation, and fibrosis in WT mice, but not in Ampkα2-/- mice. Additionally SFN also prevented T2D-induced renal lipotoxicity via AMPK-mediated activation of lipid metabolic pathways and the NRF2 function in WT diabetic mice. Similarly, these protective effects of SFN were also abolished in Ampkα2-/- diabetic mice. These results suggest that AMPKα2 plays a central role in preventing DN. SFN prevents DN by the activation of lipid metabolism and NRF2-associated suppression of oxidative stress, and more important is that both of them are AMPKα2-dependent.

1981 Adaptation of Human Podocytes and Renal Proximal Tubule Epithelial Cell Lines to Physiological Oxygen Conditions

F. Piossek, N. Schlichenmaier, A. Zielinski, S. Beneke, and D. R. Dietrich. *Universität Konstanz, Konstanz, Germany.*

In recent years it has become increasingly obvious that conventional 2D cultivation of cells cannot recapitulate their physiological environment, thereby altering the cellular phenotype. The latter limits the *in vitro* approaches usefulness in e.g. drug testing for adverse or off target effects due to limited or lack of predictivity. To overcome this issue research has increasingly focused on providing cells with conditions that mimic their physiological environment as closely as possible. Three factors of importance that need to be considered when designing *in vitro* experiments are cell-cell interactions, dimensionality and O_2 tension. Indeed, atmospheric O_2 (21%), at which nearly all *in vitro* experiments are carried out, massively exceeds physiologically normal O_2 *in vivo* tensions, e.g. 10% O_2 in the human kidney cortex, thus raising the question whether the excessive O_2 tensions lead to adaptive responses and thus to false negative and/or false positive responses upon exposure to nephrotoxicants. Two cell types critical for the structure and function of the kidney are proximal tubular epithelial cells (RPTEC) and podocytes (PODO). The objective of this work was to analyse the adaptation of RPTEC and PODO to physiological O_2 conditions and to characterise any phenotypical changes. Accordingly, RPTEC/TERT1 and PODO/TERT256 were cultured at 10% (PhysOx) and 21% O_2 (AtmOx). In order to support the polarity of the cells and thus allow for bidirectional transport, cells were cultured in transwells. Morphology, cell proliferation and cell metabolism (glucose consumption & lactate production) were assessed. Expression levels of markers for hypoxia and oxidative stress as well as structural markers and transporters were analysed at the mRNA level (RT-qPCR) and protein level (Western Blot, Immunofluorescence). Preliminary results show an increase of the HIF1α protein within 30 min at PhysOx suggesting an adaptive response. After adaptation to PhysOx for 14 days cells did not demonstrate a significant difference in cell proliferation, morphology or mRNA expression of oxidative stress and hypoxia markers when compared to their AtmOx counterparts. However, while RPTEC/TERT1 metabolism appeared to remain unchanged, a shift towards glycolysis in PODO/TERT256 metabolism was observed.

1982 Development of a Noninvasive, Multiplexed LC-MS Assay for the Quantification of Podocyte Injury Biomarkers in Human Urine

C. A. Morales Betanzos[1], H. Neubert[1], S. Hett[2], S. Berasi[2], and M. Fernandez Ocana[1]. *[1]Pfizer Inc., Andover, MA; and [2]Pfizer Inc., Cambridge, MA.* Sponsor: S. Ramaiah

The glomerulus is a specialized structure of the nephron that plays a critical role in blood filtration. An important cell type within the glomerulus required for appropriate filtration is the podocyte, which specialized foot processes interdigitate between adjacent podocytes to form the slit diaphragm, a filtration unit permeable to water and small molecules and impermeable to larger proteins. In glomerular diseases loss of podocytes compromises the ability to adequately filter blood and results in elevated glomerular filtration rate and proteinuria. Biomarkers of glomerular diseases in current use provide little information on mechanism or disease progression and thus kidney biopsy and subsequent histopathology is needed for disease diagnosis, which have limited throughput due to its invasiveness. Here, we present the method development of a non-invasive mechanism-specific biomarkers of podocyturia. We established a multiplexed immunoaffinity (IA) LC-MS assay to quantity four podocyte derived proteins, nephrin, podocin, podocalyxin and synaptopodin from clarified urine. Podocyte peptides suitable for LC-MS studies in urine were identified using proteomics and targeted MS investigations. Subsequently a high-sensitivity method was developed using a combination of online peptide IA and targeted MS. The achieved assay sensitivities were in the attomole/uL range with low limits of quantification (LLOQ) of 3.8 for nephrin, 12.1 for synaptopodin, 5.4 for podocin and 21 attomol/uL for podocalyxin. Assay inter- and intra-batch accuracy and reproducibility were determined in a three-day validation with typical CV and RE below 25%. Sample stability was demonstrated during 4-hour ice and RT and 3-day freeze/thaw stability studies. The assay performance was deemed to be suitable for clinical studies and the workflow will be implemented as an exploratory biomarker to evaluate podocyturia in glomerular disease patients in ongoing clinical trials.

1983 Modeling the Effects of Glomerular Dysfunction on the Proximal Tubule Using a 3D Microphysiological System

K. A. Lidberg[1], R. Patel, MD[2], C. K. Yeung, PhD, PharmD, MPH[1,3], J. Himmelfarb, MD[3], and E. J. Kelly, PhD, MS[1]. *[1]University of Washington, Seattle, WA; [2]Seattle Children's Hospital, Seattle, WA; and [3]Kidney Research Institute, Seattle, WA.*

Proximal tubule epithelial cells (PTECs) treated with albumin *in vitro* generate reactive oxygen species, secrete cytokines (e.g CCL2, IL-8), and produce fibrogenic molecules (e.g. TGFβ, fibronectin). This suggests that the proximal tubule may be a pathological mediator in the progression of chronic kidney disease, particularly in those with prominent glomerular dysfunction. Here, we treated a cell-based microfluidic model of the human renal proximal tubule with human serum or albumin to explore how altered glomerular filtrate composition can drive PTECs to acquire a maladaptive phenotype. Exposure of PTECs to 2% human serum increases the expression of marker of proliferation Ki-67 (KI-67) and secretion of kidney injury molecule 1 (KIM-1) and interleukin-6 (IL-6). Albumin treatment did not promote IL-6 secretion, but increased KIM-1 secretion in a donor-dependent manner. Co-treatment with cetuximab (anti-EGFR), tocilizumab (anti-IL-6R), or ruxolitinib (JAK1/2 inhibitor) did not inhibit serum-induced secretion of KIM-1 or IL-6, indicating that these processes may be independent of STAT3. Transcriptomic profiling by RNA-seq revealed that the expression of 820 genes were significantly affected by treatment with 2% human serum and Ingenuity Pathway Analysis™ identified the transforming growth factor beta and tumor necrosis factor alpha pathways as the two most likely upstream regulators mediating the transcriptional changes. Together, these data show PTECs become pro-inflammatory with serum treatment and indicate that this microphysiological system can be used to identify the signaling pathways that trigger a switch in PTEC phenotype.

1984 Development of a Model of Immune-Mediated Glomerular Injury in Cynomolgus Monkeys to Study Novel Kidney Safety Biomarkers

J. C. Gautier[1], T. Gury[1], J. F. Gallas[2], M. Jung[2], S. Hilairet[2], V. Menet[2], X. Zhou[3], O. Poetz[4], W. Naboulsi[4], and J. L. Barnes[5]. *[1]Sanofi, Vitry-sur-Seine, France; [2]Sanofi, Montpellier, France; [3]National Center for Safety Evaluation of Drugs, National Institutes for Food and Drug Control, Beijing, China; [4]SIGNATOPE GmbH, Reutlingen, Germany; and [5]ProbeTex Inc., San Antonio, TX.*

Immune-mediated glomerular injury is more frequently observed with biotherapeutics as compared to small molecules which tend to produce tubular lesions in the kidney. A model of Cynomolgus monkeys treated with anti-Glomerular Basement Membrane (GBM) antiserum was developed to investigate new biomarkers of immune-mediated glomerular injury. The antiserum was produced from sheep immunized with GBM from Cynomolgus kidney cortex. A pilot study was conducted where monkeys were given 2 intravenous administrations of a first batch of anti-GBM antiserum at 5 mL/kg on Day 1 and 4 and then sacrificed on Day 10. Kidney microscopic findings consisted of severe glomerular alterations with mesangial proliferation/expansion in all animals, and minimal to mild tubular degeneration/necrosis and regeneration in 2/3 monkeys. Increases in microalbuminuria and proteinuria were observed from Day 4 in all animals, while increases in the urinary tubular biomarkers measured (N-acetyl-β-D-glucosaminidase (NAG), clusterin, retinol-binding protein 4 and osteopontin) were observed in only one animal on Day 4 and in all animals on Day 9. BUN and serum creatinine were increased in all animals on Day 9/10. Due to the tubular injury observed, a study was performed with lower doses to just induce the glomerular injury with 4 monkeys each treated with 1 intravenous injection of a second batch of anti-GBM antiserum at 2.0, 0.7, 0.2 mL/kg or the pre-immune serum at 2 mL/kg. The animal treated at 2 mL/kg was sacrificed on Day 10 as the predefined humane endpoints were reached, and the other animals were necropsied on Day 22. Minimal glomerular alterations and mesangial proliferation/expansion in the absence of tubular degeneration/necrosis were observed at 2.0 mL/kg with increases in microalbuminuria and proteinuria from Day 8. Minimal podocyte fusions were noted at electron microscopy at 0.7 mL/kg. Increases in microalbuminuria were observed at 0.7 and 0.2 mL/kg from Day 15 without increases in the tubular biomarkers measured (NAG, clusterin and cystatin C). These results indicate that monkeys treated with anti-GBM antiserum is a useful model of immune-mediated glomerulopathy which can be used to further investigate novel biomarkers of glomerular injury.

1985 4-methylpyrazole Protects against Acetaminophen-Induced Nephrotoxicity

J. Akakpo[1], H. Orhan[2], A. Ramachandran[1], and H. Jaeschke[1]. *[1]University of Kansas Medical Center, Kansas City, KS; and [2]Ege Üniversitesi Faculty of Pharmacy, Izmir, Turkey.*

While acetaminophen (APAP) hepatotoxicity is the most common cause of acute liver failure in the United States, a significant percentage of APAP overdose patients also develop kidney injury. In contrast to APAP-induced liver injury where mechanisms of hepatotoxicity have been well studied, the molecular mechanisms involved in APAP-induced nephrotoxicity are relatively unknown. We have shown earlier that 4-methylpyrazole (4MP), a repurposed drug, protects against APAP-induced liver injury by inhibiting cytochrome P450-mediated generation of the reactive APAP metabolite, N-acetyl-p-benzoquinone imine (NAPQI). The mode of action has also been verified in human hepatocytes and in healthy volunteers. Since cytochrome P450 is also expressed in the kidney, this study explored protection by 4MP against APAP-induced nephrotoxicity, to determine if this intervention could serve a dual benefit in patients after an APAP overdose. Male C57BL/6J mice were treated with either 300 or 600 mg/kg APAP with or without 4MP for 2, 6 or 24 h, followed by measurement of APAP metabolism and tissue injury. Interestingly, levels of APAP and its non-oxidative metabolites were significantly higher in the kidney when compared to the liver at 2h after APAP. APAP-protein adducts were present in both tissues within 2h, but were absent in kidney mitochondria, unlike in the liver. While GSH depletion was seen in both tissues, activation of the MAP kinase JNK and its translocation to the mitochondria, which is a critical feature of APAP-induced liver injury, was absent in the kidney. Evaluation of tissue injury by histology, TUNEL staining, plasma BUN levels and Ngal (kidney injury marker) demonstrated a delayed kidney injury evident by 24h, notably at the 600mg/kg dose. Treatment with 4MP attenuated APAP metabolite generation, GSH depletion as well as kidney injury indicating its potential use in prevention of APAP-induced nephrotoxicity. In conclusion, since reactive metabolite formation seems to be common in both liver and kidney, 4MP mediated inhibition of Cyp2E1 protects against APAP-

induced nephrotoxicity, probably by increasing renal excretion of APAP and its sulfated metabolite. However, downstream mechanisms of APAP-induced nephrotoxicity seem distinct from the liver.

1986 Ochratoxin A Induces Epithelial to Mesenchymal Transition and Renal Fibrosis Through TGF- β/Smad2/3 and Wnt/β-catenin Signaling Pathways *In Vivo*

M. Pyo, and K. Lee. *Korea University College of Life Sciences and Biotechnology, Seoul, Korea, Republic of.*

Ochratoxin A (OTA) is a fungal toxin produced by fungi such as *Aspergillus app.* or *Penicillium spp*. OTA, which is present in various foods such as cereals, nuts, coffee beans, and beer, is a white, odorless toxin that has a very long half-life, is resistant to heat, and can accumulate when it enters the body. The main target organ that causes OTA toxicity is kidney, and it is known that epithelial to mesenchymal transition (EMT) and fibrosis are enhanced when the kidney is exposed to OTA for a long time. However, the mechanisms that cause these symptoms are not exactly known. Therefore, the aim of this study is to confirm the mechanism of OTA-induced EMT and fibrosis in mice kidneys. In this study, mice were orally administered for 12 w with various doses of OTA (200 and 1000 μg/kg body weight (B.W.)). In the group given to 1000 μg/kg B.W., blood urea nitrogen (BUN) and creatinine levels were increased 1.29-fold and 1.38-fold compared to the control group respectively. Also, fibrosis was also observed in kidney tissues. It also found that alpha-smooth muscle actin (α-SMA) and fibronectin were increased 5.65 and 2.48-folds and that E-cadherin decreased 0.26 fold compared to the control group by OTA in kidney tissues. In addition, the expression of TGF-β Receptor I, smad2/3 and β-catenin was also increased 3.71, 2.60, and 2.66-folds by OTA compared to the control group. These results examined that OTA induces EMT and renal fibrosis through Smad2/3 and β-catenin signaling pathway *in vivo*.

1987 Synergistic Toxicity between Ochratoxin A and Cadmium in Kidney Cells

J. Jeong, and K. Lee. *Korea University College of Life Sciences and Biotechnology, Seoul, Korea, Republic of.*

Ochratoxin A (OTA) is acknowledged as mycotoxin produced from several species of *penicillium* and *aspergillus* and frequently found in cereal grains such as rice and oat. Cadmium (Cd) is acknowledged as widespread toxic heavy metal and also found mainly in cereal grains. Therefore, there is a possibility that OTA and Cd may be ingested together and exposed in the body simultaneously. Although each individual toxicity of OTA and Cd have been studied, the combined toxicity has not been investigated. In this study, the combined cytotoxicity of OTA and Cd was investigated with human proximal tubule epithelial cells (HK-2 cells). HK-2 cells were exposed to OTA (25, 50, 100, 200, 400, and 800 nM), $CdCl_2$ (1.25, 2.5, 5, 10, 20, and 40 μM), and their mixture at 1:50 (OTA : $CdCl_2$) ratio for 48 h. The interaction effect of OTA and Cd on cytotoxicity was determined by the combination index method. Based on cell viability, compusyn analysis showed the interaction between OTA and Cd had synergistic effect, and the reactive oxygen species (ROS) also increased at concentration with the synergistic effect. Phase I reaction enzymes (CYP450), Phase II reaction enzyme (γ-glutamylcysteine synthetase (γ-GCS), heme oxygenase-1 (HO-1), and NADPH: quinone dehydrogenase-1 (NQO1)), and kidney injury-related marker, Kidney injury molecule 1 (KIM-1) were determined by quantitative real-time PCR. CYP450 enzymes (CYP1A1, CYP2E1), γ-GCS, HO-1, and NQO1 increased in combined treatment than in single treatment. KIM-1 also increased in combined treatment. Therefore, this study clearly showed that interaction between OTA and Cd have synergistic cytotoxicity in the kidney cells.

1988 Attenuation of 3,5-dibromoaniline Nephrotoxicity *In Vitro* by Antioxidants and Biotransformation Inhibitors

G. O. Rankin, W. M. Hicks, J. Ju, and D. K. Anestis. *Marshall University, Huntington, WV.*

Halogenated anilines are commonly used in the manufacture of a wide range of products, including drugs, agricultural agents, dyes and industrial products. Among the dibromoanilines, *in vitro* studies have shown that 3,5-dibromoaniline (3,5-DBA) is the most potent nephrotoxicant in rat renal cortical slices and isolated renal cortical cells (IRCC). The purpose of this study was to determine if free radicals and/or bioactivation played a role in 3,5-DBA nephrotoxicity *in vitro*. IRCC (3 mL 4.0 X 10^6 cells/ml) from male Fisher 344 rats were treated with DMSO (vehicle control), 0.5 mM 3,5-DBA, a pretreatment, or pretreatment plus 0.5 mM 3,5-DBA, followed by incubation for 60 min at 37°C. The pretreatments used in this study were: antioxidants [ascorbate (2.0 mM), glutathione (1.0 mM), N-acetyl-L-cysteine (2.0 mM), or α-tocopherol (1.0 mM)]; cytochrome P450 (CYP) general inhibitors [piperonyl butoxide (0.1 mM) or metyrapone (1.0 mM)]; a cyclooxygenase inhibitor [indomethacin (1.0 mM)]; a peroxidase inhibitor [mercaptosuccinate (1.0mM)]; and flavin monooxygenase (FMO) inhibitors [n-octylamine (2.0 mM) or methimazole (1.0 mM)]. Cytotoxicity was determined using lactate dehydrogenase (LDH) release analysis. LDH release was significantly increased from control levels by 0.5 mM 3,5-DBA treatment (~20-25% release of LDH). Among the antioxidants, ascorbate, glutathione and N-acetyl-L-cysteine attenuated 3,5-DBA cytotoxicity. 3,5-DBA cytotoxicity was also reduced by all biotransformation inhibitors except metyrapone. To explore CYP-induced bioactivation further, more specific inhibitors of CYP metabolism were used: oleandomycin (CYP3A4, 0.5 mM), omeprazole (CYP2C19, 0.01 mM) and DEDTCA (CYP2C/2E1, 0.1 mM). All three pretreatments attenuated 3,5-DBA. These results suggest that multiple enzyme systems may play a role in the bioactivation of 3,5-DBA to cytotoxic metabolites, and that reactive metabolites play a role in the mechanism of 3,5-DBA induced cell death. *Supported in part by NIH Grant P20GM103434 to the West Virginia IDeA Network for Biomedical Research Excellence.*

1989 Kinetic Analysis of Trichloroethylene Glutathione Conjugates and the Effect of Renal Metabolites on Mitochondrial Respiration Using Cultured Human Renal Proximal Tubular Cells

L. Capinha, J. N. Commandeur, and P. Jennings. *Vrije Universiteit Amsterdam, Amsterdam, Netherlands.* Sponsor: B. Blaauboer

Trichloroethylene (TCE), a well-studied member of the halogenated alkenes, is produced in millions of kilos per year and poses a significant hazard to human health. Animal and *in vitro* studies have demonstrated that hepatic glutathione (GSH) conjugation and subsequent renal metabolism involving gamma glutamyl transferase (GGT) and cysteine conjugate β-lyase activity leads to the formation of a reactive thioketene, causing oxidative stress and mitochondrial injury. Here we re-examined the hepatic GSH-conjugation of TCE and the effects of GSH-conjugates of TCE on human renal proximal tubule cells. Utilising human liver fractions and recombinant human glutathione S-transferases we demonstrate the formation of 1,2-dichlorovinyl glutathione (1,2 DCVG). The human proximal tubular cell line RPTEC/TERT1 cells were differentiated and treated with 1,2 DCVG for 24 hours. A rapid and complete metabolism of the initial GSH-conjugate was observed within 2 hours, with a temporal transient increase of the respective glycine-cysteine conjugate, followed by the accumulation of the cysteine conjugate. The specific effects of the GSH-conjugate on mitochondrial respiration were quantified using the Seahorse bioanalyser. A decrease in mitochondrial reserve capacity was observed for 1,2-DCVG, but not in the presence of the β-lyase inhibitor aminooxyacetic acid (AOAA). This study better clarifies the molecular processes of TCE metabolism and toxicity in human renal cells demonstrating a clear relationship between metabolism and mitochondrial perturbation. *This work is funded by the EU's Horizon 2020 research and innovation program (EUToxRisk, grant agreement No 681002).*

1990 Resveratrol Protection of Cisplatin Renal Cytotoxicity and Mitochondrial Changes in Human Proximal Tubular Epithelial Cells

M. Valentovic[1], K. C. Brown[1], M. Dial[1], and C. Y. Davis[2]. *[1]Marshall University School of Medicine, Huntington, WV; and [2]Glenville State College, Glenville, WV.*

Cisplatin is a cancer chemotherapy agent used in treating advanced testicular, ovarian and bladder cancer. Unfortunately, cisplatin is nephrotoxic. Resveratrol (RES) is a polyphenolic compound that promotes apoptosis in some cancer cell lines and reduces tumor size in clinical studies. Part of the mechanism for reducing cisplatin toxicity by RES may be mediated by preserving mitochondrial function and diminishing cisplatin induced oxidative stress. Cisplatin nephrotoxicity targets in humans, the proximal and distal tubules. HK-2 cells were selected for this study as they are a human renal proximal tubular epithelial cell line (HK-2). Our hypothesis is that RES will diminish mitochondrial impairment by cisplatin in HK-2 cells. HK-2 cells were plated for 48 h followed by a 1 h pretreated with RES or 1% DMSO (vehicle). Renal cells were co-incubated with cisplatin at a final concentration of 0-30 uM for 24 h. Viability was assessed using MTT and trypan blue exclusion cell counts. All studies were conducted a minimum of 3 independent experiments. Cells pretreated with 10 uM RES were protected from cisplatin cytotoxicity at 24 h. Cisplatin caused a concentration dependent decline in MTT viability after

24 h exposure to 0, 7.5 and 15 uM cisplatin. RES pretreatment for 1 h with 10 or 15 uM RES increased HK-2 viability relative to cells exposed only to RES Vehicle (DMSO). RES did not increase cell number as part of its protective mechanism. Mitochondrial function was decreased by cisplatin as evaluated using a Seahorse XFe Analyzer. Basal and maximal mitochondrial respiration were monitored in RES and cisplatin treated cells. Additional studies examined whether RES altered expression of mitochondrial complex proteins and markers of mitophagy. Western analysis detected an increase in protein carbonylation with 24 h cisplatin exposure which was reversed by RES. RES protects human proximal tubular epithelial cells from cisplatin cytotoxicity, preserves mitochondrial integrity and mitochondrial respiration. *Supported by NIH Grant INBRE 8P20GM103434 and a WV NASA Undergraduate Research Fellowship to MD and RM.*

1991 Dynamics of Transcriptional Responses in Cisplatin-Induced Kidney Injury Uncover Mechanistic Drivers of Toxic Renal Adverse Outcomes

L. Wijaya, S. J. Kunnen, G. Callegaro, S. E. Le Dévédec, and B. V. de Water. *Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands.*

Drug induced kidney injury (DIKI) is still becoming one of the reason for high numbers of drug candidate attrition and drug withdrawal from the market. However, the mechanism underlining this adversity is still unclear hampering the method development for predicting DIKI. In particular, there is lack of temporal dose response information of cellular stress response data that could lead the way to a quantitative pathway-based hazard prediction of DIKI. As a proof-of-concept, we performed a systematic high throughput transcriptomic cisplatin temporal-concentration response study to investigate the gene expression profiles likely delineating the mechanisms of DIKI. Immortalized human proximal tubule cells (RPTEC/TERT1) were exposed to 10 concentration levels of cisplatin ranging from 0-50 µM. Samples were collected at 6 different time points (4, 8, 16, 24, 48, 72 hours) to capture both early and late responses. In parallel high content imaging experiments apical endpoints of toxicity were assessed. High throughput whole genome targeted RNAseq TempOSeq technology (~19000 genes) was used for transcriptional analysis. We observed robust transcriptional changes in a concentration and time dependent manner. We mapped the transcriptomics data to our previously established *in vivo* DIKI TXG-MAPr: a weighed gene correlation network analysis (WGCNA) approach to characterize and quantify gene-module activation based on gene co-regulation of DIKI transcriptomics studies. The TempOSeq data provided sufficient coverage for human to rat mapping. We revealed various gene-module modulation that followed a clear time and concentration dependency, including modules representing the DNA damage response. Systematic gene network modulation correlation analysis demonstrated that our *in vitro* results show high module correlation with the cisplatin exposed rat kidney prominently at the early time point indicating the similarity in acute responses between RPTEC/TERT1 and rat kidneys. We further provide insight in point-of-departure of transcription factor activation of the cisplatin responses and the quantitative relationships with the tipping points for onset of cytotoxicity. Altogether, our results and approaches bear a prospective insight to apply HTTr TempOSeq in combination with *in vivo* WGCNA approaches in establishing mechanism-based DIKI prediction. *The work was funded by the Innovative Medicines Initiative 2 (IMI2) Joint Undertaking for the TransQST (grant agreement 116030) and eTRANSAFE (grant agreement 777365) projects. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation program and EFPIA.*

1992 Effect of Gentamicin on Renal Proximal Tubule Epithelial Cell Transporters

S. E. Thacker[1], K. Dunnick[1], T. Willstaedt[1], M. Bunger[1], and J. Schroeder[2]. *[1]Lonza Walkersville Inc., Walkersville, MD; and [2]Lonza Cologne GmbH, Cologne, Germany.*

Human Renal Proximal Tubule Epithelial Cells (RPTEC) are an important *in vitro* tool for studying normal renal physiology, renal drug transporters, and nephrotoxicity. When culturing these primary cells, antibiotics are often added to prevent microbial contamination. However, antibiotics can adversely affect renal cells. In humans, nephrotoxicity is one of the most important side effects of the aminoglycoside antibiotic Gentamicin occurring in 10 - 25% of patients. It is therefore important to carefully select antibiotics with no or minimal impact on RPTEC function. This work characterizes the effects of two antibiotics on RPTEC *in vitro*: the frequently used cell culture antibiotic Gentamicin and the tetracycline Doxycycline. Specifically, we observe the effects of these antibiotics on the Organic Cation Transporter 2 (OCT2), the Organic Anion Transporter 3 (OAT3), and the Na+/K+ ATPase pump. To make a comprehensive assessment of the effects of the selected antibiotics on RPTEC, we isolated the renal cells with either Gentamicin or Doxycycline, followed by cryopreservation in the absence of either antibiotic. Subsequent culturing of these cells were done with or without Gentamicin in the culture medium. Immunocytochemistry (ICC) staining was used to determine the presence of OCT2, OAT3, and NA+/K+ ATPase. Results indicate that there is no visible difference in the effect of isolating RPTEC with Gentamicin or Doxycycline on Na+/K+ ATPase and OAT3 presence. This is also true of culturing the cells with or without Gentamicin. For OCT2, however, the transporter expression increases in Gentamicin isolated cells when compared to cells isolated with Doxycycline. When comparing cells cultured out of cryopreservation with Gentamicin to those that are cultured without antibiotics, the same observation is made: an increase in staining of the OCT2 transporter in the presence of Gentamicin. Interestingly, OCT2 has been found to contribute to the transport of Gentamicin into cells. Taken together, our data supports differences in the RPTEC phenotype when cells are exposed to Gentamicin or Doxycycline during cell isolation as well as when cells are cultured in the presence of Gentamicin versus no antibiotic. These findings provide guidance on optimal isolation methods and culture conditions for maintaining RPTEC function in drug transporter and nephrotoxicity studies with human renal proximal tubule epithelial cells.

1993 Acute *In Vitro* Nephrotoxicity of Three Brominated Flame Retardants in Renal Cells

L. Barnett, and B. S. Cummings. *University of Georgia, Athens, GA.*

Brominated flame retardants (BFRs) are organohalogens commonly added to commercial products such as computers, electronics, textiles and furniture to reduce their flammability. BFRs have significant environmental persistence and are reported to be detected in human blood and breastmilk. In particular, tetrabromobisphenol A (TBBPA), hexabromocyclododecane (HBCD), and polybrominated diphenyl ethers (PBDEs) occupy nearly 20 percent of the global flame retardant market and are suggested to have adverse effects on humans and wildlife. As such, the mechanisms of BFR-induced toxicity are actively being explored under the US EPA Toxic Substance Control Act. We previously determined the effects of TBBPA, HBCD, and BDE 47 on cell viability in rat (NRK 52E), adult human (HK-2 and RPTEC), and human embryonic (HEK-293) kidney cells after 48 hours, and demonstrated that these compounds induce concentration-dependent effects on MTT staining. Assessment of the mechanism of cell death using annexin V staining and propidium iodide (PI) staining showed that all three compounds induce apoptosis in these cells. We subsequently performed RNAseq and pathway analysis in these cells to identify key signaling pathways involved in the mechanism of BFR-induced toxicity. Furthermore, we explored how BFR nephrotoxicity impacts neighboring cells by treating human fibroblasts with conditioned media from BFR-treated kidney cells and measuring morphological, molecular, and functional changes in fibroblast activation using RT-PCR, wound healing and high content image analysis. Ultimately, these data will aid future studies concerning the molecular mechanisms of BFR toxicity in kidney cells and how this impacts kidney epithelia-fibroblast crosstalk using chronic exposure at environmentally relevant doses.

1994 Reduction of Colistin-Induced Kidney Damage in Mice by Co-administration of the Vitamin-Like Compound L-Carnitine

S. L. Samodelov[1], M. Visentin[1], Z. Gai[1,2], and G. A. Kullak-Ublick[1,3]. *[1]UniSpital Zürich, Zürich, Switzerland; [2]Shandong University, Shandong, China; and [3]Novartis AG, Basel, Switzerland.*

Colistin is a polymixin antibiotic currently experiencing renewed clinical interest due to its efficacy in the treatment of multidrug resistant bacterial infections. The frequent onset of acute dose-dependent drug-induced kidney injury (DIKI), often leading to long-term renal damage, has limited its use and hampered adequate dosing regimens, leading to an increased risk of serum values below bacterial Minimal Inhibitory Concentrations (MIC) during treatment. The mechanism of colistin-induced renal toxicity is largely unknown but postulated to stem from its specific accumulation in the renal cortex through facilitated transport, coupled with mitochondrial toxicity and reactive oxygen species formation in proximal tubule cells after uptake during reabsorption. Several transport mechanisms for colistin in renal tissue have been elucidated, including facilitated transport over the peptide transporter 2 (Pept2) and endocytic uptake over megalin. We have recently shown that colistin is also a substrate for the carnitine/organic cation transporter 2 (Octn2/Slc22a5), expressed on the apical side of renal proximal tubule cells. Furthermore, we have shown that colistin treatment leads to structural damage at the site of the brush border membrane in proximal tubule cells, leading to loss of the sodium glucose transporter 2 (Sglt2), resulting in reduced reabsorption and

increased urinary excretion of glucose. In this study, a mouse model of subclinical DIKI was used to characterize colistin-induced kidney damage under co-administration with L-carnitine. We postulate that L-carnitine, sharing the transporter Octn2 with colistin, as well as eliciting positive effects on mitochondrial health per se, may be able to reduce colistin DIKI. Mice were treated with colistin sulfate (20mg/kg/day), L-carnitine (30 mg/kg/day), both, or PBS for seven days once per day intra peritoneally. Effects on expression, protein level, and transport capacity *ex vivo* of several proximal tubule transporters were analyzed. Assessment of tissue, urinary, and serum kidney damage markers was conducted. Treatment with L-carnitine alone did not impact kidney health but was able to protect against kidney damage in mice treated with both l-carnitine and colistin. We suggest using urinary glucose as a simple and cost-efficient marker of early kidney damage during colistin treatment and further support L-carnitine supplementation as a safe method of reducing DIKI caused by this antibiotic.

1995 Chrysin Ameliorates Cyclosporine A-Induced Renal Fibrosis by Inhibiting TGF-β_1-Induced Epithelial Mesenchymal Transition

B. Gonzalez, S. Sunilkumar, R. R. Nagavally, M. Akhtar, L. D. Trombetta, and S. M. Ford. *St. John's University, Jamaica, NY.*

Cyclosporine A is a nephrotoxicant that causes fibrosis via induction of epithelial mesenchymal transition (EMT). The flavonoid chrysin (5,7-dihydroxyflavone) has been reported to have anti-fibrotic activity and has been shown to inhibit signaling pathways that are activated during EMT. This study investigated the nephroprotective role of chrysin in the prevention of CsA-induced renal fibrosis and aimed at determining the mechanism of inhibition of chrysin against CsA-induced EMT in proximal tubule cells. We have previously reported *in vivo*, treatment with chrysin and its analogue apigenin prevents CsA-induced renal dysfunction in Sprague Dawley rats as measured by the blood urea nitrogen (BUN), serum creatinine and creatinine clearance. Histopathological examination show that co-treatment with chrysin (10 or 50 mg/Kg) or apigenin (10 mg/Kg) inhibited CsA (50 mg/Kg) induced tubular vacuolization, cast formation within tubules, and increased collagen deposition: markers of tubulointerstitial fibrosis. *In vitro*, 25 μM chrysin significantly inhibited 4.2 μM CsA or 5 ng/ml TGF-β_1 -induced EMT in LLC-PK$_1$ cells evidenced by inhibition of cell migration, increased collagen expression, presence of mesenchymal markers like α-SMA and vimentin and decreased epithelial cell marker E-cadherin expression. Protein expression analysis further indicated that chrysin co-treatment decreased CsA-induced TGF-β_1 signaling pathways; decreasing Smad 3 phosphorylation leading to a subsequent decrease in Snail expression. Protein quantification also showed that chrysin inhibited the CsA-induced Akt/ GSK-3β pathway activation. Inhibition of both pathways resulted in a decreased cytosolic accumulation of β-catenin, a known trigger for EMT. In conclusion, flavonoids like chrysin offer protection against CsA-induced renal dysfunction and interstitial fibrosis. Chrysin was shown to inhibit CsA-induced TGF-β_1-dependent EMT in proximal tubule cells by modulation of Smad dependent and independent signaling pathways.

1996 Sodium-Dependent Dicarboxylate Transport of Diglycolic Acid in the Toxicity of Diethylene Glycol

J. Tobin, C. Robinson, and K. McMartin. *Louisiana State University Health Sciences Center Shreveport, Shreveport, LA.*

Diethylene glycol (DEG) is an industrial solvent, generally found in brake fluid and chafing fuels, that has been implicated in mass poisonings worldwide due to counterfeit, adulterated medicines. The predominant metabolites of DEG are 2-hydroxyethoxyacetic acid (2-HEAA) and diglycolic acid (DGA). Exposure to DEG causes kidney proximal tubular necrosis, as well as hepatotoxicity and a delayed peripheral neuropathy. DGA has been implicated as the metabolite responsible for the renal and hepatic toxicity observed during these poisonings and has been shown to accumulate greatly in the organs. Due to this accumulation, the mechanism of transport of DGA into kidney cells was of interest as a potential therapeutic target for this toxicity. DGA is structurally similar to succinate, which makes it a possible substrate for the sodium dependent dicarboxylate transporters (NADCs) in kidney cells. Pharmacological inhibition of NADC1 and NADC3 in human proximal tubule (HPT) cells showed a reduction in DGA accumulation. However, inhibitors were not specific enough to determine which of the transporters was more important to DGA accumulation. To answer this question, a genetic approach was utilized to knock down NADC1 and NADC3 activities in HPT cells via nucleofection with siRNA. The nucleofected cells were grown on membrane inserts and dosed apically or basolaterally with DGA. Knockdown was confirmed via qRT-PCR. Cell toxicity was measured using lactate dehydrogenase (LDH) release. Both NADC1 and NADC3 were knocked down in HPT cells when targeted with siRNA, but without much selectivity. Nevertheless, knockdown of NADC transporters reduced the resulting cytotoxicity of DGA, suggesting a decreased DGA uptake into cells. These results corroborate the pharmacological studies, but which transporter is the relevant one for therapeutic targeting has not yet been determined. *Supported by the American Chemistry Council.*

1997 An Adverse Outcome Pathway for Renal Tumors in Male Rats through Chemical Induction of α2u-globulin (α2u) Nephropathy (α2u-N)

A. Franzen[1], and S. Borghoff[2]. *[1]ToxStrategies Inc., Monroe, LA; and [2]ToxStrategies Inc., Cary, NC.*

The National Research Council's vision of using adverse outcome pathways (AOPs) as a framework to assist with toxicity testing to meet regulatory demands of new and emerging chemicals has continued to gain traction since its initial release. The need to grow the current AOP knowledge base has gained urgency, with the US EPA's intent to eliminate animal toxicity testing by 2035. To meet these needs, an AOP for male rat renal tumors that occur through the ability of a chemical to induce α2u-N was organized based on extensive evidence of a specific mode of action (MoA) induced by multiple structurally diverse chemicals, including fuel additives (2,2,4-trimethylpentane), pesticides (1,4-dichlorobenzene), drugs (gabapentin), and solvents (decalin). This MoA is not relevant in humans, so it can be differentiated from other renal tumor MoAs using *in vitro* assays designed to measure the molecular initiating event (MIE) and/or key events (KEs) within an accepted AOP. Following identification and review of all relevant literature, including *in vivo* and *in vitro* studies, both the MIE and subsequent KEs were identified. The MIE is chemical binding to α2u, with KE1 being the inhibition of α2u catabolism due to chemical binding. This inhibition of α2u catabolism leads to its accumulation in the proximal tubule, resulting in the formation of protein droplets that crystalize (KE2). Exacerbated accumulation results in KE3 which is cytotoxicity, and compensatory cell proliferation. Atypical hyperplasia, along with lesions characteristic of protein accumulation, such as granular cast formation and linear mineralization, are considered to be KE4. With chronic exposure, a low incidence of renal adenoma and carcinoma development is seen in male rats. Based on the weight of evidence from the various evidence streams, the confidence in this AOP is high, and it could be used to assist with hazard identification in regulatory applications.

1998 Acute and Repeat-Dose Effects of a Panel of Electron Transport Chain (ETC) Inhibitors in Cultured Human Renal Proximal Tubule Cells

G. Carta, and P. Jennings. *Vrije Universiteit Amsterdam, Amsterdam, Netherlands.* Sponsor: B. Blaauboer

Mitochondrial perturbations play a key role in the aetiology of several diseases and chemical-induced organ toxicities including acute and chronic renal disease. However, it still unclear how mitochondrial liabilities are sensed by cells and how the appropriate adaptive responses are triggered in terms of cellular signalling. To this end we utilised a differentiated human proximal tubule cell line (RPTEC/TERT1), with proven oxidative characteristics and challenged these cells to a panel of complex I, II, III electron transport chain (ECT) inhibitors. This chemical panel was developed within the EU-ToxRisk project. The effect of acute and repeat dose exposure was quantified utilising viability and biochemical assays, fluorescent microscopy and the Seahorse Bioanalyzer, which specifically monitors mitochondrial respiration by detecting changes in oxygen consumption rate/extracellular acidification (OCR/ECAR). In addition, we quantified the alterations of approx. 3000 genes using the TempO-Seq assay. Each of the assays utilised produced unique information, but most of the assays gave similar results to the potency of the compounds. The integration of the more specific assays allowed us to rank the compounds by potency, with Antimycin A and Rotenone always the most potent and Azoxystrobin the least. We saw no effect with complex II inhibitors. Transcriptomic analysis exhibited a good correlation between OCR/ECAR impact and the no. of significantly altered genes. However, complex I inhibition in general exhibit a more pronounced effect on the transcriptome then complex III inhibition. The most prominent pathway activated was the unfolded protein response. Again, there was no effect of complex II exposure on transcriptomic responses. Repeated exposures demonstrate increased toxicity. This study has explored several methods to quantify mitochondrial respiration and demonstrates that the combination of resazurin, supernatant lactate and OCR (particularity spare respiratory capacity) is optimum and that the RPTEC/TERT1 are a good model for such studies. This data and the optimised assays will be further utilised to develop a quantitative adverse outcome pathway for chemical induced renal mitochondrial disease includ-

ing Fanconi-like syndrome. *This work was part of the EU-ToxRisk project and received funding from the EU's Horizon 2020 programme under grant agreement No 681002.*

PS 1999 Improved Phenotype of Human Proximal Tubule Epithelial Cells in a 3D Microfluidic Model

J. Vriend, K. Pye, G. Chung, M. Nicholds, L. Armstrong, and C. Brown. *Newcells Biotech Limited, Newcastle upon Tyne, United Kingdom.* Sponsor: C. Brown, International Society for the Study of Xenobiotics

Recently, renal *in vitro* models have advanced towards microfluidic three-dimensional (3D) cell cultures in which *in vivo* conditions are incorporated. Such culture platforms could enhance predictability of drug-drug interactions (DDI) and nephrotoxicity, meeting the demand of more predictable *in vitro* renal models in drug development. Here we showcase our 3D microfluidic human primary renal proximal tubule epithelial cell (PTEC) model. Fresh human kidney cortex was used to obtain PTECs, isolated following a collagenase digest and Percoll density gradient protocol. PTECs were cultured on Transwells® (Corning), referred to as aProximate™, or in a 3-lane OrganoPlate® (Mimetas), in which tubule structures were cultured on an extracellular matrix of collagen I (4 mg/mL, Bio-Techne) and exposed to fluid flow for up to 11 days. PTECs cultured in the OrganoPlate formed leak-tight tubules from day 7, as measured by leakage of Lucifer Yellow from the apical compartment. Next, cell viability, using WST-8 (Sigma), and cell membrane integrity, via cellular leakage of lactate dehydrogenase (LDH, CyQUANT™), were determined. Rate of growth of PTECs was higher in aProximate™ from day 7 to 11 (mean ± SEM; 250 ± 13%) compared to the OrganoPlate® (145 ± 6%). This was accompanied with a stark increase of LDH activity (660 ± 170%) in aProximate™, while a lower increase in LDH activity (450 ± 50%) was observed in the OrganoPlate®. Secretion of renal biomarkers (clusterin, neutrophil gelatinase-associated lipocalin (NGAL), and kidney injury marker-1 (KIM-1) into the supernatant was quantified using a custom multi-array technology plate (Meso Scale Developments). Levels of clusterin were higher in aProximate™ (341 ± 85%) as compared to the OrganoPlate® (181 ± 19%) at day 9. Secretion of NGAL increased in both cell culture platforms (237 ± 45% and 269 ± 23% in aProximate™ and OrganoPlate®, respectively) at day 9, while levels of KIM-1 were only found to be increased in aProximate™ (132 ± 31% and 92 ± 14% in aProximate™ and OrganoPlate®, respectively). These data showcased a 'healthier' PTEC phenotype when cultured in a 3D microfluidic model. Next steps include studying improved sensitivity towards DDI and nephrotoxicity, as well as incorporating other cell types to further increase biomimicry.

PS 2000 Genomic Investigation of Thrombocytopenia in Monkeys with 2'-O-Methoxyethyl Antisense Oligonucleotide (2'-MOE ASO) Treatment

R. J. Prill[1], L. Shen[1], J. Schroeder[1], S. Burel[1], D. O'Connor[2], R. Wiseman[2], T. Prall[2], J. Engelhardt[1], S. Mukhopadhyay[1], S. P. Henry[1], and P. Narayanan[1]. *[1]Ionis Pharmaceuticals, Carlsbad, CA; and [2]University of Wisconsin–Madison, Madison, WI.*

Genetic influence on the incidence of 2'-MOE ASO-induced sporadic severe thrombocytopenia (TCP) (platelet counts 50<μL) in nonhuman primates (NHPs) is not well understood. Based on an integrated safety database of 102 distinct 2'-MOE ASOs from 61 studies and >2200 NHPs, severe TCP is observed at a low incidence (2%-4% at doses >5 mg/kg) in Asia-sourced cynomolgus monkeys (ACMs) (Henry SP, et al., NAT, 2017). Anecdotal evidence from various internal and external sources suggests that Mauritian-sourced cynomolgus monkeys (MCMs) have a markedly higher incidence of 2'-MOE ASO induced TCP compared to ACMs. The MCM population descended from small founder population introduced to the geographically isolated island of Mauritius in the 1500s (Sussman and Tattersall, Folia Primatology, 1986). The close-relatedness of MCMs may be advantageous for identifying genetic influences, if any, that play a role in ASO-induced TCP in NHPs. A study investigating subcutaneous 40mg/kg/wk dosing of ISIS 405879, a 2'-MOE ASO, induced severe TCP and mean platelet volume increase in 7/9 MCMs and 0/9 ACMs after 16 weeks of treatment. We performed exome sequencing of the 18 monkeys in this study along with banked samples from 52 ACMs treated with a variety of 2'-MOE ASOs picked in a 1:1 ratio of cases to controls. Multiple lines of evidence support an immune-mediated mechanism for severe TCP and it is possible that genetic variants could influence the immune response. The initial analysis of SNPs in genes that had been implicated in immune or drug-induced thrombocytopenia did not reveal an association with severe TCP. We noted 18 deletion variants (>100bp) in some NHPs compared to the *Macaca fascicularis* reference genome (MacFas5). These variants did not, however, segregate with TCP incidence and further analysis is needed is to draw a connection to TCP. Ongoing work includes strategies to aggressively limit the 450,000 typed SNPs to a handful of SNPs-of-interest to reduce multiple hypothesis testing *a priori*. Finally, we are doubling the number of monkey exomes from 70 to 140 to improve robustness in our genomic investigations.

PS 2001 Mapping of a Highly Repetitive Enhancer Region within the IGH Gene Using Long-Read-Single Molecule Nanopore Sequencing

C. P. Allex-Buckner, A. Snyder, and C. Sulentic. *Wright State University, Dayton, OH.*

Recently the cost of whole genome sequencing (WGS) has decreased while accuracy has increased. WGS of the human genome can be completed faster for cheaper utilizing "short read" sequencing (Illumina). Although these technologies provide highly accurate genotyping within simple regions, they lack the ability to map more complicated regions within the genome. Such regions include areas of high GC% bias, segments with large semi-palindromic sequences, and multiple tandem repeats. These regions make the *de novo* construction of more complete human genomes difficult. Single molecule technologies have provided a method to aid in the mapping of these difficult to sequence regions. The MinION nanopore sequencer (Oxford Nanopore Technologies) is one such technology that utilizes a bacterial protein pore to sequence intact strands of DNA. One benefit of this system is the ability to sequence large strands (> 100kb) without the need for PCR. Accuracy of single molecule sequencers is lower than that of short read sequencers. This has led to the development of algorithms that utilize long read data in tandem with the short read data to provide better *de novo* assembly of hard to map regions. Recently we induced edits in an enhancer (hs1.2) found within the 3'Immunoglobulin heavy chain gene regulatory region (3'IGHRR) in a human B cell line (CL-01). Both the regulatory region and hs1.2 enhancer are duplicated. The hs1.2 enhancer contains a 53bp invariant sequence (IS) that can be repeated one to four times in tandem. Flanking the hs1.2 enhancer are simple repeats and semi-palindromes. Because of these repeats, sequencing of this region cannot be done using short read sequencing, requiring the need for long read sequencing. To determine the exact edits we induced, we utilized MinION sequencing in conjunction with a protocol to obtain ultra-long reads. We made a reference genome of our cell line utilizing 1D MinION sequencing and performing analysis by hybridizing MinION reads and Illumina HiSeq X read. Because sequencing with the MinION does not require PCR amplification, we also have the ability to evaluate epigenetic modifications within the 3'IGHRR. Exact hs1.2 gene edits were determined through sequencing of amplicons capturing the full duplicated hs1.2 enhancer region. Long-read-single molecule sequencing using the MinION has been essential to determining the exact edits induced within the hs1.2 enhancer and to assemble a complete reference genome of our cell line.

PS 2002 Evaluation of Connectivity Mapping Methods Using TempO-Seq Gene Expression Profiles

P. Shepard, B. Key, B. Seligmann, M. Babic, and J. Yeakley. *BioSpyder Technologies, Carlsbad, CA.*

Gene expression profiling has proven to be useful in identifying relationships between diseases, cell physiology, and therapeutics. Functional relationships underlying a disease, genetic perturbation, or treatment with a compound can be inferred by comparing the similarity of the experimentally derived "query" expression profile to a database of gene expression signatures linked to functions, diseases, or perturbations. A large-scale perturbation database that uses transcriptional expression data is The Connectivity Map (CMap). TempO-Seq® is a gene expression technology well suited for high throughput transcriptomics because it uses crude lysates, avoiding the need to extract or reverse transcribe RNA, permits pooling of many samples in a single sequencing run, and automated TempO-SeqR™ analysis software that does not require a bioinformatics expert to align the data, generate count tables, and identify differentially expressed genes or pathways. We evaluate the ability of TempO-Seq gene expression data to accurately identify signatures in the CMap database. We experimentally determined the TempO-Seq gene expression signatures for 4 compounds known to be included in the CMap database and asked how accurately the TempO-Seq signatures mapped to the CMap database signature for each. The 4 profiles were generated by treating MCF7 cells with cicloprox, genistein, sirolimus, and tanespimycin, with DMSO as a no treatment control. Signatures were generated by obtaining the log2fold change for each treatment versus control. These 4 signatures were mapped against the CMap build 02. Each signature was compared to the cmap database using three commonly used methods; the Kolmogrov-Smirnov method (KS), the extreme sum method (XSum), and the eXtreme cosine method (XCos). We find that for all 3 methods, cicloprox, sirolimus and tanespimycin are returned as

one of the top 5 results and genistein is in the top 20 results.We further evaluated the performance of each method by generating Receiver Operating Characteristics (ROC) curves. The areas under the ROC curves (AUCs) were calculated for each method. The xCos method (AUC =0.86) outperforms both the XSum (AUC=0.82) and KS (AUC=0.76) methods. Based on these results, we have incorporated the XCos method into the TempO-SeqR app, allowing for the user to align, perform QC analysis, obtain differential expression, fold changes and perform connectivity mapping of gene signatures using a single software application.

2003 Characterization of Reference RNAs and Lysates for Use as Gene Expression Controls

M. Raghunathan, E. Imler, M. Marron, P. Shepard, J. Yeakley, and B. Seligmann. *BioSpyder Technologies, Carlsbad, CA.*

Reference RNA samples are important positive controls for gene expression analysis. They provide a standard sample for quality control and a method of normalization between assay runs. The first widely adopted reference RNA samples were the MicroArray Quality Control (MAQC) reference A (Universal Human reference RNA, UHRR, Agilent) and B (FirstChoice® Human Brain Reference RNA, Ambion), described in papers published in Nat. Biotechnol. 2006, 24 (9) 1115-1169. MAQC A is a pool of total RNA extracted from 10 cell lines. MAQC B was a pool of total RNA from brain tissue of 23 donors which is no longer available. No other reference RNAs have been broadly adopted, nor is there any information about whether additional batches of these reference RNA's can be manufactured once they are exhausted, and little performance data is available. Most reference RNAs are complex mixtures of cells or tissues, with unclear manufacturing reproducibility. With EPA funding, we pursued the manufacture of reference RNAs that could be reproducibly manufactured in successive batches and which provide comparable performance to the MAQC references. We observed that when the contribution of accumulated cell lines to the total number of expressed genes was measured, the first cell line contributed ½ - ¾ of the genes, with each successive cell line providing diminishing additive contributions approaching an asymptote of 12,000-15,000 genes after incorporating 6-10 highly diverse cell lines. In contrast, we found that by treating cells with select compounds, we could achieve maximal numbers of expressed genes, differentially expressed genes, and differential expression range with only 3 cell lines and 2 compounds, pooled in different proportions, permitting repeatable culture and preparation of reference batches. We generated reference lysates first (EPA L1 and L2), then extracted the RNA for the matched reference RNA (EPA R1 and R2). We manufactured several batches to define repeatability and characterized performance; >5 logs dynamic expression range, >12,000 to 13,000 genes expressed by each, >11,000 expressed genes in common, with a range of 29 log2 fold change in differential expression between the samples of >5,000 genes (padj <0.05) at a sequencing depth of 8M reads. These results suggest that the EPA R1, R2, L1 and L2 reference controls should perform well as positive control samples, with particular utility in toxicology and drug discovery due to inclusion of cell responses to compound exposure.

2004 A Deep Learning Framework for Integrating Heterogeneous Data in Predictive Toxicology

L. Wu, S. Thakkar, J. Xu, and W. Tong. *US FDA/NCTR, Jefferson, AR.*

It remains a challenge to integrate multiple data sources for the prediction of toxicological endpoints. Utilizing the recent advancements in artificial intelligence, we developed a deep learning framework to integrate different data sources generated for the same objects, which produces more informative features for predictive model construction. In this study, we reported a deep neural network combined with an autoencoder, one of unsupervised learning architectures, for the purpose of integrative feature representation. Instead of restricting the input and output for the autoencoder to be the same, we allowed cross pairing between heterogeneous data sources. As a result, the generated features could represent the salient information from both platforms which would in turn improve the performance and robustness of the predictive model. We first demonstrated its utility in the SEquencing Quality Control (SEQC) neuroblastoma benchmark dataset, as our framework reached 0.854 in AUC for prediction patients' overall survival, which improved by 15% to 35% compared to previously established models. We then applied it to the prediction of Drug-Induced Liver Injury (DILI) potential via cell-line based assays of the drugs. The result showed our framework reached 0.261 of MCC in cross-validation, where the performance of other algorithms such as KNN, Random Forest and SVM were much lower, ranging from 0.094 to 0.161. In summary, we introduced a deep learning framework as a novel solution for integration of heterogeneous data to advance predictive toxicology.

2005 Mapping the Transcriptional Regulatory Landscape of Arsenic-Exposed Beta Cells

R. Beck[1], T. Dinh[1], R. Sritharan[2], M. Styblo[1], and P. Sethupathy[2]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]Cornell University, Ithaca, NY.*

Type 2 diabetes (T2D) is a complex metabolic disorder characterized by hyperglycemia and pancreatic β-cell dysfunction. Laboratory and population studies have shown arsenite (iAs) or its methylated trivalent metabolite (MAs) can impair glucose stimulated insulin secretion (GSIS) by β-cells, but the underlying mechanisms remain uncharacterized. Transcriptional regulatory elements (TREs), including promoters and enhancers, which together control transcriptional regulation of gene expression, are important mediators of cellular response to environmental perturbations; however, they remain poorly understood in the context of arsenic exposure. Enhancers are classically defined as stretches of non-coding DNA that promote gene transcription by serving as binding sites for transcription factors, transcriptional coactivators, and RNA polymerase. We exposed rat insulinoma cells (INS-1 832/13) to non-cytotoxic concentrations of iAs (1 μM), MAs (0.5 μM) for 24 hours followed by RNA sequencing to investigate changes in gene expression. Matched chromatin run-on sequencing (ChRO-seq) was also performed to identify differentially active TREs in these cells. While both iAs and MAs significantly inhibited GSIS, high-throughput RNA sequencing revealed distinct gene expression profiles specific to each exposure. Specifically, we found that genes up-regulated by iAs are enriched in the NF-κB signaling pathway, a proinflammatory pathway previously associated with iAs exposure in other cell types. Genes downregulated by MAs are enriched in the regulatory network of FoxM1, a transcription factor (TF) necessary for the maintenance of adult β-cell mass, β-cell proliferation, and glucose homeostasis. ChRO-seq analysis revealed that more TREs are significantly altered by MAs exposure than by iAs (iAs: 9 up, 80 down; MAs: 312 up, 335 down). Exposure to iAs reduced the activity of TREs enriched in binding motifs for Rfx6 which regulates insulin transcription, content and secretion and for NeuroD1 in MAs-exposed cells, which controls insulin gene expression. Both exposures resulted in reduced activity of TREs enriched in binding motifs for Pdx1, a TF that is critical for establishing and maintaining β-cell identity. These altered TREs may represent an additional mechanistic link between arsenic exposure and disease.

2006 Utilizing FDALabel to Investigate Adverse Drug Reaction Patterns in Antidepressant Drug Labeling

N. Hill[1], T. Ingle[1], Z. Liu[1], J. Yang[1], G. Zhou[1], M. Yang[2], W. Tong[1], and H. Fang[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]University of Arkansas at Little Rock, Little Rock, AR.*

Depression, one of the most common mental illnesses in the US, is known to increase the risk of suicide, which is the tenth overall leading cause-of-death and second-leading cause-of-death among adolescents and young adults. As depression rates increase, so does the use of prescribed antidepressants, which can have potentially severe and sometimes life threating adverse drug reactions (ADRs), including suicide. FDA-approved drug labeling includes ADR information to help ensure the safe and effective use of prescribed drugs like antidepressants. This reliable source of information can be used to investigate and research potential ADRs to promote drug safety and public health. FDALabel is a searchable database containing drug labeling that can be used as a resource to locate important ADR information. DrugBank was used to identify 32 single active-ingredient drugs classified as antidepressants. A unique ingredient identifier for each of these drugs was used to query FDALabel for updated drug product labeling documents. Oracle SQL was used to extract ADR terms from different sections of these labeling documents. An ADR profile of the most frequently occurring terms was constructed to identify distribution patterns across the different labeling sections. All 32 antidepressant drugs identified had Boxed Warnings associated with the increased risk of suicidality in teens and young adults. Seven ADRs (*Depression, Completed suicide, Obsessive-compulsive disorder, Dizziness, Agitation, Mania, Seizure*) were identified among Boxed Warning, Warnings and Precautions, Pediatric Use, and Adverse Reactions sections of the labeling documents. Multiple ADR patterns were identified within the Warnings and Precautions sections. For example, Hepatic ADRs *Liver injury*, *Jaundice*, *Hepatotoxicity*, and *Hepatitis* occurred among two serotonin and norepinephrine reuptake inhibitor drugs, duloxetine hydrochloride (Cymbalta) and milnacipran hydrochloride (Savella). ADR patterns in antidepressant drugs could provide valuable information to assess risks and to promote safe and effective treatments for patients with depression. Here, information queried from drug labeling using FDALabel provided data for ADR analysis and pattern discovery in support of drug-safety research and public awareness of antidepressant drugs.

2007 How Complete Is Our Map of the Human Toxome? Functionally Enigmatic Genes as Targets of Chemical Perturbations

V. Tran, A. Maertens, A. Kleensang, and T. Hartung. *Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.*

The implementation of mechanism-based regulatory toxicology requires knowledge of the functions and pathways of target genes of chemicals. Incomplete information about genes in the human toxome can introduce biases to toxicological studies relying on annotation-based approaches. The purpose of this study was to identify the categories of gene annotation that are likely to be missed in chemical perturbation databases. We performed weighted gene co-expression network analysis (WGCNA) on human transcriptomic data sets, and correlated number of PubMed publications - an indication of annotation level - to various gene significance metrics. We showed that the amount of research was not correlated to the gene's biological importance. Moreover, these genes were not missing at random but reflected that our information about genes was gathered in a biased manner: poorly studied genes were more likely to be primate-specific and less likely to have a Mendelian inheritance pattern, tended to cluster in some biological processes and not others. Finally, many functionally enigmatic genes in diverse pathways - including primate specific genes - were potentially druggable or susceptible to chemical perturbations. In conclusion, underannotated genes would be invisible in a rodent model as well as in approaches based on prior pathway knowledge, underscoring the need for unsupervised analysis of human-relevant data sets in toxicology.

2008 A Machine-Learning Model Accurately Predicts TCDD-Induced Gene Expression

S. Bhattacharya[1], W. Qi[1], V. Tanwar[2], C. Jose[2], and S. Cuddapah[2]. *[1]Michigan State University, East Lansing, MI; and [2]New York University, New York, NY.*

The Aryl Hydrocarbon receptor (AhR) is a ligand-activated transcription factor that regulates a variety of genes to mediate the toxic actions of the persistent environmental contaminant 2 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD). Joint analysis of AhR ChIP-Seq and RNA-Seq data from TCDD-treated MCF-7 cells showed that only 24 out of 218 up-regulated genes and one out of 87 down-regulated genes are AhR-bound in their proximal promoter regions. Several genes (228) show AHR binding in their promoter regions but are not differentially induced by TCDD. The underlying regulatory mechanisms for these observations are not clear. Epigenetic features including chromatin accessibility, DNA methylation, and histone modification have been reported to play important roles in controlling gene regulation. In this study, we have developed a machine learning model that predicts the gene expression (up-regulated, down-regulated, or unperturbed) in TCDD-treated cells based on histone modifications and chromatin accessibility, AHR ChIP-Seq data as well as DNA sequences in the gene promoter regions. Our predictive model is interpretable, clarifying the complex interactions among these multiple genomic and epigenomic features regulating TCDD-induced gene expression. The model will be validated with RNA-Seq data from TCDD-treated HepG2 cells and primary human hepatocytes. This work will: i) Improve our understanding of AHR-mediated gene regulatory networks and combinatorial gene regulatory effects of epigenetic modifications; and ii) provide a quantitative framework to predict inducible gene expression upon exposure to non-genotoxic chemicals.

2009 Prediction of Genome-Wide Aryl Hydrocarbon Receptor Binding from DNA Sequence, Chromatin Accessibility, and Histone Modifications

W. Qi[1], S. Bhattacharya[1], and S. Cuddapah[2]. *[1]Michigan State University, East Lansing, MI; and [2]New York University, New York, NY.*

The Aryl Hydrocarbon Receptor (AhR) is an inducible transcription factor (TF) whose ligands include the potent environmental contaminant 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). The AhR regulates genes involved in a variety of physiological and developmental processes, and its dysregulation has been linked to multiple adverse outcomes like liver toxicity and immune suppression. Mapping of AhR-mediated gene regulatory networks is critical for improved understanding of the intracellular events that lead to tissue-specific adverse health effects upon exposure to TCDD-like chemicals. However, the identity of *in vivo* AhR binding sites is unknown in most human tissues; and computational prediction of genome-wide binding sites and identification of target genes for the AhR and other environmentally induced TFs remains a formidable challenge. In this study, we applied XGBoost, a supervised machine learning model, to predict DNA binding sites of the AhR in MCF-7 breast cancer cells and human hepatocytes. We trained the model on DNA sequence features and epigenetic marks including chromatin accessibility and histone modifications (HMs). Our results showed that a combination of DNA sequence and specific epigenetic marks can predict AhR binding sites with high accuracy. Comparison of the HM patterns surrounding bound vs. unbound DNA sequences centered on the canonical 5′-GCGTG-3′ AhR binding motif showed significant differences in HMs both within specific tissues and across tissues. We also found the relationship between epigenetic marks and AhR binding affinity to be region-specific across the genome. Our work provides a robust modeling framework to predict binding sites for the AhR and other ligand-inducible transcription factors in a tissue-specific manner.

2010 How Similar among Different Toxicogenomics Study Designs for Liver?

Z. Liu[1], R. Roberts[2], and W. Tong[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]ApconiX, Alderley Edge, United Kingdom.*

Toxicogenomics (TGx) is an important tool to gain an enhanced understanding of toxicity at the molecular level. A broad ranges of TGx study design has been reported, some based on the existing animal models (e.g., one-day short-term assay or repeated dosing for 28 days) and the other applied *in vitro* systems (e.g., cell lines from rat, humans and cancer). A question is naturally rasied: how similar among different TGx study designs? In fact, this question can be asked in many different ways: (1) is a one-day *in vivo* short-term assay able to replace the 28-day standard and expensive toxicological assay? (2) are some biological processes more conservative across different preclinical testing systems than others? (3) do these preclinical testing systems have the similar resolution in differentiating drugs by their therapeutic uses? (4) Is it possible for *in vitro* to *in vivo* extrapolation? And (5) can genomic profiles from a cancel line predict drug-induced liver injury? These questions were explored using several large genomics datasets including Open TG-GATEs and L1000 for assesing drug-induced livery injury with proposed PRank methodology. For rat *in vivo*, one-day single dosing is very similar to the 28-day repeated dosing (score=0.9). A better IVIVE concordance was obtained for rat primary hepatocytes (score =0.71) than for human primary hepatocytes (score =0.58), indicating species difference playing a critical role in IVIVE. When limiting the analysis to only these drugs causing severe DILI, the IVIVE concordances were improved for both rats (from 0.71 to 0.76) and humans (from 0.58 to 0.62). Furthermore, we observed an encouraging similarity between HL60 and human primary hepatocytes (score = 0.70), suggesting the two cellular assays could be potentially interchangeable. In conclusion, this study provided valuable information for selecting the 'fit-for-purpose' TGx assay for drug safety evaluation.

2011 Transcriptional Comparison of Liver Cells to Reveal Biological Networks and Pathways Differentially Regulated for Each *In Vitro* Liver Model Systems

K. Yamanaka, H. Kohara, A. Miyawaki, and T. Shinozawa. *Takeda Pharmaceutical Company Limited, Fujisawa, Japan.*

Hepatic injury by drugs continues to be a major concern in drug development. There is a requirement for predictive and mechanistically informative models to aid the risk assessment. In the early phase of drug development, *in vitro* cell-based assays were proposed as potential solutions to predict drug induced liver injury (DILI). Although several types of liver cells are often used for developing such *in vitro* assays, it is not understood what biological networks and pathways are similar or differ between each *in vitro* liver model and human liver tissue. In this study, transcriptome analysis was performed with human liver tissues, human hepatocytes freshly isolated from liver-humanized mice (PXB-cells), cryopreserved primary human hepatocytes, HepaRG, and HepG2 cell lines by using RNA-seq to understand the gene expression characteristics of each liver model. We used the Weighted Gene Co-expression Network Analysis (WGCNA) approach to reconstruct gene co-expression networks for human liver model cells and liver tissues. This analysis generated 26 modules for 14,826 transcripts. The result suggested that genes related to FXR/RXR, PXR/RXR, and LXR/RXR activation pathways were differentially regulated among the liver models. Those genes showed higher expression in human liver tissues and less expression in HepG2 and HepaRG cell lines. Human primary hepatocytes and PXB-cells showed a gradual increase in those genes over time of culture. Because nuclear receptors like PXR, RXR, and LXR play a key role in the transcriptional control of critical steps of hepatobiliary transport and phase I/II metabolism of endo- and xenobiotics such as bile acids and drugs, our result indicated that primary hepatocytes and PXB-cells would be better models to capture cholestatic liver injury than the other

liver cell lines. When we developed an *in vitro* assay which could quantitate drug-induced bile acid efflux transport inhibition with the liver model cells by using synthesized fluorescent analogue of natural bile acid cholylglycine (cholyl-L-lysyl-fluorescein: CLF), PXB-cells detected cyclosporine A induced dose dependent CLF efflux inhibition with higher sensitivity than HepaRG. By understanding biological network and pathway differences among the liver model cells to develop *in vitro* mechanistic assays for liver toxicity, we can improve the predictability of DILI.

PS 2012 FAIRtox: A Web Application to Promote Data FAIRness at the Michigan State University Superfund Research Center

T. Zacharewski, J. Dodson, H. Pimentel, J. LaPres, N. Kaminski, and R. Nault. *Michigan State University, East Lansing, MI.*

The Michigan State University (MSU) Superfund Research Center (SRC) has produced vast amounts of data characterizing the mechanisms and impact of exposure to aryl hydrocarbon receptor (AHR) ligands. These data, ranging from single-endpoint *in vitro* assays to *in vivo* omics, are a valuable resource to the research community, yet their reuse is hampered by limitations in existing repositories and resources for re-analysis and integration. Findability, Accessibility, Interoperability, and Reusability (FAIR) data principles have been developed to maximize the impact of publicly funded research data. To further advance the FAIRness of MSU SRC data, we have developed a web application, FAIRtox, to access, query, integrate, and reuse SRC data. Currently, FAIRtox manages microarray and RNA-sequencing datasets for TCDD, PCB126, or PCB77 exposures in mouse, rat, and human *in vivo* and *in vitro* models with comprehensive metadata that provide study design details and context to support independent analysis and interpretation. Querying and analysis tools within FAIRtox enable comparisons and integration of deposited datasets for dose-response, time-course, and circadian regulated study designs to further characterize how diurnal rhythm and treatment duration impact hepatic gene expression. Furthermore, basal expression levels across multiple samples provides additional insight into interactions between sex, diurnal rhythm, and toxicity. FAIRtox serves as a centralized resource to access the diverse data types generated by the MSU SRC, along with meta-data, and tracked to persistent locations in publicly available repositories such as the Gene Expression Omnibus (GEO) and Dataverse. FAIRtox is developed using R Shiny (RStudio) to leverage the various packages to process and analyze various biological data types. Distribution of the web-application through code-sharing repositories, and packaged as a Docker Image, will make the tools and data publicly available. The goal of FAIRtox is to improve data sharing, reuse, and reproducibility to further elucidate mechanisms of toxicity and support the human risk assessment of chemicals of concern. *Funded by the Superfund Research Program P42ES04911.*

PS 2013 Machine-Learning Prediction of Cyanobacterial Toxin (Microcystin) Toxicodynamics in Humans

S. Altaner[1], S. Jaeger[1], R. Fotler[1], I. Zemskov[1], V. Wittmann[1], F. Schreiber[1,2], and D. R. Dietrich[1]. *[1]University of Konstanz, Konstanz, Germany; and [2]Monash University, Melbourne, Australia.*

Blue algae, cyanobacterial blooms and the concomitant presence of highly toxic cyanotoxins in surface waters used for drinking water and recreational purposes are a serious recurring health hazard. Among the most frequently reported cyanotoxins microcystins (MC) represent a family of cyclic peptides with approx. 250 congeners demonstrated to be harmful to human health due to their ability to inhibit ser/thr-proteinphosphatases (PPP). Indeed, the Caruaru incident in Brazil in 1996, where a high number of dialysis patients died following exposure to MC contaminated water during dialysis, or the most recent closing of the drinking water supply for the inhabitants of Toledo, Ohio, USA, resulting from recurrent *Microcystis aeruginosa* blooms in Lake Erie, dramatically emphasize the health hazards present. Despite the latter and recent efforts by WHO to improve the basis for human risk assessment and management all current hazard and risk assessments (HA/RA) are based on data of MC-congener (MC-LR), i.e. 1 of the 250 known MC congeners, only. Indeed, the fact that no MC-LR but rather a mixture of several MC congeners was deemed causal in the Caruaru incident in Brazil, only compounds the present situation with regard to HA/RA. MC congener structural diversity is a challenge for the risk assessment of these toxins, especially as in addition the several different PPPs have to be included in the HA/RA. Consequently, the inhibition of PPP1, PPP2A and PPP5 was determined with 18 structurally different MC and demonstrated MC congener dependent inhibition activity and a lower susceptibility of PPP5 to inhibition than PPP1 and PPP2A. The latter data were employed to train a machine learning algorithm that should allow prediction of PPP inhibition (toxicity) based on MCs 2D chemical structure. PPP inhibition IC_{50} values were classified in toxicity classes and three machine learning models were used to predict the toxicity class, resulting in 80-90% correct predictions.

PS 2014 A Predictive Classifier to Distinguish Nuclear Receptor Binding Sites Involved in Hepatic Cytochrome P450 Gene Regulation

O. Z. Kana, and S. Bhattacharya. *Michigan State University, East Lansing, MI.*

The liver is the central processing hub of xenobiotic chemicals and drugs in the human body. A handful of Cytochrome P450 (CYP) enzymes: CYP3A4, CYP2C9, CYP2C8, CYP2E1, CYP1A2, CYP2A6, CYP2D6, CYP2B6, CYP2C19, CYP3A5, CYP2J2, CYP1A1 and CYP1B1, account for more than 90% of liver xenobiotic metabolism. Expression of CYP genes is regulated by a network of hepatic nuclear receptors including hepatocyte nuclear factor-4-alpha (HNF4α), peroxisome proliferating factor alpha (PPAR), and retinoic X receptor (RXR). Recently assembled publicly available functional genomic data sets have allowed for a systems approach to understanding genome-wide regulation of toxicological responses. Using the CYP regulatory network as a model, we collected relevant epigenomic datasets. Visualizations of these epigenomic datasets reveal overlaps between transcription factor binding sites, DNaseI hypersensitivity sites, contextual histone modifications and pioneer factor binding in liver cells. These visualizations suggest a generalizable and predictable set of features for nuclear receptor binding sites. Using ChIP-Seq peaks, characterized binding sites and their flanking sequences using motif scanning. We utilized a combination of dimensionality reduction algorithms to graphically represent sequence and epigenetic differences among nuclear receptor binding regions. Using statistically and visually differential features in our dataset we developed machine learning classifiers to annotate putative response elements for hepatic nuclear receptors. This work will provide a dynamic framework to assemble gene regulatory networks underlying biological responses to a broad class of non-gentoxic chemicals.

PS 2015 Prediction and Analysis of miRNA Targets for Genes Conferring Risk to Breast Cancer Susceptibility

S. Yeguvapalli[1], and K. Chitrala[2]. *[1]Sri Venkateswara University, Tirupati, India; and [2]Temple University School of Medicine, Philadelphia, PA.*

Breast cancer is a leading cause of death among women worldwide. The constant acquisition of genetic and epigenetic alterations leading to tumor heterogeneity causing a major problem in designing effective therapies for most cases. Previous studies showed that the genes *BRCA1*, *BRCA2*, *PTEN,* and *TP53* are responsible for most of the inherited syndromes in breast cancer. MicroRNAs, on the other hand, are known to show a regulatory role in breast cancer. In the present study, we aimed to predict and analyze miRNA targets for the genes conferring high risk to breast cancer susceptibility using computational approaches. To this end, we have identified the miRNAs targeting the genes *BRCA1*, *BRCA2*, *PTEN,* and *TP53* across the 3′ UTR, 5′UTR and CDS regions using miRWalk, miRDB, and Targetscan databases. Our results showed miRNAs hsa-miR-4524b-3p, hsa-miR-384, hsa-miR-4524b-3p, hsa-miR-384, hsa-miR-4684-5p for *BRCA1;* hsa-miR-186-5p, hsa-miR-450a-1-3p, hsa-miR-450b-3p, hsa-miR-3176, hsa-miR-4432 for *BRCA2*; hsa-miR-7152-3p for *PTEN* and hsa-miR-138-5p, hsa-miR-587 for *TP53* were predicted as top five significantly aligned miRNAs at a p-vlaue of < 0.0001 in the CDS region. Further results showed enrichment of Gene ontology (GO) terms dna damage response, positive regulation of cell cycle arrest, apoptotic process, dna repair, cell cycle in *BRCA1*, multicellular organism growth, nucleotide excision repair, regulation of cytokinesis, histone h4 acetylation in *BRCA2*, t cell receptor signaling pathway, regulation of protein stability, protein stabilization, cell proliferation, cell migration in *PTEN* and base excision repair, cell proliferation, cell cycle arrest, cell aging in *TP53*. In conclusion, results from our study indicate that these miRNAs can be used as potential biomarkers for early cancer diagnosis and therapy.

2016 Discrepancy in the Safety Information of the US FDA and EMA Package Insert Has a Clinical Impact

Y. Wu[1], J. Borlak[2], W. Tong[1], and M. Chen[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]Hannover Medical School, Hannover, Germany.*

Ensuring the safe use of medicine is a major responsibility of the US Food and Drug Administration (FDA), which is listed as a priority in the FDA's Strategic Policy Roadmap. Hepatic adverse reaction is a main concern in drug safety and a leading cause of drugs being withdrawn from the market. To minimize the occurrence of the adverse event, the FDA issues a package insert (or drug label) for each approved drug, which provides evidence-based safety information as a reference for both healthcare professionals and patients. Regulatory agencies such as the FDA and its counterpart in Europe, European Medicines Agency (EMA) independently review and approve package inserts, which results in some degree of discrepancy in the safety features of the package insert. This raises critical concerns that such discrepancy could be misleading to physicians and thus increases the risk of adverse events. Here, we performed a systematic comparison of the hepatic safety information in the FDA's and EMA's package insert by using two sets of classification schemes. The labeling discrepancy regarding hepatic adverse reactions and clinical monitoring requirement was estimated to be 22-32% and 31% respectively. Much higher discrepancy rates were observed in contraindications (74%) and dose adjustment recommendations (67%) for pre-existing liver diseases. Notably, based on the analysis of the FDA's global adverse events report data, serious hepatic adverse events were found to be more commonly associated with drugs that have labeling discrepancy than those without labeling discrepancy. Therefore, the difference in risk perception and management between the two agencies has an impact on the patient clinical outcomes. The labeling discrepancy is mainly due to the differences between the FDA's and EMA's Guidelines, which are followed in making the package insert. This is not expected to be fully resolved considering the nature of the two agencies but could be at least minimized. Efforts in enhancing international communications and collaborations would be appreciated for the improvement of public's health.

2017 Predicted Genetic Networks Associated with Isocyanate Biomarkers of Exposure and with Susceptibility to Isocyanate-Induced Asthma

L. W. Taylor, J. E. French, E. J. Price, C. Poole, and L. Nylander-French. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Isocyanates in polyurethane paint and spray-foam insulation are known respiratory and skin sensitizers of global concern because they are a leading cause of occupational asthma. However, only a subset of about 5 - 15% of isocyanate exposed workers develop asthma. Thus, we hypothesize that inter-individual genetic variance may influence biomarkers of exposure and asthma susceptibility. We investigated genetic markers associated with variability in isocyanate biomarker levels and reviewed published data reported on isocyanate-induced asthma susceptibility markers in exposed workers. We quantified personal exposure and biomarker levels and performed genome-wide associations using mononuclear blood cell DNA of 33 male spray-painters. Using logistic regression and controlling for inhalation and skin exposure as covariates, we identified 20 single nucleotide polymorphisms (SNPs) associated with differences in isocyanate biomarker levels. These SNPs were within or proximal to 16 genes: ACVR1, ACVR1C, FHOD3, GDNF, RIMS1, C2orf71, DGKB, ETV1, BMPR1B, CNTN3, GRK5, KCNQ5, L3MBTL4, PDZRN3, PHF2, and SALL1. To identify genes associated with isocyanate toxicity, we systematically searched the literature for genetic markers that were over-represented in individuals with isocyanate-induced asthma. We found 166 non-duplicate publications, of which 24 contained relevant human data that were included in our analysis. Multiple studies reported significant markers within 17 genes: CDH17, CTNNA3, GSTM1, GSTM3, GSTP1, GSTT1, HLA-A, HLA-B, HLA-C, HLA-DPB1, HLA-DQA1, HLA-DQB1, HLA-DRB1, NAT1, NAT2, TNF-α, and ZBTB16. Gene ontologies associated with these combined gene sets were evaluated using GeneMANIA, a gene ontology enrichment database that predicts network associations. Our analysis shows interactive networks that include cell-cell adhesion, transcription modulation, regulation of ossification, and immune cell activation. These predicted genetic networks can help direct future research on allergic airway sensitization by isocyanates and development of better at-risk worker protections.

2018 New Potential Targets for Phosphodiesterase-5 Inhibitors

D. Pajaro-Valenzuela, W. Maldonado-Rojas, and J. Olivero-Verbel. *Universidad de Cartagena, Cartagena, Colombia.*

Male sexual enhancement supplements (MSES) are prescribed for erectile dysfunction and premature ejaculation. Most commercially available MSES are derived from sildenafil, a known phosphodiesterase type 5 (PDE5) inhibitor. In many countries, these drugs are sold to the public without a prescription, becoming a concern due to several adverse effects for which there is little information on their biochemical mechanisms. The aim of this work was to identify plausible human pharmacological targets for PDE5 inhibitors utilizing a computational approach. Optimized 3D structures of ten common PDE5 inhibitors were used as input ligands to search for potential target identification employing PharmMapper server. Best protein targets were subsequently examined by using protein-ligand docking methods with AutoDock Vina program. Results showed protein-ligand complexes with greater promissory scores (kcal/mol) were obtained for aromatase (PDB, 3EQM)/taladafil (-10.3); ribosyldihydronicotinamide dehydrogenase (3GAM)/aildenafil (-10.1) and mitogen activated protein kinase-10 (1PMV)/sildenafil (-9.6). These data suggest PDE5 inhibitors have the potential to modulate different biochemical processes, including hormone homeostasis, coagulation, and neuronal proliferation, differentiation, migration and programmed cell death, among others. Molecular re-docking experiments demonstrated the reliability of the docking protocols (RMSD <0.8 Å). Biological data for 47 PDE5 inhibitors (PubChem BioAssays, AID: 446781) displayed good correlation with the binding affinity from AutoDock Vina (r=0.640, p<0.001). These findings should encourage additional toxicological evaluations to better guarantee the safety use of MSES. *Colciencias-Unicartagena (528, 2011).*

2019 US FDA-Approved Drug Labeling: A Rich Resource for Pharmacogenomic Information in the Application of Precision Medicine

D. Mehta[1], R. Uber[2], T. Ingle[1], C. Li[3], Z. Liu[1], S. Thakkar[1], B. Ning[1], L. Wu[1], J. Yang[1], S. Harris[1], G. Zhou[1], J. Xu[1], W. Tong[1], L. Lesko[4], and H. Fang[1]. *[1]US FDA/NCTR, Jefferson, AR; [2]University of Pittsburgh, Pittsburgh, PA; [3]US FDA/CDER, Silver Spring, MD; and [4]University of Florida, Orlando, FL.*

Pharmacogenomics (PGx) is the study of how genomics and genetic variants affect drug response. FDA-approved prescription drug labeling includes important drug safety and efficacy information needed to prescribe drugs appropriately. Drug Labeling is a critical foundation for evidence-based medicine and include PGx information. However, for many drugs, PGx information is presented among different sections of labeling, making it challenging for the healthcare community to effectively identify and utilize the information. We summarized drug labeling PGx information obtained by searching FDALabel (https://nctr-crs.fda.gov/fdalabel/), a publicly available database developed by FDA/NCTR. A total of 261 prescription drug labeling documents were identified by querying 75 known biomarkers. The most frequently observed biomarkers by drug counts occurred in the order of CYP2D6 (66) > G6PD (39) > CYP2C19 (22) and covered a broad range of therapeutic classes (e.g., Psychiatry, Cardiology, Oncology, Endocrinology). In addition, four categories of applications were discussed according to information provided within the labeling: (1) Indication - useful for identifying responders and non-responders, (2) Safety - predicting patients at greatest risk for drug-induced adverse drug reactions, (3) Dosing - forecasting precision dosage adjustments for patient subgroups defined by PGx, and (4) Information - descriptive clinical pharmacology related to pharmacokinetics or pharmacodynamic information. This information could enhance the mechanistic understanding and clinical utility of PGx information in drug labeling and enable bench-to-bedside implementation of individualization of drug therapy for patients. In summary, this study provides a comprehensive assessment of PGx data in FDA drug labeling and offers researchers, regulators, drug developers, and physicians, an effective and efficient way to use the information to advance precision medicine.

2020 Using ANOVA-Based Clustering to Evaluate Chemical Response Patterns in Quantitative High-Throughput Screening Data

K. R. Shockley[1], and S. D. Peddada[2]. *[1]NIEHS, Research Triangle Park, NC; and [2]University of Pittsburgh, Pittsburgh, PA.* Sponsor: R. Paules

Quantitative high throughput screening (qHTS) experiments can simultaneously test thousands of chemicals for potentially adverse effects by generating concentration-response data for each chemical. However, artifacts and influential experimental factors may lead to distinct clusters of response pat-

terns within a single tested chemical. We describe a novel approach based on analysis of variance (ANOVA) to reliably identify separate response clusters within each chemical. Correlations between 7,229 chemical response patterns were assessed across 43 bioassay data sets from phase II of the Tox21 collaboration. The fraction of chemicals in an experiment with consistent response patterns (f_1) and the fraction with inconsistent response patterns (f_2) describe the extent of assay response and provide a measure of assay quality. Here, no relationship between f_1 and assay noise was detected across assay readouts, but a significant association between f_2 and assay noise was found (spearman $p < 0.01$). The proportion of hits with consistent responses among all detectable hits (r_1) was largest when there was only one supplier, one site of preparation or one compound purity per chemical. For example, in agonist assays the median r_1 was larger when chemicals were represented by only one supplier (median $r_1 = 0.25$) compared to cases in which chemicals were represented by two different suppliers (median $r_1 = 0.11$) or three different suppliers (median $r_1 = 0.07$). When performing a large-scale correlation analysis between all 72 assay readouts generated in the 43 bioassay data sets, most agonist assay readouts were positively correlated with each other in a single "activator" correlation block. Similarly, antagonist and cell viability assay readouts were positively correlated with each other in a separate "inhibitor" correlation block. However, response patterns from 8 out of 24 agonist assay readouts appeared in the inhibitor correlation block, with 5 out of these 8 readouts exhibiting negative overall mean responses. This correlation between bioassay responses from agonist assays and antagonist or cell viability assays may be due to widespread cytotoxicity effects. Overall, these results suggest that correlation analyses between bioassay response patterns can be used to assess bioassay quality and flag specific experiments for unexpected chemical response signatures.

2021 Integration of Transcriptomic Point-of-Departure Metrics into the MoAviz Visualization Framework

M. B. Black[1], K. Bronson[1], S. N. Pendse[1], R. A. Clewell[2], M. E. Andersen[1], and P. D. McMullen[1]. *[1]ScitoVation, Research Triangle Park, NC; and [2]21st Century Tox Consulting, Chapel Hill, NC.*

Gene expression profiling is emerging as a viable way to evaluate mode of action and points of departure and has the potential to drastically reduce testing costs and product development time. The first steps of using transcriptional responses as a basis of safety assessment are being taken. However, several important considerations remain unresolved, including how to translate expression changes into adverse outcome pathways or other definitions of mode of action, and the best manner with which to summarize gene expression data into a point of departure. Recently we developed an interactive browser application, MoAviz, to facilitate the examination of gene expression data across dose and time for mode of action studies of chemical perturbation for 204 compounds (spanning 290 million gene expression change values). We used MoAviz to quantitatively compare pathway-level transcriptomic signatures across compounds with well-known modes of action, and across different model systems, providing the groundwork for performing "biological read-across" between compounds based on their transcriptomic fingerprints. We evaluated the extent to which gene expression changes from in-life exposures could be associated with mode of action by developing a novel similarity index—the Modified Jaccard Index (MJI)—that provides a quantitative description of genomic pathway similarity. While typical compound-compound similarity is low (MJI = 0.026), clustering of the TG-GATES compounds identifies groups of similar compounds. Some clusters aggregated compounds with known similar modes of action, including PPARα agonists (MJI = 0.330) and NSAIDs (MJI = 0.327). We continue to extend the MoAviz interface and database by incorporating whole transcriptome benchmark dose analyses and point of departure (POD) summary, including the command line modeling features of the BMDExpress2 software. This integration will include statistical pre-filtering of transcriptomic gene expression data, dose response modeling of individual genes, ontology over-representation of genes, and POD summary based on current proposed best practices for gene-based and pathway-based derivation of POD. By combining mode of action and POD tools in an interactive interface, MoAviz will facilitate the use of transcriptomics data over a variety of chemical safety contexts.

2022 Binding Proteins for Curcumin and Bixin

M. Taboada-Alquerque, D. Pajaro-Valenzuela, and J. Olivero-Verbel. *Universidad de Cartagena, Cartagena, Colombia.*

Curcumin and bixin are natural pigments obtained from *Curcuma longa* and *Bixa orellana*, respectively. These chemicals are widely used in cosmetic products and exhibit diverse pharmacological properties that make them promising cosmeceuticals. Although both natural products protect against toxicity induced by diverse xenobiotics, little is known about their interaction with signaling transduction pathways. The objective of this work was to find binding proteins for these two molecules, aiming to link them to their reported biological activities. A total of 977 human proteins were evaluated as potential targets for these two chemicals through docking-based virtual screening. *In silico* molecular protein-ligand docking protocols were performed using AutoDock Vina, and proteins with best binding affinity values were further uploaded to public databases in order to reveal potential underlying pharmacological mechanisms. Protein-protein interaction networks were constructed using String server and Cytoscape, based on information provided by KEGG, PDB and Uniprot databases. Proteins complexes with best docking binding affinities (kcal/mol) included 4EY7-curcumin (-11.4), 3PM0-curcumin (-10.7), 1HK4-bixin (-10.5) and 4EY7-bixin (-10.4). The results showed curcumin and bixin have the potential to modulate signaling pathways related to estrogen receptor, steroid hormone biosynthesis, PI3K-Akt, cancer, and aminoacid metabolism, among others. Findings presented here may provide information that will improve our understanding of the pharmacological mechanisms of bixin and curcumin, and will pave the way for additional therapies employing these cosmeceuticals. *COLCIENCIAS-UNICARTAGENA, FP 44842-212-2018.*

2023 Does Transcriptional Response Add Value to Predicting Drug-Induced Liver Injury?

P. Koza-Taylor[1], E. Ozioloa[1], M. Gosink[1], E. Watt[1], S. Oda[2], T. Yokoi[2], M. Hizue[3], S. Kumpf[1], J. Qian[1], J. Whritenour[1], and M. Aleo[1]. *[1]Pfizer Inc., Groton, CT; [2]Nagoya University, Nagoya, Japan; and [3]Pfizer Inc., Nagoya, Japan.*

Drug induced liver injury (DILI) is caused by widely diverse mechanisms that can be specific to various drug classes. Variable types of injury (hepatocellular, cholestatic, steatosis) have led to the withdrawal or black box warnings for many efficacious compounds. DILI risk annotation for compounds is complicated and controversial. The federal drug administration has established a set of suggested risk classification groups, leading to four categories: most, less, no and ambiguous DILI concern. We tested 69 drugs from the most and no DILI concern categories in a novel *in vitro* model comprised of the HepG2 cell line and human peripheral blood monocytes (PBMCs) to elicit an immune response, often observed as a component of DILI. We then performed transcriptome evaluation (TempOseq) of the PBMCs and explored the pathways that were differentially activated between the two risk categories of compounds. The most significant dysregulated pathways within the most DILI concern include innate and immune response and apoptosis. In addition, we built a random forest machine learning model to evaluate the predictive value of transcriptomic *in vitro* screening. Even in the absence of final clinical dosing information, the model was able to identify a significant proportion of the compounds of most DILI concern compounds. We then compared this transcriptomic-only model to a model built using simple physical/chemical properties and found that the transcriptomic-only model does not add additional quantitative value to computational prediction of overall DILI risk. However, we suggest that transcriptomic response adds novel value for understanding mechanisms of DILI for certain classes of compounds, in particular immune mediated toxicity.

2024 Enhancing the US EPA Adverse Outcome Pathway Database (AOP-DB): Recent Updates and Semantic Integration

H. M. Mortensen. *US EPA, Research Triangle Park, NC.*

There is a need for more efficient use of existing data to characterize human toxicological response data for environmental chemicals of interest to the US Environmental Protection Agency (EPA). The Adverse Outcome Pathway (AOP) framework helps to organize existing mechanistic information, where AOP data is currently submitted directly by users and stored in the AOPwiki. Automatic and systematic parsing of AOPwiki data is challenging, so we have created the EPA AOP-DB. The AOP-DB is an AOP profiler, developed to assist in biological and mechanistic characterization of AOP data and provide a broad, systems-level overview of the biological context of AOPs. Here we present recent updates to AOP-DB version 2, including 262 AOPs from the AOP-wiki xml, AOP-Tissue Network and Human Susceptibility modules, and a computationally-predicted AOP Builder. We also present updates to the GUI frontend with search and download capabilities. Lastly, we describe recent semantic mapping efforts for the AOP-DB, and how this process integrates AOP-DB data with other toxicologically relevant datasets. *This abstract does not reflect US EPA Policy.*

2025 Hepatic and Renal Concentrations of General Chemicals Estimated after Virtual Oral Administrations Extrapolated Using Simple Physiologically Based Pharmacokinetic Models and Rat Plasma Data

H. Yamazaki, and M. Shimizu. *Showa Pharmaceutical University, Machida, Japan.*

Recent high-throughput *in vitro* screening assays combined with *in silico* computational models might provide suitable alternative methods to conventional animal testing. The aim of the present study was to model the plasma, hepatic, and renal pharmacokinetics of approximately 70 disparate types of chemicals and drugs after virtual oral administrations in rats based on reported rat plasma values and experimental pharmacokinetics determined after oral administration to rats for evaluating toxicological potential. To ensure that the substances analyzed exhibited a diversity of chemical structures, the structures defined by 196 chemical descriptors in a chemoinformatics tool were calculated for 50,000 randomly generated molecules in the original chemical space. To allow visualization, the resulting chemical space underwent projection onto a two-dimensional plane using generative topographic mapping. The current study employed a one-compartment model recently recommended by US authorities and a physiologically based pharmacokinetic (PBPK) model made up of chemical receptor (gut), metabolizing (liver), excreting (kidney), and/or central (main) compartments. The plasma concentration curves and the maximum concentrations of a varied selection of approximately 70 chemicals obtained by high-throughput one-compartment models and our simple PBPK models were consistent. However, the hepatic or renal and plasma concentrations or the areas under the concentration-time curves of 70 chemicals were different between the PBPK modeling and empirically obtained values. Although the numbers of compounds were limited, the lowest observed effect level values for hepatoxicity or nephrotoxicity of several compounds from the Hazard Evaluation Support System Integrated Platform in Japan and the areas under the hepatic or renal concentration-time curves estimated using PBPK modeling were inversely associated. The present models could estimate the relationships between plasma/tissue concentrations of chemicals and drugs after oral doses using both forward and reverse dosimetry with a view to predicting hepatic or nephrotoxic toxicity as a part of chemical risk assessment. *Supported by the METI Artificial Intelligence-based Substance Hazard Integrated Prediction System Project, Japan.*

2026 Gaining Confidence in Combined Methods: Uniting Structural Alerts, Random Forests, and Neural Networks for Use in Risk Assessment

T. E. Allen[1,2], A. J. Wedlake[2], M. Folia[3], S. Piechota[3], E. Gelžinytė[2], J. M. Goodman[2], S. Gutsell[3], P. Kukic[3], and P. J. Russell[3]. *[1]MRC Toxicology Unit, Cambridge, United Kingdom; [2]University of Cambridge, Cambridge, United Kingdom; and [3]Unilever, Sharnbrook, United Kingdom.*

Molecular Initiating Events (MIEs) provide good targets for computational modelling, as they are well defined chemical-biological interactions. When compared to trying to predict biological endpoints, MIE predictions do not pass over large amounts of biological complexity. Computational approaches based on the chemistry of chemical binders have been developed to make predictions at pharmacologically important human MIEs, and these approaches have been combined to provide a high performing model. The first computational model uses structural alerts developed automatically using maximal common substructure searches and Bayesian statistics in KNIME. In addition to this, two different machine learning algorithms have been used - random forests and neural networks. The random forest models were constructed using sklearn in RDKit, with 200 physicochemical descriptors as the input. The neural networks were developed in Python 3 using TensorFlow. Extended connectivity fingerprints were used as inputs and a variety of network architectures considered to give the highest level of statistical performance. All three computational approaches consistently provide models with over 90% accuracy against test data. The data used for model construction was consistent across all three approaches, with ChEMBL and ToxCast data being combined to provide a relatively balanced dataset between experimental positives and negatives. Biological targets assessed include G-protein coupled receptors, nuclear receptors, enzymes, ion channels and transporters to give a balance of different human MIEs. While the developed computational models provide high levels of performance, combining them in a decision-making context allows us to use the advantages of each method to provide the best possible prediction. In addition, this procedure shows an increase in model performance. Applicability domains and confidence scores for test chemicals can be used to better understand how new chemicals compare to the data set used in model construction. Finally, these models have been assessed on truly external biological data to test their effectiveness. This is the ultimate goal of such predictive approaches as it gives the best impression of their usefulness outside the training and test data. While there is a reduction in model performance in this scenario, it helps us understand how models perform when novel chemicals are assessed, and hence how they are useful in risk assessments.

2027 *In Silico* Prediction and Suggestion to Alleviate Promiscuity of Compounds

H. Hara, T. Sameshima, and M. Miyamoto. *Takeda Pharmaceutical Company Limited, Fujisawa, Japan.* Sponsor: M. Miyamoto, Japanese Society of Toxicology

Since safety is one of the most influential factors of drug attrition in drug discovery, the selection of compounds with less toxicity concerns is important to increase the success rate of drug discovery. To estimate the concern of off-target toxicity during early research stages, we originally constructed a small-scale assay panel, promiscuity panel (PP) [Sameshima, T. et al. Chem. Res. Toxicol. 2019], consisting of eight targets (ROCK1, PDE4D2, GR, PPARγ, 5-HT_{2B}, Adenosine A_3, M1 and $GABA_A$) to evaluate binding properties towards a wide range of gene families. To promote the optimization of compounds more efficiently, cheminformatics analysis of large amount of assay results is expected to be useful. We applied two types of *in silico* approaches to assay results of PP. One is a quantitative structure-activity relationship (QSAR) modeling to aim prediction of binding property. In this study, we constructed QSAR models based on PP assay results of approximately 3000 compounds by using random forest method. Although the QSAR model of GR showed low predictability because of its low hit rate, the other seven QSAR models showed high predictability with more than 0.86 of AUC value of ROC curve by 5-fold cross validation. By using PP QSAR models, we evaluated compounds from Liver Toxicity Knowledge Base (LTKB) of FDA, and confirmed the relationship between a hit count of PP QSAR models and DILI severity. The other type of *in silico* approaches is a matched molecular pair (MMP) analysis to aim suggestion of structural modification. MMP is defined as a pair of molecules that differ only by a single localized structural change. By analyzing assay results of PP, several dozens to several hundreds of MMPs were successfully extracted in each target except GR. Among them, several dozens of substructure pairs contributed to alleviation of each target potency. Interestingly, some of them reduced multi-target potency simultaneously. Extracted knowledge about structural transformation would provide more useful suggestion for chemical design to reduce potency on targets in PP by simple transformations. Prediction by PP QSAR models and suggestion based on MMPs would provide useful information in optimizing compounds to alleviate binding promiscuity.

2028 Predictive Models for Human Organ Toxicity Based on *In Vitro* Bioactivity Data and Chemical Structure

T. Xu[1], D. Ngan[1], L. Ye[1], M. Xia[1], H. Xie[2], B. Zhao[2], A. Simeonov[1], and R. Huang[1]. *[1]NIH/NCATS, Rockville, MD; and [2]Chinese Academy of Sciences, Beijing, China.*

Traditional toxicity testing reliant on animal models is costly and low throughput, posing a significant challenge with the increasing numbers of chemicals that humans are exposed to in the environment. The purpose of this investigation was to build optimal prediction models for various human *in vivo*/organ level toxicity endpoints using chemical structure and *in vitro* quantitative high-throughput screening (qHTS) bioactivity assay data. Several supervised machine learning algorithms were applied to model 14 human toxicity endpoints such as vascular, kidney ureter and bladder and liver. Three metrics were used to evaluate model performance: area under the receiver operating characteristic curve (AUC-ROC), balanced accuracy (BA), and Matthews Correlation Coefficient (MCC). Overall, the three metrics showed the same trend for each endpoint. Models for the three endpoints achieved good performance with AUC-ROC values >0.8, including musculoskeletal (0.84±0.02), endocrine (0.82±0.01), and peripheral nerve and sensation (0.81±0.01) toxicities. In addition, the model performance was found to be dependent on the specific dataset and model type. Nonetheless, *in vitro* assay data combined with chemical structure improved the predictive accuracy for most endpoints (8 out of 14). Chemical structure and assay data showed different levels of contribution to the prediction of different toxicity endpoints. The top performing models from this study can be further applied as a tool for hazard assessment to screen large sets of chemicals for potential human toxicity. In addition, the models identified structure features and cellular targets that contributed the most to each toxicity endpoint, which could serve as a guide for chemical prioritization and better understanding of toxicity mechanisms.

2029 Exploring IVIVE for Exposure and Health Impacts of E-Cigarette Flavor Mixtures

X. Chang[1], J. Abedini[1], S. Bell[1], and K. M. Lee[2]. [1]*Integrated Laboratory Systems Inc., Research Triangle Park, NC; and* [2]*Altria Client Services LLC, Richmond, VA.*

In vitro to *in vivo* extrapolation (IVIVE) refers the processes that leverage *in vitro* experimental results to predict corresponding *in vivo* measurements. This approach can be used to estimate clinical exposure scenarios that may pose an adverse health risk based *in vitro* responses, potentially bypassing the need for animal testing. Interpretation of IVIVE results and confidence in modeling predictions are affected by model type, exposure route and kinetic assumptions for the test article, and choice of *in vitro* assay(s). Exposure scenarios can be complicated, particularly for mixtures. For example, clearance rates for individual chemicals are obtainable experimentally or via QSAR models but generating comparable rates for mixtures remains an open research area. The *in vitro* assay selected and its relevance to the *in vivo* endpoint of interest are also critical in interpreting biological relevance of prediction results. Choosing an assay unrelated to the mode of action for human toxicity endpoint will lead to misrepresentation of *in vivo* effects. Here we use e-cigarette (EC) aerosols, a complex mixture including carriers, flavors and nicotine, as a case study to explore IVIVE modeling approach. We utilized literature *in vitro* cytotoxicity data on EC flavor mixtures to predict exposure scenarios that could lead to adverse toxicities. Several pharmacokinetic models were explored including a simple steady state model and a 3-compartment model with repeat dosing and multiple exposure routes. Additionally, impacts of *in vitro* assay endpoints on e-liquid consumption (number of cartridge or pod) estimates were evaluated using publicly available mechanistic (Tox21) *in vitro* data for individual flavors. Our results suggest that depending on the modeling approach and *in vitro* assay selection, the e-liquid consumption predicted to obtain corresponding *in vivo* plasma levels can be unrealistically high. For example, >1,000 pods (>700 mL e-liquid)/day was estimated for human exposures for certain flavors using standard cytotoxicity measures. In contrast, mechanistic (Tox21) assays yield a lower but wider exposure range (3 to 100,000 pods) for some flavors. These proof-of-concept results highlight challenges and complexities in IVIVE for mixtures. Limitations and considerations for assay selection and an example decision tree to facilitate use of IVIVE in projecting exposure and health impacts of complex test materials such as flavor mixtures is provided.

2030 Using SEND Datasets to Enable Large-Scale Data Analytic Approaches for Preclinical Toxicology Data

M. A. Carfagna[1], C. Eley[2], T. Fukushima[3], J. Horvath[4], W. Houser[4], C. Sloan[4], J. Anderson[5], K. Snyder[5], M. Whittaker[5], and T. Page[1]. [1]*Eli Lilly and Company, Indianapolis, IN;* [2]*Pfizer Inc., Groton, CT;* [3]*Shionogi & Co, Osaka, Japan;* [4]*Bristol-Myers Squibb Company, New Brunswick, NJ; and* [5]*US FDA/ CDER, White Oak, MD.*

BioCelerate, a subsidiary of TransCelerate BioPharma, Inc., is a preclinical industry consortium driving initiatives to increase efficiency and productivity in early stage R&D. The Standard for Exchange of Nonclinical Data (SEND) is a standardized format for capturing a wide range of toxicology-study data. Since 2016 the US FDA has required sponsors to submit data from certain types of toxicology studies in SEND format. The implementation of the SEND model represents a tremendous opportunity to apply large-scale data analytic approaches to preclinical toxicology data. Before this opportunity can be realized, differences in SEND implementation that make it difficult to conduct cross-study analysis must be addressed. The BioCelerate consortium has been engaged in an effort to better enable these analytic approaches and identify solutions since 2016 and more recently has been in collaboration with the US FDA. The collaboration has identified areas in SEND data sets that are significant drivers of variability that negatively impacts cross-study analysis. Currently, BioCelerate and the FDA are working to propose an approach to address some of these issues that prevent more efficient cross-study analysis, and we have created six use cases for this evaluation. In this presentation we will focus on our background-control data use case and present a potential approach for improved data harmonization. Generating and analyzing background-control data can play a significant role in nonclinical development by defining the frequency of incidental findings across a range of specified conditions that can be used to interpret low incidence findings in a study of interest. For each parameter of interest in the background control use case, we present how to extract this information from SEND data and transform it if needed for analysis and a proposed methodology for how to structure database queries. While the current presentation will focus on background-control data, these approaches can be used for all six of our identified use cases. By implementing our proposed approaches, stakeholders will be able to take advantage of the opportunity presented by SEND datasets to enable increased efficiency and productivity in early stage R & D.

2031 Development of a Computational Profiler for Inhibition of Mammalian Steroidogenesis

A. Patel, S. J. Wijeyesakere, S. A. Jackson, and K. Bentley. *FMC Corporation, Newark, DE.*

The conversion of cholesterol to steroid hormones is a key process in physiology and development. Disruption of the steroidogenesis pathway is associated with developmental disorders and as such, it is prudent to identify chemical disruptors of steroidogenesis within the early stages of the product development cycle. To this end, we compiled a database of chemicals that inhibit the enzymes which catalyze key steps in the synthesis pathway for estrogens and androgens (P450scc, CYP17A1, 3β-HSD, 17β-HSD, aromatase and 5α-reductase). These data were curated from public data sources and peer-reviewed literature. Using the open-source KNIME platform, we developed computational models to identify conserved structural motifs (scaffolds) associated with organic compounds that inhibit each of these enzymes. The resulting profiler output was combined into a pan-steroidogenesis profiler wherein a chemical that contains a scaffold known to inhibit any of the assessed enzymes is flagged as a potential steroidogenesis disruptor. To validate the model, we tested its ability to identify compounds that decrease estradiol production in the ToxCast high-throughput H295R assay. Our model was able to identify chemicals flagged as inducing a reduction in cellular estradiol production with 75% sensitivity, 83.3% specificity and 79.1% balanced accuracy. Given the heterogeneity of targets associated with the modeled endpoint and the fact that our profiler involves identification of conserved structural scaffolds, these concordance statistics are considered sufficiently accurate. We further validated our model against a second dataset of 31 compounds from the NTP integrated chemical environment (ICE) dashboard that were assessed for their ability to inhibit estrogen biosynthesis *in vitro*. Of the 20 chemicals that decreased estrogen biosynthesis, our model flagged 14 compounds, yielding 70% sensitivity (with 81.8% specificity and 75.9% balanced accuracy). Assessment of the remaining 6 chemicals suggest they are likely false-positives from the *in vitro* assay since they represent potential mitochondrial toxicants that inhibit oxidative phosphorylation or agonists of nuclear receptors (AhR and androgen receptor). In conclusion, these findings demonstrate the utility of our profiler in identifying potential steroidogenesis inhibitors as a first-tier screen for new chemicals.

2032 Using *In Silico-In Vitro* to *In Vivo* Extrapolation to Predict the Oral Dose Required to Activate the Aryl Hydrocarbon Receptor (AhR)

M. Lawless, R. Fraczkiewicz, and J. DiBella. *Simulations Plus, Lancaster, CA.*

Activation of AhR can have toxic effects on mammalian hosts. We used *in silico* and *in vitro* to *in vivo* extrapolation to automate the prediction of the dose required to activate AhR in humans. About 1,000 compounds were identified as human AhR activators (AC50 < 100 uM) by a Tox21 assay. We extracted human hepatocyte intrinsic clearance (CLint) and human fraction unbound to plasma (Fup) experimental data from the httk R Package[1] to use as *in vitro* inputs in the simulations. All other parameters, e.g., solubility, logP, pKa, used were estimated with *in silico* models. The final data set was comprised of 160 compounds. The dose required to reach a steady state unbound plasma concentration equal to each compound's AhR AC50 concentration was predicted using the HTPK Simulation Module in ADMET Predictor® 9.5. If the AhR AC50 value isn't reached with a 1,000 mg dose, then the run is terminated. The percent fraction absorbed (%Fa) and oral bioavailability was then predicted using the estimated dose. The AhR AC50 values in the data set ranged from 0.043 to 74.1 µM. *In vitro* Fup values ranged from 0.0 - 1.0, with 38 compounds having values less than or equal to 0.005. Fup values below 0.005 were set to 0.005 in the simulations. CLint values ranged from 0 to 1,000 µl/min/million cells, with 35 of the compounds having CLint=0 µl/min/million cells. A large majority of the compounds (142) were unable to reach an unbound steady state concentration equal to their AhR AC50 value with up to a 1g dose. 30 of these compounds were predicted to have low %Fa (<= 30%), mostly due to low solubility. 18 compounds were predicted to be potential *in vivo* AhR activators with a dose below 1 g. The minimum, maximum, average, and median predicted dose are 13, 912, 438, and 451 mg, respectively, for these compounds. Among these, isoniazid, an antibiotic used for the treatment of tuberculosis, was predicted to have the lowest dose to reach its AhR AC50 value (0.573 µM). Isoniazid's drug label contains a warning for hepatitis and an acetaminophen drug-drug interaction. It has been proposed that isoniazid increases the amount of acetaminophen converted to its toxic metabolite since activation of AhR induces cytochrome P450 expression[2]. [1]Pearce RG,

Setzer RW, Strope CL, Sipes NS, and Wambaugh JF. httk: R Package for High-Throughput Toxicokinetics, *J Stat. Software*, 2017, 79, 4. [2]Larigot L, Juricek L, Dairou J, and Coumoul X. AhR signaling pathways and regulatory functions, *Biochimie Open 7*, 2018, 1-9.

2033 ComptoxAI: A Tool Kit for AI Research in Computational Toxicology

J. D. Romano, T. M. Penning, and J. H. Moore. *University of Pennsylvania, Philadelphia, PA.*

Cutting-edge data science and informatics techniques stand to revolutionize computational applications in toxicology, but data and techniques for interacting with toxicological phenomena are fragmentary, sparse, and poorly understood. With this in mind, we present ComptoxAI - an artificial intelligence toolkit for toxicology that integrates public data from diverse sources and enables a wide array of advanced computational analyses. ComptoxAI includes a large graph database of toxicology-related concepts, a Python library for interacting with the data, a collection of graph algorithms and machine learning models for making new discoveries, and a complete ontology to formally define entities in toxicology research and the complex relationships between them. At the present time, the graph database and ontology contain structured representations for 72,921 entities and 1,848,307 relationships between those entities. Development of ComptoxAI is ongoing and highly active, and we have already used it to make several new discoveries related to toxicology data. For example, we computed the most influential nodes in ComptoxAI's graph database using the PageRank algorithm, and found that when Adverse Outcome Pathway (AOP) data are included in the analysis, the list of the most influential genes in the network is dominated by those involved in metabolizing and clearing toxicants from the human body (such as *abcb1* and various Cytochrome P450 genes). When AOP data are excluded from the analysis, this effect disappears almost entirely, which suggests that AOPs effectively encode important information about mechanisms of toxicity, and that ComptoxAI can easily detect such patterns using graph theory alone. The planned future work on ComptoxAI includes the inclusion of deep learning models to discover new associations between toxic exposures and downstream adverse effects, and creating improved interfaces for querying and interacting with toxicology data (particularly for researchers without computer programming expertise), among other research projects. ComptoxAI is open-source, and can be found online at https://comptox.ai. *Supported by grants P30-E013508 and T32-ES019851.*

2034 Evaluation of Existing QSAR Models and Structural Alerts and Development of New Consensus Models for Genotoxicity Using a Newly Compiled Experimental Dataset

P. Pradeep[1,2], R. Judson[2], and G. Patlewicz[2]. *[1]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [2]US EPA/ORD, Research Triangle Park, NC.*

Genotoxicity is among the toxicological endpoints that pose the highest concern for human health and is subject to regulatory assessment. Integrated testing and assessment approaches (IATA) are applied to evaluate the genotoxic potential of chemicals using a combination of *in silico*, *in vitro* and *in vivo* approaches. A major effort was undertaken to compile data from several sources (TOXNET, COSMOS, eChemPortal and ECVAM) and harmonize the names and outcomes of different assay types (bacterial mutagenicity (Ames), chromosomal aberrations (Clastogen), and others). The data was evaluated using a conservative IATA to assess genotoxic potential using the classification scheme by Williams et al., 2019. The dataset comprised 4828 chemicals, of which 2553 chemicals were categorized as genotoxic and 1819 as non-genotoxic using the IATA. The IATA assigned a chemical as genotoxic if any single Ames or Clastogen assay was positive; ~16% chemicals active in <50% Ames assays were classified as genotoxic and ~15% chemicals with inconclusive Ames data were classified as genotoxic. So, a new cut-off-based classification scheme was developed where genotoxicity classifications were made based on percentage of Ames and Clastogen assays a chemical was active in. Next, QSAR tools (TEST and Lazar) and the OECD Toolbox structural alerts/profilers (e.g. OASIS DNA alerts for Ames, CA) were used to make *in silico* predictions for genotoxicity. The performance of individual QSAR tools and alerts was evaluated against the IATA and newly defined cut-off-based genotoxicity classifications. The balanced accuracies ranged from 64-80%. Finally, a naïve Bayes consensus model was developed using two combinations of QSAR tools and alert predictions. The consensus models do not result in significant differences in the overall prediction across various combinations, with balanced accuracies ranging from 50-76%. Overall, the predictivity of individual tools and the consensus models is slightly improved using the experimental activity cut-off-based classification scheme relative to the Williams et al., 2019 scheme for genotoxicity prediction. These models will provide a robust support framework for assessing genotoxicity potential for new and untested chemicals. *This abstract does not necessarily represent US EPA policy.*

2035 A Pipeline for Prediction of Developmental Toxicants: Screening in Zebrafish and Correlation to HTS Data

M. Bondesson[1], S. Thrikawala[2], R. Mirchandani[3], C. McCollum[3], R. S. Judson[4], and C. Stephan[5]. *[1]Indiana University, Bloomington, IN; [2]Clemson University, Clemson, SC; [3]University of Houston, Houston, TX; [4]US EPA, Research Triangle Park, NC; and [5]Texas A&M Health Science Center, Houston, TX.*

The zebrafish embryo is an effective alternative *in vivo* model to rodents for studying chemically-induced perturbations because of its small size and rapid development. In addition, the availability of transgenic embryos that express fluorescence in specific tissues or organs allows for detection of tissue-specific structural malformations (apical end-points). We performed screening for skeletal and angiogenic disruption in transgenic zebrafish embryos caused by exposure to Phase I chemicals from EPA's Toxicity Forecaster (ToxCast) program. Around 300 chemicals were screened and we identified 38 skeletal and 10 angiogenic disruptors. The identified sets of skeletal and angiogenic disruptors were used to identify ToxCast assays that were affected by the same chemicals using univariate correlation analysis. Identified assays included those that measure vitamin D_3 metabolism and dopamine transporter activity, and oxidative stress and nuclear receptor signaling for skeletal and angiogenic disruption, respectively. We further used the identified assays to make predictions of other chemicals, tested in the Tox21 screening project, but not tested for skeletal and angiogenic disruption in zebrafish embryos, using the Toxicological Priority Index (ToxPi) program. This program ranks compounds based on their AC50 value for the selected assays. Predicted disruptors were tested in the laboratory, and several new skeletal and angiogenic disruptors were identified. We conclude that medium throughput screening data from an *in vivo* model in combination with modeling of ToxCast high throughput *in vitro* data can be used to produce testable hypotheses on modes of action of chemical exposures, and to predict apical end-point specific effects of chemical exposures. *Disclaimer: This abstract does not necessarily represent US EPA policy.*

2036 Harnessing *In Silico*, *In Vitro*, and *In Vivo* Data to Understand the Polycyclic Aromatic Compound (PAC) Landscape

J. Hsieh[1], A. Sedykh[2], E. Mutlu[3], S. Waidyanatha[3], S. S. Auerbach[3], and C. V. Rider[3]. *[1]Kelly Government Solutions, Morrisville, NC; [2]Sciome LLC, Durham, NC; and [3]NIEHS/NTP, Research Triangle Park, NC.*

Polycyclic aromatic compounds (PACs), including polycyclic aromatic hydrocarbons (PAHs), are ubiquitous environmental contaminants that can arise from incomplete combustion or thermal decomposition of organic matter. While many of the PACs are linked with carcinogenicity and some are linked with reproductive/developmental toxicity, still many members of the class do not have toxicity data available. Thus, there is a need to leverage the available data (e.g., *in silico*, *in vitro*, and *in vivo*) for rapid hazard characterization. To this end, we created a computational workflow to automatically identify PACs in a library (e.g., Tox21, ~ 9K compounds). Then, we clustered the PACs based on their *in silico* toxicity profiles including 8 different categories (carcinogenicity, cardiotoxicity, developmental toxicity, genotoxicity, hepatoxicity, neurotoxicity, reproductive toxicity, and urinary toxicity). We found that PACs with the same parent structure (e.g., fluorene) were predicted to have diverse toxicity profiles. Moreover, PACs with similar substituted groups (e.g., alkylated-PAHs) or heterocycles with varying ring sizes (e.g., N-PACs) were predicted to have similar toxicity profiles. By surveying the *in silico* toxicity and *in vitro* activity profiles in Tox21 assays, we found that toxicity endpoints related to genotoxicity/carcinogenicity and effects related to xenobiotic homeostasis (aryl hydrocarbon receptor -AhR, constitutive androstane receptor -CAR) and stress response (p53 and Nrf2 pathways), respectively drive the activity variation seen in the PACs. The availability of *in vivo* data (e.g., carcinogenicity) in conjunction with toxicity/activity profiles were inspected to identify 'hot spots' - either data-poor (hydroxylated PAHs) or data-rich (unsubstituted, parent PAHs) regions. These regions are targets for read-across evaluation of the unknowns, and potentially, *in vivo* assessment. In summary, we have developed a strategy to explore the PAC landscape utilizing *in silico*, *in vitro*, and *in vivo* data. This strategy can be extended to other types of compounds which need hazard evaluation.

2037 Development of a Computational Prediction Model for Modulators of the Androgen Receptor (AR)

S. J. Wijeyesakere, A. Patel, S. A. Jackson, and K. Bentley. *FMC Corporation, Newark, DE.*

Endocrine signaling via the androgen receptor (AR) plays a crucial role in mammalian physiology, development and pathology. As an initial step towards modeling the key events within adverse outcome pathways (AOPs) for AR-mediated endocrine disruption, we developed an *in silico* model to predict the likelihood that an unknown compound will or will not bind the AR. We mined existing public data and compiled a database of >2400 AR binders, together with >2100 controls (non-binders) from multiple sources (ToxCast, CHEMBL, published literature, etc.). We developed a random-forest machine-learning model using structural fingerprints and the presence or absence of 2D-structural motifs (scaffolds) conserved within the known AR binders as covariates. Our prediction model was built by iteratively and randomly retraining it using 90% of the compiled active and inactive (control) compounds, with the remaining compounds serving as the test set. The resulting model shows very high sensitivity (92.8%), specificity (94.6%) and balanced accuracy (93.7%). This is coupled with high positive (95.2%) and negative (91.9%) predictive values, highlighting the confidence with which assessed substances can be aligned as AR binders or non-binders. By iteratively building our model using 1-90% of the actives (AR binders), we show that <39% of the curated AR binders are needed to yield >90% sensitivity, highlighting the robustness of the model and suggesting that it will not change for the foreseeable future. In conclusion, these findings demonstrate the feasibility and utility of using public *in vitro* data to develop a computational model to identify potential AR binders as a first-tier *in silico* endocrine disruption screen for new chemicals.

2038 Using Gene Expression Data to Identify Liver and Kidney Injuries

P. Schyman[1,2], R. L. Printz[3], S. K. Estes[3], T. P. O'Brien[3], K. L. Boyd[3], M. Shiota[3], and A. Wallqvist[1]. *[1]US Army Medical Research and Development Command, Fort Detrick, MD; [2]Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD; and [3]Vanderbilt University School of Medicine, Nashville, TN.*

The immense resources required and ethical concerns for animal-based toxicological studies have driven the development of *in vitro* and *in silico* approaches. Using gene expression data from liver and kidney tissues of rats exposed to diverse chemical insults, we previously derived a set of gene modules associated with specific organ injuries (i.e., injury modules). Recently, we validated this approach in a study using thioacetamide, a known liver toxicant that promotes fibrosis. Our first aim was to test whether we could use gene expression from rat primary liver and kidney cells (*in vitro*) exposed to thioacetamide to predict organ injuries in rats *in vivo*. Second, we sought to establish interspecies concordance between the gene module responses in rat and human primary cells exposed to thioacetamide to predict organ injuries. In all cases, the most activated liver gene modules were those associated with fibrosis. Histological analyses supported these results, demonstrating the potential of gene expression data to identify organ injuries. The *in vitro* predictions were significantly correlated with the *in vivo* predictions, with an R^2 value of 0.64. Finally, the top-ranked liver injuries in human primary cells correctly identified known pathological changes such as fibrosis. Our proposed approach could potentially be used with *in vitro* assays to screen large number of chemicals and predict liver and kidney injuries *in vivo*.

2039 Use of Computational Toxicology (CompTox) Tools to Predict *In Vivo* Toxicity for Risk Assessment

M. H. Silva. *Retired, Davis, CA.*

Open access CompTox tools were examined for use in risk assessment by comparing *in vitro* predictions to *in vivo* pesticide toxicity. The pesticides, propyzamide (PZ: amide), carbaryl (CB: carbamate) and chlorpyrifos (CPF: organophosphate), were chosen because of their well-characterized toxicological profiles. The CompTox tools included: 1) CompTox Chemistry Dashboard *in vitro* bioassays (AC_{50} μM: activity at 50% concentration) with values below the cytotoxicity limit for each chemical (region where activity may not be specific); with assay components relevant to the toxicity pathways and with no disqualifying flags; 2) The selected CompTox AC_{50}s were converted by *in vitro*-to-*in vivo* extrapolation (IVIVE) to produce oral equivalent doses (OED: mg/kg/d; steady state plasma concentration Css); and 3) the CompTox AC_{50}s were entered in the high throughput toxicokinetics (HTTK) R program to get age-adjusted equivalent doses (mg/kg/d; Css). Data conversions by IVIVE or HTTK were compared to known *in vivo* lowest effect levels (LEL÷10x interspecies extrapolation) from repeat dose studies as follows: CB and CPF LELs (0.1 mg/kg/d) from preweaning rat studies had P450 (CYP) induction and brain acetylcholinesterase (AChE) inhibition as a mode of action (MOA). PZ LEL (1.0 mg/kg/d) from a pubertal rat study had decreased T_4 after CYP and glucuronosyl-transferase (UGT) induction as a MOA. AC_{50}s for assays with components known to be associated with these MOAs (e.g. PZ: CYP1A2, UGT1A1, CB: CYP1A1/2, AChE, AhR; CPF: PXRE, PXR) produced IVIVE results with OED:LEL ratios of 9.8 - 38 (PZ), 8 - 69 (CB) and 3.4 - 4.17 (CPF) indicating that each chemical had a ratio within an order of magnitude of their respective *in vivo* LELs. HTTK produced *in vivo*-equivalent doses for children 6-11 and 11-15 coinciding with the preweaning and pubertal ages of the rats in studies determining the *in vivo* LELs. HTTK age-adjusted equivalent dose-to-LEL ratios for PZ and CPF were 2.3 - 9.2 and 1.43 - 2.09, respectively (predictive association), where CB had a much higher ratio (44 – 373, less predictive ratios). Overall the tools had value for predicting equivalent doses that were close to the known *in vivo* LELs for the relevant metabolic pathways. However, data interpretation was limited by having few *in vitro* assays below the cytotoxicity limit that were key to the toxic pathways (e.g. AChE for CPF) which may have been due to a lack of metabolic activation. Nevertheless, these tools may facilitate mechanistic insights or selection of a point of departure in risk assessment for chemicals with unknown toxicity.

2040 An *In Vitro-In Silico* Model for Characterizing Hazard and Population Variability in Cardiotoxicity Induced by Environmental Chemicals

A. D. Blanchette[1], S. D. Burnett[1], F. A. Grimm[1], J. S. House[2], D. M. Reif[2], F. A. Wright[2], I. Rusyn[1], and W. A. Chiu[1]. *[1]Texas A&M University, College Station, TX; and [2]North Carolina State University, Raleigh, NC.*

Population variability in toxicodynamic (TD) susceptibility remains a critical data gap in toxicology, with human health risk assessments largely relying on a default $10^{1/2}$-fold factor. This creates a need to establish a high-throughput, physiologically relevant, and accurate framework to address this data gap. We tested the hypothesis that combining a population-based human induced pluripotent stem cell derived (HiPSC) cardiomyocyte model and Bayesian Markov Chain Monte Carlo modeling could be used to characterize cardiotoxicity hazard and quantify population TD variability in a chemical- and endpoint-specific manner. Here we screened 138 different compounds, representing pharmaceuticals, environmental chemicals, industrial chemicals, and food additives, in cardiomyocytes derived from 43 distinct individuals. TD variability is calculated for cell viability as well as for functional parameters related to beat rate, prolonged action potential, and irregular beating. For each of the 138 chemicals, Bayesian population concentration response modeling was employed to estimate points of departure for each endpoint. For compounds that caused significant population level responses in the tested concentration range, a toxicodynamic variability factor (TDVF) was also derived, which can be used as a chemical-specific adjustment factor to replace the default $10^{1/2}$ uncertainty factor. Overall, TDVF values tended to be larger than the default TD uncertainty factor and the functional endpoints were more variable than the viability endpoint. Despite the increased population variability however, an IVIVE analysis shows that there is a large margin of exposure between most environmental compounds and functional endpoint PODs. In this study, we demonstrate how our model can be used as an accurate, animal-free, human-relevant, and tissue-specific predictive tool for addressing the challenge of incorporating population TD variability in human health risk assessments.

2041 Identifying Individual and Co-occurring Chemicals That Induce Changes in Transcription of Cancer and Inflammation-Related Genes upon *In Vitro* Exposure to Ambient Air Pollution in Houston, Texas

L. A. Eaves[1], H. T. Nguyen[1], J. Rager[1], T. Howard[1], L. Smeester[1], K. M. Aagaard[2], C. Shope[2], B. Lefer[3], J. H. Flynn[3], S. Alvarez[3], M. H. Erickson[3], R. C. Fry[1], and W. Vizuete[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Baylor College of Medicine, Houston, TX; and [3]University of Houston, Houston, TX.*

Atmospheric pollution represents a complex mixture of air substances that continually interact and transform, making it difficult to accurately evaluate toxicity responses attributable to individual and/or co-occurring chemicals. *In vitro* studies that evaluate air pollution mixture toxicity have largely been

reliant upon laboratory-generated exposure scenarios that do not reflect real-world conditions, heavily weighted towards individual chemical-based assessments. To address this gap, this study set out to evaluate lung cell toxicity directly induced by outdoor atmospheric pollution using field-based exposure conditions in the industrialized Houston Ship Channel. The tested hypothesis was that individual and co-occurring chemicals in the atmosphere induce transcriptional changes of critical genes involved in cancer and inflammation signaling. Human lung cells were exposed at an air-liquid interface to ambient air mixtures using the novel Gas Phase *In Vitro* Exposure System (GIVES) for four hours, with experiments replicated across five days. Real-time monitoring of 31 primary and secondary gas-phase pollutants, as well as other atmospheric conditions, was simultaneously carried out. Co-occurring chemicals were identified and aggregated using weighted co-expression statistics. Transcriptional analysis of the exposed cells identified critical genes showing differential expression associated with individual chemicals, as well as aggregated measures of co-occurring chemicals. The individual pollutant identified with the largest associated transcriptional response was benzene, identified to associate with the increased expression of genes relevant to the inflammasome complex formation, including the NLR family pyrin domain containing 3 (*NLRP3*). Analysis of transcriptional response to co-occurring chemicals have identified overlapping responses, though also indicate a subset of discrete modulations involving separate gene sets. This study is among the first to measure lung cell transcriptional responses to both individual and co-occurring chemicals in relation to real-world, ambient air mixtures.

PS 2042 Expanding Access to Safer Chemistry for Consumer Products throughout the Supply Chain: Tools and Trends

C. E. McLoughlin, P. J. Beattie, M. C. Ruhter, N. Y. Arief, S. G. Davis, and J. P. Rinkevich. *Scivera LLC, Charlottesville, VA.*

Historically consumer product safety has focused on regulatory compliance through Safety Data Sheet disclosure, Authoritative List Checking (ALC), and analytical testing. Leading consumer products brands (LS&Co, Nike, H&M, among others) are driving safer chemistry selection throughout the supply chain, moving beyond compliance by evaluating human and environmental health characteristics. The authors present recent work on tools in use by chemical suppliers, product formulators, textile mills, brands, and retailers, transforming the way chemical selection is occurring for consumer products. The chemical selection process is facilitated by an innovative combination of Qualitative and Quantitative Comprehensive Hazard Assessment (QQCHA) methods, safer alternative selection via functional use groups (FUGs), chemical and formulation scoring, and integrative methods for downstream knowledge, all of which are aided by online software. The textile industry is at the forefront of the movement towards upstream safer chemical screening, assessment, scoring, and selection. One highly successful program is Screened Chemistry (SC). SC requires Confidential Full Formulation Disclosure (CFFD) in textile formulations. The authors have screened over 350 formulations with hundreds of chemicals under this program. The results show progress throughout the supply chain in achieving CFFD and selecting safer chemistries. For CFFD, information exchange via software allows formulators to quickly share SC scores with redacted ingredient data, maintaining confidential business information. Instant availability of QQCHA results for over 2,000 commonly-used chemistries dramatically reduces the cost of safer chemistry selection in consumer products with thousands of additional instant results for unacceptable or potentially safer alternatives available for formulators to explore. The authors will discuss the QQCHA methods, the critical deficiencies of list-based "hazard screening", trends in scored chemistries used in textile formulations to date. The results show how the tools and use of software have effectively made comparative evaluation of potential safer alternatives more robust than traditional methods such as ALC or testing used alone or combined. Looking forward the authors will discuss integrative methods to inform brands, retailers, and consumers of safer chemistry achievement for products and processes.

PS 2043 Developmental Computation with Embryonic Stem Cells

T. B. Knudsen[1], T. J. Zurlinden[1], N. C. Baker[2], and R. M. Spencer[3]. *[1]US EPA, Research Triangle Park, NC; [2]Leidos and US EPA, Research Triangle Park, NC; and [3]General Dynamics and US EPA, Research Triangle Park, NC.*

New approach methodologies (NAMs) that enable *in vitro* profiling of chemical-biological interactions come with the need for *in silico* models that translate vast amounts of data and information into toxicological prediction. For fetal systems, these models must reflect the best available knowledge of embryology. A new ToxCast platform using pluripotent embryonic stem cells (H9 line) identified a signal for developmental toxicity potential in 183 of 1065 chemicals (17%) [Zurlinden et al., submitted]. Recursive partitioning using 5-fold cross validation on 80/20 split produced binary classifier models for ToxRefDB developmental toxicity with balanced accuracies of 65% (431 chemicals) to 88% (127 chemicals). PI3K-FOXO signaling was hypothesized as a major determinant of sensitivity. RNAseq profiles for retinoic acid-induced effects on endoderm-directed stem cells (eg, FOXA2, SOX17, TBXT, EOMES, LHX1, BMP4) revealed a tipping at 17 nM [Saili et al., 2019]. Here, we expand the performance-based models by a deep-learning strategy that brings embryology of these pathways into the fold using a Compucell3D agent-based model (ES-ABM) to unravel chemical effects on signals/responses for self-renewal (unlimited proliferation), pluripotency (broad differentiation potential), and self-organization (rudimentary anatomical structures). ES-ABM is initially designed to model stochastic dynamics of locally interacting stem cell agents during retinoid concentration x time exposure, conveying mechanistic hypotheses about key events for chemical-induced alterations of stem cell differentiation and self-organization. *This abstract does not reflect US EPA policy.*

PS 2044 Gene Co-regulated Network Analysis Applied to Big Data in Toxicology: TXG-MAPr, a Flexible Tool to Integrate and Understand Transcriptomic Data

G. Callegaro[1], S. J. Kunnen[1], J. J. Sutherland[2], J. Mollon[3], Y. W. Webster[4], M. C. Niemeijer[1], W. den Hollander[1], P. Trairatphisan[3], E. Guney[5], J. Piñero Gonzalez[6], J. L. Stevens[1], and B. van de Water[1]. *[1]Universiteit Leiden, Leiden, Netherlands; [2]Novartis Institutes for BioMedical Research, Cambridge, MA; [3]AbbVie Deutschland GmbH & Co. KG, Ludwigshafen, Germany; [4]Eli Lilly and Company, Indianapolis, IN; [5]Pompeu Fabra University, Barcelona, Spain; and [6]Universitat Pompeu Fabra, Barcelona, Spain.*

What are the gene expression patterns underpinning adverse outcome occurrences *in vivo*? How can we measure sensitivity of primary cell donors towards a toxicant by deconvoluting their transcriptomic profiles? These and similar questions can be tackled by applying gene network approaches to large toxicogenomic datasets. Herein, we present weighted gene co-expression network analysis (WGCNA) based on TG-GATEs datasets, including primary human hepatocytes (PHH), rat *in vivo* liver and rat *in vivo* kidney, housed in a web-Shiny App, the TXG-MAPr. The TXG-MAPr presents functional clusters of co-expressed genes (modules) that bridge between individual gene variations and emergent global properties, capturing dynamics of experimental conditions (compounds, doses and time). Modules are annotated for biological function and transcription factor regulation. Newly generated transcriptomic data can be analyzed in the context of the established gene networks in both cellular and *in vivo* systems. We show that PHH-derived modules can discern individual primary hepatocyte donor variability upon exposure to the same drug. Also, we show connectivity between activation of rat liver modules with the clinical chemistry and histopathology variations, thus identifying gene expression patterns concurrent and predictive of organ-specific apical endpoints. Moreover, selected module responses can serve as key events for Adverse Outcome Pathway construction. In conclusion, the TXG-MAPr represents a flexible and innovative tool contributing to the mechanistic understanding of potential adverse drug reactions. *The work received funding from the Innovative Medicines Initiative 2 (IMI2) Joint Undertaking for the TransQST (agreement 116030) and eTRANSAFE (agreement 777365) projects, supported by the European Union's Horizon 2020 research and innovation program and EFPIA. This work was also supported by the EU-ToxRisk project, funded by the European Union's Horizon 2020 research and innovation program (agreement 681002).*

PS 2045 Use of a Computational Model for Transient Receptor Potential Vanilloid Subfamily Type 1 Protein (TRPV1) to Profile Sensory Irritants

S. Krieger[1], S. Wijeyesakere[2,1], T. Auernhammer[1], A. Parks[1], J. Hotchkiss[1], and D. Wilson[1]. *[1]Dow, Midland, MI; and [2]FMC Corporation, Philadelphia, PA.*

We are developing computational models that predict interactions with important biological targets, including those that could be informative for setting inhalation exposure guidelines. Sensory irritation of the nose, throat and eyes is frequently used as a critical effect in setting occupational exposure limits (OELs). Sensory irritation potential is determined by inhalation exposure of rodents to different concentrations of test material to derive the concentration that causes a 50 percent reduction in respiration rate (RD_{50}). Threshold limit values (TLVs) often fall within 0.01 - 0.1 RD_{50}. We developed a computational model to predict interaction with one important target for sensory irritation: the transient receptor potential vanilloid subfamily type 1 protein (TRPV1; capsaicin receptor). Using public sources, we compiled a database

of compounds known to interact or not interact with TRPV1 and developed a random-forest machine-learning model that analyzes their structural fingerprints and conserved scaffolds while also incorporating binding energies and topologies from protein-ligand docking. The model is sensitive (96%) and accurate (83%), with a specificity of 70%. TRPV1 compounds had significantly higher binding energies vs. controls. When we queried a database of RD_{50} values for 205 compounds, our model preliminarily identified 130 that potentially involve interaction with TRPV1. Follow-up analysis is planned including examination of subcategories of the scaffolds as well as interaction via additional biological targets that affect sensory irritation.

2046 Computational Association of Talc Exposure and Ovarian Cancer

F. Lin, J. Dinh, J. Sierra, K. Shah, and D. E. Johnson. *University of California Berkeley, Berkeley, CA.*

Talc is a fibrous magnesium silicate used in industrial and consumer products as a lubricant, thickener, or moisture-absorbing agent. Toxic impurities include asbestos, other silicates, and heavy metals. This study investigates a potential association of talc usage and ovarian cancer where it is hypothesized that interactions between talc and endogenous estrogen contribute to carcinogenesis. To investigate this, online databases, docking software, predictive molecular modeling software, and literature were used to study whether the contaminants in talc induce similar interactions as asbestos in the human body. From this, a potential adverse outcome pathway (AOP) with three primary carcinogenic pathways was generated: upregulation of the estrogen receptor (ER), activation of the epidermal growth factor receptor (EGFR), and generation of reactive oxygen species (ROS). Talc was hypothesized to aggregate endogenous estrogen to the ER via cations along its long and spindle-like structure. Activation of ER induces the Ras pathway for downstream anti-apoptotic effects via c-Jun and c-Myc. Second, phagocytosis of talc molecules was hypothesized to stimulate presentation of matrix metalloproteinases (MMPs) on macrophage and neutrophil surfaces via interactions with the metallic components and contaminants of talc, promoting migration and proliferation of keratinocytes and activation of the EGFR. In addition, the similar structures of talc and asbestos is hypothesized to allow talc to dimerize and activate EGFR in a similar fashion. Activation of EGFR induces unregulated anti-apoptosis, cell proliferation, DNA transcription, metabolism, and expression of oncogenes. Lastly, phagocytosis of talc exposes the macrophages and neutrophils to its heavy metal contaminants that are hypothesized to trigger inflammasome activation and upregulation of HMGB1 and NaIp3 pathways, resulting in the release of inflammatory cytokines such as IL-1B and TNF-a. Furthermore, upon necrosis, NADPH oxidase generates ROS species that upregulate growth factors and inflammatory pathways and disrupt iron homeostasis, causing further DNA damage.

2047 Toxicity Prediction of the In-Commerce List Using High-Throughput Screening and Pathway Analysis

G. Chausse, L. Tamming, C. Yauk, and A. Nong. *Health Canada, Ottawa, ON, Canada.*

New approach methodologies have reshaped the way to evaluate health risks from chemicals. Research efforts are finding new ways to identify potential toxic hazards from laboratory tests or even broader screening tests. This case study shows the use of computer modeling to convert non-animal toxicity data into human exposure levels that can be applied in a public health context. Experiments to predict body burdens of substances, also known as *in vitro* toxicokinetics, are used with computer models to convert experimental toxicity data into biologically relevant doses. New computer generated toxicokinetic data have been released from the latest release of the HTTK R-Software package. Bioactivity profiles of In-commerce List chemicals were converted into equivalent biological exposure levels in human and daily consumer product exposure. Dream-TK is a computer application designed to derive equivalent human doses from high throughput toxicity screening in the US EPA ToxCast™ database. With the aid of new predicted *in silico* and *in vitro* toxicokinetic data, Dream-TK was able to estimate daily exposure ranges and biologically potential hazard levels for various chemicals from Health Canada In-Commerce List. The analysis identified 43 of 80 chemicals that displayed substantial amounts of bioactivity across a wide range of biological endpoints and pathways. 22 of the most potent chemicals exhibited sub-micromolar bioactivity. 20 chemicals were identified as having multiple genotoxicity flags, across both the *in vitro* ToxCast™ and *in silico* QSAR results. In addition to positive endocrine activity predictions for 7 steroidal chemicals, 5 non-steroidal chemicals also had significant endocrine disrupting potential. Computer simulations suggests that 41 of 43 equivalent biologically exposure doses are several orders higher then estimated daily consumer exposure of these chemicals. The research work is supporting evidence for new tools and technology advancing risk assessments at Health Canada.

2048 Image-Based Assessment of *In Vitro* Toxicity Using Deep Learning

P. Pande[1], D. G. Thomas[1], N. O. Hodas[1], P. M. McLendon[2], D. W. Cowan[2], and J. G. Teeguarden[1]. *[1]Pacific Northwest National Laboratory, Richland, WA; and [2]Air Force Research Laboratory, Wright-Patterson AFB, OH.*

In vitro toxicity testing is an important, time and cost-effective way of assessing the drug and compound toxicity profiles and investigation of toxicant mechanism of action. However, current *in vitro* methodologies are limited in scope due to a restricted ability to extrapolate bioeffects/MOA from previously studied compounds. To address this limitation, we explored the potential of using deep learning techniques to assess *in vitro* toxicity from phase contrast microscopy images of human B-lymphocytes, along with corresponding images fluorescently labeled for nucleus and cell-viability, in attempt to perform comparative analysis of cellular phenotypes from previously-studied chemical toxicants. Deep convolutional neural networks have shown state-of-the-art performance in various image recognition tasks due to their ability to detect and learn highly nonlinear and complex image-based representation or features that can be used for image classification tasks. Specifically, we explored the following related hypotheses: (i) non-lethal exposure of human lymphocytes to a compound causes gross morphological changes in cells that are captured in the microscopy images with sub-micron resolution; (ii) the morphological changes are dependent on dose and the mechanism of action of a compound; and, finally (iii) convolutional neural networks have the potential to effectively use the information about the aforementioned morphological cellular changes as image features to learn the differences between cell exposure either or both to different doses of a compound or to different compounds having different modes of action. A preliminary convolutional neural network model trained on the image data was successfully able to distinguish between different doses, however, unsurprisingly, similar doses were less distinguishable. Likewise, some but not all compounds tested showed different morphological changes unique to each compound. This pilot study demonstrates the strengths and limitations of using microscopy images with convolutional neural networks for assessing toxicity in an *in vitro* system.

2049 Predicting Developmental Toxicity Potential Using Pluripotent Embryonic Stem Cell Assays and the ToxCast Library

T. J. Zurlinden[1], N. C. Kleinstreuer[2], A. Lumen[3], M. Xia[4], N. C. Baker[5], and T. B. Knudsen[1]. *[1]US EPA, Research Triangle Park, NC; [2]NIEHS/NICEATM, Research Triangle Park, NC; [3]US FDA/NCTR, Jefferson, AR; [4]NIH/NCATS, Bethesda, MD; and [5]Leidos, Research Triangle Park, NC.*

New approach methodologies are being explored for their ability to quickly evaluate the human toxicity potential of chemicals with less reliance on animal testing using ToxCast/Tox21 generated *in vitro* data on thousands of chemicals utilizing high-throughput screening (HTS) assays. Leveraging a high-confidence reference set (127 compounds) of prenatal developmental toxicity, we trained numerous machine learning algorithms using AC50s from the broader ToxCast/Tox21 HTS portfolio (1411 assay features) to develop a deterministic predictive model for human developmental toxicity. Within the ToxCast/Tox21 portfolio is the Stemina devTOXqp assay that measures a critical drop in the ornithine/cystine (O/C) ratio in the culture medium of H9 human embryonic stem cells (hESCs) maintained pluripotent for a 3-day exposure window to provide a predictive biomarker for human developmental toxicity potential. We obtained a positive signal on 183 (17%) of 1062 ToxCast chemicals tested to date. Balanced accuracy (BAC) of 62% was shown for 432 chemicals having any developmental toxicity evidence from studies in pregnant rats or rabbits (Toxicological Reference Database: ToxRefDB); however, BAC exceeded 77% (63% sensitivity, 90% specificity) for a subset of 127 compounds with strong evidence of developmental toxicity or non-toxicity. The winning model was L2-penalized logistic regression, with an overall 5-fold cross validation BAC of 81% (70% sensitivity, 92% specificity) against the 127-compound training set. Evaluation of the log-odds coefficients from the logistic regression model selected the hESC devTOXqp O/C ratio as the most predictive ToxCast assay feature. Finally, we trained a Bayesian logistic regression model with L2-regularization on the entire 127-compound training set to develop a probabilistic model for predicting developmental toxicity. Using ToxCast bioactivity profiles, the model predicted developmental toxicity potential of the remaining 305 chemicals with *in vivo* prenatal developmental toxicity evidence from ToxRefDB and the literature, allowing for external validation of these predictions. Overall, this model leverages hESC biology and

complementary pathways to make probabilistic predictions of developmental toxicity potential for chemicals across the broader ToxCast landscape. *This abstract does not reflect US EPA policy.*

2050 *In Silico* Prediction of Organ Toxicity: Development of *In Silico* Models from *In Vivo* Drug Histopathology Data from Regulatory Toxicity Study Reports

A. Amberg[1], K. Kopanska[1], L. T. Anger[1,2], M. Schaefer[1], H. Spirkl[1], M. Stolte[1], B. Durchfeld-Meyer[1], G. Myatt[3], and A. Czich[1]. [1]*Sanofi, Frankfurt, Germany;* [2]*Genentech Inc., South San Francisco, CA; and* [3]*Leadscope Inc., Columbus, OH.* Sponsor: D. Keller

Diverse activities are ongoing regarding *in silico* predictions in the regulatory context. An example is the "*in silico* Toxicology Protocols" consortium defining internationally harmonized & regulatory agreed principles of *in silico* toxicology analysis. Another example is the EMA "Reflection paper on the qualification of non-genotoxic impurities". In this context, we developed *in silico* models that were trained with findings from preclinical toxicity study reports for regulatory submissions. The sources of these *in vivo* data were the eTOX database with unpublished toxicity studies from 13 industry partners (1,947 drug candidates, 8,196 studies), approved drugs from PharmaPendium as well as other publicly available data, e.g. Leadscope database. In a first step, we focused on most important *in silico* models for regulatory decisions based on histopathology data from the main target organs liver, kidney and heart. The following compilation steps were applied to receive usable *in silico* model training datasets: Initially, the verbatim toxicity finding terms were harmonized using special ontologies. To receive model training sets with sufficient compound numbers and chemical space coverage, all primary histopathology terms were then combined to different clusters of similar toxicity mechanisms. For the most general clusters, terms were grouped into "tissue damage", "inflammatory changes", "structural alterations" or "accumulative lesions" clusters. Examples of more specific "tissue damage" cluster terms include "necrosis", "steatosis", "degeneration" etc. This resulted in many training datasets for which different modeling approaches were applied (structural alerts, fragment-based, molecular descriptor-based machine learning approaches). Models were validated and optimized by internal and external validation using Sanofi's confidential data. For example, for necrosis models (110-230 positives, 180-200 negatives) sensitivities of 76-80% and specificities of 77-78% were obtained when using fragment-based models to predict necrosis effects in liver, kidney and heart. These validation results show that by reasonable clustering of histopathology data, it's possible to develop *in silico* models with good predictivity for toxicity findings in main target organs.

2051 Improvement of Ames Test Database for Developing QSAR Prediction Models

T. Kasamatsu, A. Kitazawa, K. Sugiyama, T. Suzuki, and M. Honma. *National Institute of Health Sciences, Kawasaki, Japan.* Sponsor: A. Hirose

For predictive toxicology such as development of *in silico* predictive models and/or safety assessment using read-across approach, databases of toxicological testing are crucial. Especially GLP testing conform to the study guidelines have been categorized as "reliable without restriction" and preferred for utilization. We established a unique proprietary Ames test database containing 12,140 new chemicals based on the registration of new chemicals under the Industrial Safety and Health Act (ANEI-HOU) in Japan. Essentially studies in the database conform the study guideline of ANEI-HOU, which is practically equivalent to OECD TG471, under GLP compliance. We previously provided information of just outcome (positive or negative) with chemical structure to QSAR vendors for developing their predictive models. Recently we could obtain study reports of these registered chemicals and reviewed them of 1,743 positive chemicals enabling us to add further information, including judgement of each strain, purity of the chemicals tested, and solvent used, into the database. We also identified ambiguous data through the review and revised the judgment of 22 positive chemicals as negative or not applicable, based on a consensus of experts. Key reasons for the revisions attributed evolving interpretation of the study guideline as well as difficulty of uniform application of defined criteria on biological responses. Our results indicate that there are still gaps among testing facilities in judgement and/or interpretation even in GLP testing and suggest the need to re-evaluate actual study data when a result conflicts with growing knowledge on structure-activity relationship. Within restriction of confidentiality, our database is freely available for developing *in silico* predictive models.

2052 Optimization of Culture Conditions and Identification of Reference Chemicals for Combination Screening Using TempO-Seq and Cell Painting

M. Culbreth, J. Nyffeler, C. Willis, and J. Harrill. *US EPA, Research Triangle Park, NC.*

The recently released Next Generation Blueprint for Computational Toxicology at the USEPA advocates the use of broad-based high-content profiling assays as a first step for characterizing the biological activity of environmental chemicals. Two such high-throughput profiling approaches being evaluated are whole transcriptome targeted RNA-Seq (i.e. TempO-Seq) and high content imaging-based phenotypic profiling (i.e. Cell Painting), both of which can be applied to a variety of human-derived cell types. This work describes the optimization of the U-2 OS human osteosarcoma cell model for combination screening with TempO-Seq and Cell Painting. First, a time course experiment was performed in 384-well format to identify an initial seeding density (i.e. 3,000 cells/well) that would yield enough cells / well to satisfy TempO-Seq lysate requirements (i.e. $0.25x10^6$ - $2x10^6$ cells / mL lysate) and result in non-confluent monolayers for Cell Painting at 48 h, post-seeding. Next, a set of eleven chemicals with known molecular modes-of-action were screened in concentration-response mode (n = 7 concentrations, ½ log10 spacing) in order to identify a set of three phenotypic / gene expression reference chemicals for use in evaluating TempO-Seq and Cell Painting assay performance during large-scale screening campaigns. Following 24 h of treatment, each candidate reference chemical produced concentration-dependent changes in phenotypic profiles in the Cell Painting assay that were similar to those previously observed in experiments using lower initial seeding densities (400 cells / well). The benchmark concentration for onset of phenotypic changes was similar between low and high density cultures whereas benchmark concentrations for cytotoxicity were right-shifted at the higher cell density. Baseline gene expression profiling of U-2 OS cells with whole transcriptome TempO-Seq confirmed expression of the glucocorticoid (NR3C1) and retinoic acid (RARA) receptors. Well-characterized agonists of these receptors (dexamethasone and all-trans-retinoic acid, respectively) produced concentration-dependent changes in mitochondrial and endoplasmic reticulum morphology. These chemicals, plus the topoisomerase II inhibitor etoposide, were selected as reference chemicals for high-throughput profiling studies in the U-2 OS cell model. *This abstract does not reflect US EPA policy.*

2053 Molecular Docking of Putative Novichok Nerve Agent Isomers into Human Acetylcholinesterase

D. T. Hicks, and R. J. Richardson. *University of Michigan, Ann Arbor, MI.*

Organophosphorus (OP) nerve agents owe their extreme toxicity to potent inhibition of nervous system acetylcholinesterase (AChE). Novichok agents, such as A-234, are claimed to be as much as 8 times more toxic than VX, but the structure of A-234 has not been definitively assigned. Two versions of A-234 structures have been published: one by Hoenig (HA-234) and the other by Mirzayanov (MA-234). However, neither version specifies the possible stereoisomers or protonation states of these compounds nor precisely how they interact with AChE. Moreover, although it is known that S-VX is more toxic than R-VX, due in part to its much greater inhibitory potency against AChE, it is not entirely clear which features of VX-AChE interactions confer the inhibitory advantage to the S-isomer. To test the hypothesis that at least one molecular form of A-234 has higher potency against human AChE than S-VX, we characterized OP-AChE interactions by molecular docking. Our 17 ligands consisted of 8 stereoisomers of HA-234, 4 stereoisomers and 2 protonation states of MA-234, two stereoisomers of VX, and another OP compound, echothiophate. We used covalent docking with the YASARA 19.7.20 implementation of Autodock 4.2.6 to form the trigonal bipyramidal transition state of each compound with human AChE (PDB 4M0E). This was followed by successive bond deletions, energy minimizations, and local-search docking to generate the following respective additional states for each ligand: reversible, inhibited, and 1-2 possible aged states. Assessments for each state included overall and normalized (per number of heavy atoms, Nh) binding energy, hydrogen-bond energy, residue contacts, and atom contacts. Similarities among atom contacts per residue were analyzed by generating frequency distributions and calculating the overlap (OV) among the 136 possible ligand pairs. Contrary to our hypothesis, the results did not indicate OP-AChE interactions that favored any A-234 form over either isomer of VX. Indeed, one of the most striking findings was that S-VX exhibited a higher aged-state hydrogen-bond energy per Nh (4.25 kcal/mol/atom) than any of the other ligands (1.07 - 2.73 kcal/mol/atom). Moreover, whereas the greatest OV scores (0.90 - 0.94) were between HA and MA isomers, the lowest were between S-VX and MA or HA isomers (0.38 - 0.51) as well as between S-VX and R-VX (0.41), indicating that S-VX forms a unique set of OP-AChE contacts compared to its enantiomer and the A-234 molecular forms.

2054 Quantitative *In Vitro* to *In Vivo* Extrapolation (QIVIVE) for Potential Endocrine Disruptors: Simple Generic PBTK Model versus Physiological 26-Compartment PBTK Model Including Uncertainty and Variability Aspects

P. Kalra, E. Fabian, B. van Ravenzwaay, and R. Landsiedel. *BASF SE, Ludwigshafen am Rhein, Germany.*

In animal-free risk assessments, effect concentrations are obtained *in vitro* and are translated to external doses (e.g. oral) by physiology based toxicokinetic (PBTK) modeling (reverse dosimetry). This approach was applied for potential endocrine disruptors - Caffeine (CAF), Ketoconazole (KET), Genistein (GEN) and Bisphenol A (BPA) to translate quantitatively lowest effect concentrations (LOEC) from *in vitro* assays to lowest observed effect levels (LOEL). Dose dependent maximum plasma concentrations C_{max} (unbound) were used to bridge *in vitro* to *in vivo*. This was modelled by 1) an 8 compartment PBTK model [1] and 2) physiological 26 compartment PBTK model (PK-Sim®[2]) for the rat. The established models were compared for predicted C_{max} to the *in vivo* C_{max} reported for various doses in the literature. Furthermore, the estimated versus measured LOELs were compared. Variability on input parameters were taken into consideration. For PBTK models 1) and 2), *in vitro* based estimated LOELs were calculated to be > 39 and 27.5, 100 and 100, 143 and 21 and 515 and 375 mg/kg bw for CAF, KET, GEN and BPA, respectively. For CAF and KET, both models predict in similar magnitude to the *in vivo*-derived LOELs. However, for GEN and BPA model 1) overpredicts the dose by a magnitude of 7-fold and 1.5-fold as compared to model 2). Furthermore, as an example, on introducing the variability on the intestinal permeability for CAF, the predicted LOEL C_{max}, varies 1.5-fold, AUC varies 1-fold and the t_{max} slows down 0.5-fold. This demonstrates that variability should be considered for more precise QIVIVE. In conclusion, this work is a significant step towards establishing full blown PBTK model using variability based QIVIVE to simulate rat TK utilizing all available *in silico*, *in vitro* and *in vivo* data for the compounds. This work attempts to determine the most appropriate assumptions to use in prospective predictions of absorption, distribution and clearance to aid chemical candidate nomination along with identifying the limitation of the bottom-up approach.

2055 Role of a Chemoinformatics Platform in Industry Research Programs and Risk Assessments for Cosmetics Ingredients

M. Cronin[1], M. Dent[2], B. Desprez[3], A. Detroyer[4], J. Fisher[5], S. Gutsell[2], M. Klaric[3], C. Mahony[6], J. Marusczyk[7], G. Ouedraogo[8], A. Tarkhov[7], E. Vandenbossche[2], and C. Yang[7,9]. *[1]Liverpool John Moores University, Liverpool, United Kingdom; [2]Unilever Safety and Environmental Assurance Centre, Sharnbrook, United Kingdom; [3]Cosmetics Europe, Brussels, Belgium; [4]L'Oréal, Paris, France; [5]Procter & Gamble, Cincinnati, OH; [6]Procter & Gamble, Egham, United Kingdom; [7]Molecular Networks GmbH, Nuremberg, Germany; [8]L'Oréal, Paris, France; and [9]Altamira LLC, Columbus, OH.*

Cosmetics Europe (CE) research activities in non-animal methods are managed by the Long Range Science Strategy (LRSS) program in the areas of systemic (toxicokinetics/dynamics), genetic and ocular/dermal toxicity. The LRSS explores the use of New Approach Methodologies to complete cosmetics safety assessments using a combination of *in silico* and *in vitro* data. To this end, a global safety assessment system, CE-TOXGPS, has been developed based on a chemoinformatics platform, integrating data and knowledge to allow for toxicity predictions and safety assessments relevant to the cosmetics industry. Safety assessment case studies that apply the SEURAT-1 safety assessment workflow and the International Cooperation on Cosmetics Regulation principles of next generation risk assessment are at the center of the system design. Two case studies are exemplified in this study that guided and demonstrated the system design and capabilities: *ab initio* safety assessment of phenoxyethanol and read-across of parabens. To allow hypothesis generation, the system provides data from COSMOS DB and IUCLID from REACH, as well as the compilation of ADME and kinetics data. In addition to the chemoinformatics features of structural searching/matching, CE-TOXGPS also offers molecular/physicochemical property calculations, mode-of-action derived profilers (DNA/protein binders, structural rules for liver and reproductive/developmental toxicity), and hepatic/dermal metabolic reactivity profiles. For skin sensitization, several prediction models from various CE members are available. Other safety assessment tools such as Threshold of Toxicological Concern (TTC) and the Read-Across-Ready table are used as evidence in the workflow. Our goal is to provide an open and extendable system that can interface with and leverage other knowledge systems such that the cosmetics industry and global regulatory bodies can share a common assessment language and paradigm.

2056 CYP Machine-Learning Models for Predicting Metabolism and Drug-Drug Interactions of Xenobiotics

T. Lane[1], and P. Madrid[2]. *[1]Collaborations Pharmaceuticals Inc., Raleigh, NC; and [2]SRI International, Menlo Park, CA.* Sponsor: R. Moyer

Little is known about the metabolism of organophosphate (OP) compounds (i.e. pesticides by human drug metabolizing enzymes). OP pesticide accidental exposure kills hundreds of thousands of people every year. Over the past 20 years, large quantities of *in vitro* and *in vivo* data have accumulated on human drug metabolism. Machine learning methods have been applied to many datasets in pharmaceutical and toxicological research over the past decades to enable prospective prediction and increase efficiency by minimizing testing. The availability of drug metabolism and inhibition data enables the building of predictive computational models that can aid in predicting metabolism and drug-drug interactions using molecular structure. We now describe our process for curating these data for human metabolizing enzymes from ChEMBL, PubChem and other sources, followed by the building of Bayesian and other machine learning models. For the prediction of drug-drug interactions K_i or IC_{50} models were generated using ECFP6 descriptors for CYPs including CYP1A2, 2B6, 2C9, 2C19, 2D6 and 3A4 (Bayesian Five-fold cross validation Receiver Operator Characteristics (ROC) = 0.89, 0.79, 0.88, 0.85, 0.89, 0.87, respectively). Prediction of CYP inhibition of OP compounds is critically important to identify possible drug-drug interactions leading to unforeseen toxicity. Individual CYP K_m data from databases such as ChEMBL and PubChem are remarkably limited considering the decades of primary literature on substrate metabolism and a major component of this project focuses on the manual extraction and curation of these data from the public domain to generate machine learning models. There are publicly accessible data for drugs (CypReact, drugbank.ca, bioinformatics.charite.de, etc) with the metabolizing CYPs identified via genetic polymorphisms, as well as through various experimental techniques such as human liver microsomal correlations using a phenotypic probe compounds, metabolism by recombinant CYPs and individual CYP inhibition using selective chemical inhibitors in liver microsomes. Using these data for approximately 1600 compounds, we have developed Bayesian models for all the major CYP isoforms and with the inclusion of 1000 dummy (XenoSite), negative compounds, which produced cross-validation ROCs of ~0.9. The next phase of the project will be applying these models to predict OP compounds followed by *in vitro* verification.

2057 *In Vitro* Cardiotoxicity Testing Using Video-Based Contractility Analysis and Deep Learning

M. Maddah[1], M. Mandegar[2], and K. Loewke[1]. *[1]Dana Solutions LLC, Palo Alto, CA; and [2]Tenaya Therapeutics, South San Francisco, CA.* Sponsor: J. Lin

Numerous studies have demonstrated that induced pluripotent stem-cell-derived cardiomyocytes (iPSC-CMs) display physiologically relevant characteristics and recapitulate aspects of patient cardiac pathology/phenotypes *in vitro*. Accurate and reliable characterization of these cells, and their response to different chemical compounds, plays a critical role in their successful utilization in drug development and safety testing. We present a novel technique for video-based analysis of iPSC-CMs, called Pulse, which combines optical flow and correlation analysis to provide reliable measurements of contractility displacement (in microns). After motion signal estimation, noisy signals are detected and rejected using a deep learning model that has been trained on many signals across a large number of experiments. Signal processing techniques are then used to generate robust and automated measurements of beating parameters such as beat rate, contraction displacement, contraction velocity, duration of contraction and relaxation. We present a case study for using Pulse in high throughput to measure contractility parameters for a panel of drugs with known cardiotoxicity profiles. iPSC-derived cardiomyocytes from CDI were cultured on standard 384-well plates. Multiple doses of 10 different compounds (Aspirin, Bortezomib, Doxorubicin, Erlotinib, Quinidine, SAHA, Sorafenib, Terfenadine, Verapamil, and a test drug) were applied, in addition to DMSO only. Brightfield videos at each well were captured by an SI8000 Imaging System with duration of 8-seconds per video, at 3 different timepoints: at baseline, and after 24 hours and 48 hours of drug exposure. Videos of beating cardiomyocytes were analyzed using Pulse. For Aspirin, no significant changes to any beating parameters were observed at either 24 or 48 hours of exposure. For Bortezomib, an anticancer therapeutic with known cardiotoxicity, Pulse shows an increase in beat rate and beat rate variation, and a decrease in contraction, duration, and prevalence of beating cells at both 24 and 48 hours of exposure. For Verapamil, a calcium channel blocker, Pulse shows a decrease in beat duration and displacement at lower doses while higher doses cause inhibition of contraction and cell death. Conversely, for Quinidine, a sodium channel blocker and hERG inhibitor, Pulse shows a significant increase in total beat duration, which is more pronounced in the

duration of relaxation. Our results demonstrate the ability of Pulse for detecting dose-dependent changes to contractility, enabling high-throughput contractility studies of cardiotoxicity.

2058 A Developmental Ontology-Based Computational Model for Mammalian Neural Tube Closure

Y. C. Staal[1], H. J. Heusinkveld[1], R. Spencer[2], G. Daston[3], T. B. Knudsen[2], and A. H. Piersma[1]. *[1]Rijksinstituut voor Volksgezondheid en Milieu (RIVM), Bilthoven, Netherlands; [2]US EPA/ORD, Research Triangle Park, NC; and [3]Procter & Gamble, Cincinnati, OH.*

Computational models of biological processes are expected to revolutionize chemical safety assessment in the not too far future. Such models provide the template for establishing quantitative adverse outcome pathway (AOP) networks that define critical key events that need monitoring in *in vitro* cell models, and provide algorithms for data integration towards defining safety profiles of chemicals at the level of the intact human. This project aims at modelling mammalian neural tube closure *in silico*, as a tool for defining the related AOP network and its critical key events that need monitoring in selected *in vitro* assays. The starting point was the retinoic acid pathway, given that this morphogen plays a crucial role in cell fate, pattern formation and morphogenesis in the early mammalian embryo. We have extensively mined the developmental biology and toxicology literature to generate the gene and cell compartment interaction map including ±40 genes and 6 cell compartments and their interactions. A cascade of gene expression changes programmed in the embryo in space and time causes location-specific cell proliferation and differentiation patterns, ultimately resulting in the development of a closed neural tube from the initial neural plate. For example, notochord-derived *sonic hedgehog* drives medial hinge point formation in the neural plate, followed by dorsolateral hinge point formation by *noggin*. Neural tube closure and neural crest cell delamination are mediated a.o. by E- and N-cadherin expression driven by *Snai1* and *Slug*. Epidermis formation over the closed neural tube is induced by *Smad1*. Longitudinal neural proliferation versus differentiation is driven by gradients of *retinoic acid* versus *Wnt* rostrally and *Fgf8* caudally. We have translated this map, produced in CellDesigner software, into a three-dimensional *in silico* neural tube closure model, produced in CC3D software, which is driven by the gene expression map. This model visualizes neural tube closure, starting from a flat surface of ectoderm in which the notochord triggers formation of the median hinge points causing the first invagination of the neural plate, after which closure of the tube occurs following formation of the dorsolateral hinge points. Subsequently, the neuroectoderm and the non-neuroectoderm fuse and the neural crest cells detach and migrate away from the fusion area. This model will allow to study *in silico* the consequences for neural tube closure of model compound-induced gene expression changes detected in relevant *in vitro* assays. *This abstract does not necessarily reflect US EPA policy.*

2059 Flexfilters: A Scalable and Flexible QSAR Platform for Addressing Complex and Diverse Types of *In Silico* Safety Assessment of Chemicals

S. Chakravarti. *MultiCASE Inc., Beachwood, OH.*

Computational toxicity assessment techniques are currently undergoing a significant and rapid change due to the emphasis on adaptation of alternatives to animal testing. Computational prediction of a toxicity endpoint using one algorithm, one software and one model does not seem to be adequate anymore. Continuous discovery of new adverse outcomes and toxicity pathways (AOPs and TOPs) are creating new opportunities and challenges. Availability of numerous large datasets of variety of biological events caused by chemicals are also intriguing. These changes are affecting almost all involved parties: model builders, toxicity testers and regulators. Here we will describe the development of a platform to address some of these challenges. In contrast to the conventional approach, where a fixed algorithm uses one model to make a prediction, this platform relies on a set of external instructions to perform complex risk assessment tasks. For example, every descriptor in a regression model is actually treated as an instruction that operates on a chemical and returns a value. This seemingly insignificant change enables quick creation of sophisticated and different workflows, e.g. simple models with continuous or classification outcomes, logical aggregation of multiple models to reach a decision, read across methods etc. It can also perform non-predictive operations, e.g. chemical database search, imposition of domain applicability constraints, alert identification, fingerprint generation, clustering etc. It allows scalability when new data or new mechanistic knowledge become available. We will present illustrative case studies from diverse toxicity endpoints, e.g. eco-toxicity, genotoxicity, acute toxicity, skin sensitization etc.

2060 Collaborative Modeling Project for Predicting Acute Oral Toxicity

K. Mansouri[1], A. L. Karmaus[1], J. Fitzpatrick[2,3], G. Patlewicz[4], P. Pradeep[4,3], D. G. Allen[1], W. Casey[5], and N. C. Kleinstreuer[5]. *[1]Integrated Laboratory Systems Inc., Research Triangle Park, NC; [2]ScitoVation, Research Triangle Park, NC; [3]Oak Ridge Institute for Science and Education, Oak Ridge, TN; [4]US EPA/CCTE, Research Triangle Park, NC; and [5]NIEHS/NICEATM, Research Triangle Park, NC.*

Regulatory agencies have a pressing need to accurately assess an increasing number of chemicals for acute oral systemic toxicity potential (LD50). With the lack of *in vitro* approaches and the availability of existing LD50 data for a broad range of chemicals, *in silico* models provide an alternative to predict acute oral toxicity and bridge data gaps. NICEATM and the ICCVAM Acute Toxicity Workgroup organized an international collaborative project to develop *in silico* models for predicting acute oral toxicity. In total, 35 groups participated, submitting 139 predictive models built using a dataset of 11,992 chemicals split into training (75%) and evaluation sets (25%). Crowdsourced models were developed for five endpoints: LD50 value, US EPA hazard categories, GHS hazard categories, very toxic (LD50 < 50 mg/kg), and non-toxic (LD50 > 2000 mg/kg). Predictions within the applicability domains of the submitted models were evaluated using external validation sets, then combined into consistent consensus predictions based on a weight-of-evidence approach, forming the Collaborative Acute Toxicity Modeling Suite (CATMoS). The resulting consensus model leverages the strengths and overcomes the limitations of individual modeling approaches. The consensus predictions are fully reproduceable and performed as well as the *in vivo* acute oral toxicity assay with evaluation set balanced accuracy ranging from 0.74 to 0.84 for the four categorical endpoints predictions and an R^2 of 0.65 for LD50. The CATMoS consensus model is available via the free and open-source tool OPERA (Open Structure-activity/property Relationship App). OPERA also provides predictions for physicochemical and pharmacokinetic properties, and other toxicological endpoints with applicability domain assessments and accuracy estimates (https://github.com/NIEHS/OPERA). CATMoS predictions for the ~850k chemical structures in DSSTox are being made publicly accessible via NTP's Integrated Chemical Environment (ice.ntp.niehs.nih.gov) and US EPA's CompTox Chemicals Dashboard (comptox.epa.gov/dashboard). *This project was funded with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C. This abstract does not necessarily reflect US EPA policy.*

2061 The Comparative Toxicogenomics Database: A Comprehensive View of Chemical Exposures, Mechanisms, and Biological Effects

C. Mattingly, C. J. Grondin, R. J. Johnson, D. Sciaky, J. A. Wiegers, T. C. Wiegers, and A. P. Davis. *North Carolina State University, Raleigh, NC.*

The Comparative Toxicogenomics Database (CTD; http://ctdbase.org) is a public resource that elucidates connections between environmental chemical exposures, molecular mechanisms, and consequent biological effects. CTD provides manually curated interactions that link chemicals, genes, phenotypes, diseases and population-based exposures. Data curation using community-accepted ontologies and controlled vocabularies enables seamless integration of key external data sets and links to other public resources in the biomedical and environmental spaces. This information can be explored with user-friendly query and analytical tools to generate testable hypotheses about chemical exposures and environmentally-influenced diseases. CTD includes manually curated data for more than 16,000 chemicals, 48,000 (cross-species) genes, 5,000 phenotypes, and 7,000 diseases. We demonstrate how users can access CTD to learn about these chemicals, genes, phenotypes, diseases, or exposure studies. Integration of all five modules allows adverse outcome pathways (AOP) for systems toxicology applications to be constructed, from molecular initiating events to population-level health outcomes. We provide case studies of CTD applications for discovery including a) construction of mechanistic pathways relating air pollution exposure to cardiovascular disease using the AOP framework, and b) identification of potential health outcomes associated with vaping based on its constituent chemicals. The applications of CTD for environmental health research are broad and ever-expanding; we look forward to your feedback.

2062 Toward Mechanistic-Based Assessment: Rapid Elucidation of the Protein Binders of Diketones Using Phenotypic and Proteomic Profiling and Biomolecular Modeling

J. Lee[1], M. Nguyen[1], H. Chang[1], C. Jaladanki[1], V. Limviphuvadh[1], Y. Kanagasundaram[1], S. Maurer-Stroh[1], H. Fan[1], C. Tan[2], and L. Loo[1]. *[1]Agency for Science, Technology and Research (A*STAR), Singapore, Singapore; and [2]South University of Science and Technology, Shenzhen, China.*

New approach methods based on mechanistic reasoning have the potential to provide more human-relevant information for chemical safety assessment. In particular, the thermal stabilization property of ligand-bound proteins may be exploited to elucidate xenobiotic-protein interactions that may be associated to the molecular initiating events (MIEs) of an adverse outcome. Recent advances in cellular thermal shift assays (CETSA) coupled with mass spectrometry have enabled rapid identifications of the potential protein binders of a xenobiotic in intact human cells at proteomic scale. However, most environmental agents may interact with many proteins at low affinities, and the relevancy of the identified protein binders is limited by the cell models used. We have developed the Toxicity Mode of Action (MoA) Discovery (ToxMAD) Platform to address these challenges. First, we used high-throughput imaging-based phenotypic profiling (HIPPTox) to rapidly screen and identify human cell models most sensitive to a chemical of interest. Secondly, we used isothermal dose response-CETSA ($ITDR_{CETSA}$) to identify potential protein binders in the chosen cell model. Finally, we ranked all the identified candidates using two *in silico* biomolecular modeling methods: CLICK, an algorithm that compares different candidates to a ligand based on 3D-structure superimpositions of their potential binding pockets, and molecular docking that estimates the binding affinities between the candidates and the ligand. We applied ToxMAD to study diketones, a class of favoring compounds that may lead to an obstructive airway disease, bronchiolitis obliterans (BO). Using HIPPTox, we found that a lung bronchial epithelial cell line, BEAS-2B, is the most sensitive to a diketone called diacetyl. Using $ITDR_{CETSA}$, we identified 745 proteins from BEAS-2B that may bind to diacetyl. CLICK and molecular docking analysis further reduced the candidates to 56 hits, which include several known binders of diacetyl, such as L-xylulose reductase (DCXR) and aldehyde reductase (AKR1A1). Some of these identified hits may be related to the MIEs of BO. They may help us to better understand the MoAs of diketones, and search for safer replacements.

2063 Evaluation of the *In Vitro* Toxicological Profile of Ultraviolet (UV) Filters Using Tox21/ EDSP21

D. O. Onyango, B. Selman, and J. F. Nash. *Procter & Gamble, Mason, OH.*

Sunscreen products are composed of UV filters and formulated for different purposes, e.g., recreational use or daily facial application. The UV filters in such products reduce the dose of solar UV thereby lessening skin damage. In 2019, the Food and Drug Administration (FDA) reclassified 12 organic UV filters as Category III, most notably octinoxate, homosalate, octocrylene, ensulizole, octisalate, avobenzone and oxybenzone, citing safety "data gaps". The key safety concerns include lack of data for endocrine disruption, dermal and systemic carcinogenicity and multi-generational reproductive and developmental toxicity. Tox21/EDSP21 program, i.e., CompTox previously ToxCast, is a high-throughput screening program of chemicals from a broad background ranging from pesticides to pharmaceuticals. Tox21 and EDSP21 identify Adverse Outcomes Pathways (AOP), Key Events (KE) and Endocrine Disruption (ED). Using the CompTox website to access Tox21/EDSP21 data, all UV filters were found to have been screened in the high-throughput bioassays. These seven organic UV filters showed low activity in the bioassays with most activity detected above the range of "cytotoxic burst" as defined by Judson *et al.* (Tox Sci. 152:323-339, 2016). The pathways that were most affected were cell cycle (5 out of 7), and, to a lesser extent, the nuclear receptor pathways (2/7) and cytokine (1/7). Most activity was observed in liver and kidney-based bioassays. These seven organic filters showed weak endocrine disruption activity when tested on bioassays measuring Androgen Receptor (AR), Estrogen Receptor (ER), Thyroid Receptor and steroidogenesis activity. With the exception of oxybenzone, all activity in the endocrine assays were at concentrations 3-10 times greater than the cytotoxic burst. For avobenzone and octocrylene, AC_{50} for androgen antagonism (53uM) and estrogen agonism (18.73 uM) were 3785 and 851 times higher, respectively, than estimated plasma concentrations calculated from C_{max} measured in humans (Matta *et al.* JAMA 321:2082-2091, 2019). These data are consistent with *in vivo* animal/ human studies showing no or very weak endocrine activity. In sum, the results from this work show that organic UV filters, which have been marketed as sunscreens for decades, have relatively low activity and, by extension, toxicological potential and endocrine disruption in humans.

2064 The Preliminary Study on Single Cell Transcriptome Sequencing of Bone Marrow Hematopoietic Stem Cells in Mice by Benzene Exposure

K. Xu, R. Sun, S. Ji, Y. Pu, L. Yu, J. Zhang, L. Yin, and Y. Pu. *Southeast University School of Public Health, Nanjing, China.* Sponsor: Y. Pu, Environmental Mutagenesis and Genomics Society

Benzene is a common environmental pollutant and widely used in industrial production. Continuous exposure to benzene can cause bone marrow (BM) suppression, leading to pancytopenia, anemia, aplastic anemia and even leukemia. Previous studies in our lab confirmed that the damage of hematopoietic stem cells (HSCs) was one of the causes of benzene-induced hematotoxicity. The aim of this study was to identify the differentially expressed genes (DEGs) of BM HSCs in mice exposed to benzene, and to explore the potential mechanism of benzene-induced hematotoxicity in HSCs. C57BL/6 mice were treated with corn oil or 150 mg/kg b.w. benzene for 30 consecutive days. HSCs (approximately one in ten thousand or less of bone marrow cells) were sorted by flow cytometry, and single-cell RNA-seq was applied to analyze the gene expression. Compared with the control group, the number of WBCs in Peripheral blood and the proportion of BM HSCs were decreased after benzene exposure, indicated that the mouse model of benzene poisoning was successfully established. RNA-sequencing data indicated that benzene disturbed 1514 genes by more than 2 folds in mice BM HSCs, including 400 up-regulated DEGs and 1114 down-regulated DEGs. Top 5 upregulated DEGs related to cell proliferation were Lgr5, Tnfrsf8, Dll1, Ifit3b and Tcf7, while Zfp503, Acvr1c, Prkd1, Ddr1 and Serpinb7 were downregulated. Gene ontology enrichment analysis with all DEGs found that regulation of cellular and biological process, and negative regulation of nitrogen compound or macromolecule metabolic process were statistically overrepresented. KEGG enrichment analysis revealed that many DEGs were related to signaling pathways regulating pluripotency of stem cells, Wnt and VEGF signaling pathway. Our findings reveal significant differences in HSCs transcriptomic profiles of mice BM after benzene exposure which provide novel insights into the further mechanism study of benzene-induced hematotoxicity. *This work was supported by the National Natural Science Foundation of China (Grants no. 81730087, 81573189).*

2065 Small Heat Shock Protein 27: A Critical Determinant in the Maintenance of *Drosophila* Male Germ Line Stem Cell Functions on Exposure to Cadmium Chloride

A. Nandi[1,2], and D. K. Chowdhuri[1,2]. *[1]CSIR-Indian Institute of Toxicology Research, Lucknow, India; and [2]AcSIR, Ghaziabad, India.* Sponsor: H. Gupta

Stem cells, like any other cells, experience different kinds of cellular stress affecting their normal functions including self renewal and differentiation. As a stress responsive pathway, alteration in heat shock proteins (HSPs) expression has been shown to affect the stem cells behavior. Maintenance of the adult male germline stem cells (GSCs) and their functions is a crucial biological process for spermatogenesis. Several studies reported the effects of cadmium (Cd) on reproductive endpoints like reduced semen quality parameters and hence failure in male fertility. However, studies involving GSCs functions under the Cd stress affecting spermatogenesis remains unknown. Therefore, the present study was designed to investigate the effects of cadmium chloride ($CdCl_2$) exposure on GSCs maintenance and in this context, evaluating the role of HSPs using *Drosophila* testes as an *in vivo* model for male germline stem cell toxicity and hence male sub fertility. Developmental exposure of $CdCl_2$ lead to significant reduction in the GSC number in $CdCl_2$ (20 µg/ml) exposed males as compared to controls. The resulting testes also showed precocious and incomplete differentiation and reduction in mitotically active spermatogonial cells along with significantly reduced reproductive performance of $CdCl_2$ exposed male flies. Furthermore, significant elevation of reactive oxygen species (ROS) level was seen in the apical region of the testes on $CdCl_2$ exposure altering small HSP 27 expression levels among various other screened HSPs. However, cell death was not induced by ROS. Genetic screens altering HSP 27 expression affected adhesion molecules at the stem-hub cells interface in the apical region of the testes on $CdCl_2$ exposure. In summary, the study infers the elevated levels of ROS resulted in altered HSP 27 expression reducing GSCs number accompanied by inappropriate differentiation leading to reduced number of sperms and eventually the fertility of male *Drosophila.* This study provides a basis of chemical stress induced dysregulation in HSP 27 expression and also suggests that small HSP 27 plays a critical role in the maintenance of germline stem cell homeostasis in Cd-induced failure in male fertility and further advocates *Drosophila* as an alternative animal model for evaluating male germline stem cells toxicity.

2066 Engineering Human Neural Organoids to Explore Impaired Neurogenesis Induced by Arsenic

X. Wu, A. L. Luz, D. Dixon, and E. J. Tokar. *NIEHS/DNTP, Research Triangle Park, NC.*

Modeling the development and function of the human brain is challenging due to the vast complexity of the organ. Recent advances in the derivation of brain-like organoids from human pluripotent stem cells (PSCs) have provided new tools to study the biology of the human brain. These 3D *in vitro* models have the potential to enhance our understanding of the mechanisms of developmental neurotoxicity during the early stages of neurogenesis and offer a cost-effective approach for assessing chemical safety. Here, we have used PSC-derived embryoid bodies (EBs) from 384-well plates to develop neural organoids for chemical developmental neurotoxicity testing. There is overwhelming evidence that environmental factors play a role in the development and progression of a host of central nervous system disorders. Arsenic (As) is a widespread environmental contaminant. Human exposure to As occurs mainly through ingestion of contaminated food or water. Exposure to inorganic As is associated with developmental neural diseases; however, the mechanisms of As on developmental neurotoxicity are not well-defined. We used 3D EBs to recapitulate events involved in early embryogenesis and neurogenesis. We found that a 7-day exposure to a human-relevant, non-cytotoxic dose (0.5 μM; 35 ppb) of As showed irregular early neural rosette-like structure formation and increased ectoderm differentiation within the EBs through upregulated expression of genes PAX3, PAX6, SOX1, COL2A1 and the Notch signaling pathway, which all play critical roles in early embryonic development. During neural induction stage (day 7) of neuron organoid formation, As exposure increased expression of neural progenitor cell marker genes NESTIN and PAX6. Histologic assessment of day 40 control neuron organoids validated the presence of neuroepithelial cells forming neural rosette-like and neuropil structures. Immunohistochemistry showed regions of vimentin+ astrocytes and nestin+ neural stem cells in the organoid structures. The neural rosette-like structures were disrupted in day 40 neural organoids with As exposure. Using the neural organoid 3D model described here can provide valuable insights into the cellular events and molecular mechanisms to address adverse outcome pathways associated with As-induced developmental neurotoxicity.

2067 Impact of Trisomy 21 and Pesticide Exposure on Cell Fate Lineage Specification in Directed Neural Differentiation

K. M. Prutton, A. Jain, J. Marentette, and J. Roede. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

Down syndrome (DS) is a complex genetic insult caused by triplication of chromosome 21. The ubiquity of cognitive deficits in DS has made structural and cellular changes in the brain the focus of much research effort. However, no prior studies have utilized DS induced pluripotent stem cells (iPSC) to assess the effect of trisomy 21 and environment on embryoid body formation and neural lineage specification. Accumulating evidence has shown that phenotypic features of the DS brain originate in early developmental stages. We aim to study the interface between genetic mechanisms, developmental processes, and environmental exposures to elucidate the stages where normal patterns of development may diverge in DS. Here we show neural induction by monolayer culture system and embryoid body formation - two processes that generate neural progenitor cells (NPC). NPCs are multipotent, and generate the major cell types of the central nervous system (CNS). In our preliminary experiments involving an isogenic model of euploid and DS iPSCs, we observed differences in EB size, as well as several neural differentiation markers, such as TuJ1 (neurons) and GFAP (glial cells), to be upregulated in DS. Furthermore, pluripotency (OCT4) and mesodermal (brachyury) markers remain elevated in DS during neural induction in EB formation and monolayer culture. Trisomic iPSCs may be biased towards particular germ lineages or stem cell self-renewal despite directed differentiation. These observations, along with the lack of proper neural rosette formation in DS iPSCs, suggest accelerated neural and glial differentiation, prolonged pluripotency, and reduced progenitor cell development. As the developing brain is particularly sensitive to toxic environmental exposure, the pesticide, maneb (MB), was incorporated to identify critical developmental periods and pathways that are vulnerable in the context of trisomy 21. Our preliminary data demonstrate that DS cells display greater toxicity to the fungicide, MB. In the presence of MB, DS EBs showed altered morphology and caspase activity compared to their euploid counterparts. Together, these data indicate that variability in DS phenotypes may not be a direct product of trisomy 21, but rather a consequence of an interaction between genetic and environmental factors.

2068 Protective Role of Mesenchymal Stem Cells and Mesenchymal Stem Cell-Derived Exosomes in Cigarette Smoke-Induced Mitochondrial Dysfunction

K. P. Maremanda, I. K. Sundar, and I. Rahman. *University of Rochester Medical Center, Rochester, NY.*

Cigarette smoke (CS)-induced lung inflammation and chronic obstructive pulmonary disease (COPD) involves mitochondrial dysfunction. Mesenchymal stem cells (MSC) and MSC-derived exosomes (EXO) are reported to show their therapeutic effects in animal models of inflammation/injury. We hypothesized that MSC and EXO combination (MSC+EXO) treatment may have protective effects against acute CS-induced lung inflammation and mitochondrial dysfunction compared to individual treatments (MSC or EXO alone). EXO were characterized by Western blotting, tunable resistive pulse sensing (qNano) and transmission electron microscopy. Mitochondria reporter mice (mt-Keima and mito-QC) were exposed to air or CS for 10 days. mt-Keima mice were treated with intraperitoneal injections of MSC or EXO or MSC+EXO for 10 days. Total cell counts and differential cell counts were analyzed using cellometer and flow cytometry respectively. Pro-inflammatory mediators in bronchoalveolar lavage fluid were measured by ELISA. Mitochondrial, DAMPs, inflammation and mitophagy markers were further analyzed by Western blot analysis, qPCR and confocal microscopy in acute CS exposed mouse lungs. Seahorse flux analyzer was used to measure the oxidative-phosphorylation (OXPHOS) in the BEAS2B cells and mMSC co-culture experiments. CS exposure increased the inflammatory cellular infiltrations in the lungs of the mt-Keima mice, while treatments showed varied degrees of protection. There were no changes in the mitophagy proteins like Pink1 and Parkin, which was also found using the mito-QC mice. Acute CS exposure increased the protein abundance of DRP1 (mitochondrial fission), S100A4 and S100A8, HMGB1, RAGE and AGE (DAMPs markers). MSC+EXO treatment increased the gene expression of *mfn1, mfn2* and *opa1* (mitochondrial fusion) and *rhot1* (mitochondrial trafficking). BEAS2B+MSC co-culture showed protective response against the CSE-induced mitochondrial respiration (OXPHOS) confirming the beneficial effect of MSC to lung epithelial cells. MSC+EXO treatment showed attenuation of selected inflammatory and DAMPs markers such as MMP9, S100A4 and HMGB1. MSC+EXO treatment may act against these early events caused by CS exposure owing to its anti-inflammatory and other mitochondrial transfer mechanisms. *Supported by the NIH R01 HL135613, R21 ES028006, R01 HL133404, and R01 HL137738.*

2069 Fluid from Popular Electronic Cigarettes Negatively Impacts Early Prenatal Development as Assessed Using Human Embryonic Stem Cells as a Model

G. Vasudevan. *University of California Riverside, Riverside, CA.*

Electronic cigarettes (ECs) are often recommended to pregnant women as an alternative to smoking. However, their effects on embryonic and fetal health have not been rigorously assessed. Recently, vaping-associated pulmonary illness (VAPI) has raised awareness regarding possible harm that ECs may cause. ECs expose the user and conceptus to nicotine, flavor chemicals, solvents, metals and reaction products. This project examined the effect of fluid from two popular ECs and pure nicotine on early development using H9 human embryonic stem cells (hESC) taking a "toxicology in a dish" approach. hESC were cultured on Matrigel and maintained in mTeSR Plus medium. To examine the effect of e-liquids on attachment, cells were plated into 1% dilutions of JUUL Virginia Tobacco, JUUL Classic Menthol, Vuse Original and Vuse Menthol e-liquids, allowed to attach for 24 hours, then the number of attached colonies was determined in micrographs of nine fields of view/treatment. Attachment of hESC was inhibited in both JUUL and Vuse treatments. The impact of the e-liquids and nicotine on cell proliferation was also studied. hESCs were plated on 24-well plates, and after a 24-hour attachment period, treated with various concentrations of nicotine or e-liquids. Time-lapse images were collected over 48 hours in a BioStation CT. MTT assays were performed to determine the effects of treatment on mitochondrial reductases. Images were analyzed using CL-Quant to obtain growth rates. Proliferation of cells exposed to e-liquids was not affected in the 0.1% and 0.3% e-liquid treatments, but was impaired in the 1.0% treatments, and cell death was seen in the 3% treatment groups. Cells exposed to the nicotine concentrations in 0.1%-1% e-liquids (0.034-0.160 mg/ml) showed growth rates like the control. Exposure to 1.01-1.83mg/ml nicotine (found in 3% e-liquids) resulted in cell death. The MTT assay results showed that 1% e-liquid impaired mitochondrial reductase for each flavor. Nicotine MTT results showed that lower concentrations stimulated mitochondrial reductase but higher concentrations were toxic. Failure to attach to substrates and reduced proliferation could have detrimental effects during early human development. Based on these data, women should avoid using ECs during early pregnancy when the embryo is most susceptible to toxicants.

2070 Toxicogenomic Profiling of Human Neural Progenitor Cells Exposed to Alternative Flame Retardants

H. Chen, K. E. Williams, M. Y. Kim, N. Iyer, C. Yan, U. Jigmeddagva, and J. F. Robinson. *University of California San Francisco, San Francisco, CA.*

Due to their environmental persistence and suspected ability to cause developmental neurotoxicity (DNT), polybrominated diphenyl ether (PBDE) flame retardants (FRs) are gradually being phased out of consumer products. Organophosphorous FRs (OPFRs) are being introduced as replacements. Alarmingly, select alternative FRs and/or their metabolic products are widely-detected in human maternal blood, urine, and placental tissue. While the developmental health effects of exposures to these compounds remains unknown, initial *in vitro* assessments suggest that select compounds may induce developmental toxicity at similar potencies as legacy FRs. Human embryonic stem cell (hESC) models are promising tools to evaluate the ability of chemicals to cause DNT. Previously, we demonstrated that hESC-derived neural precursor cells (NPCs) are sensitive to PBDE-induced DNT, altering cell function and global gene expression. In subsequent analyses, we expanded our assessments to include 12 alternative FRs. We discovered 9 of the 12 tested FRs (0-30μM) induced significant cytotoxicity, reducing cell viability and increasing cell death in NPCs. To identify possible common mechanisms underlying FR toxicity, we performed sequential window acquisition of all theoretical mass spectra (SWATH-MS) proteomic profiling of NPCs exposed to BDE-47 or one of three FRs identified to be as potent as BDE-47: IPP (isopropylated phenyl phosphate), EHDP (2-ethylhexyl diphenyl phosphate), or F550 (Firemaster 550) at 3 or 10 μM. In total, we identified 2,511 unique proteins in all NPC samples (n=30). Significant alterations in protein abundance were observed with all four compounds ($p<0.05$; absolute fold change > 1.2) as compared to the vehicle control (0.1% DMSO): BDE-47 (75); IPP (99); EHDP (54); and F550 (70). In general, proteins were altered in a concentration- and FR-dependent manner. The largest overlap in dysregulated proteins was observed between the two OPFRs, IPP and EHDP (9 proteins). Functional analysis of differentially expressed proteins suggested potential common mechanisms across FRs, including altered mitosis (BDE-47, F550), hormone response (EHDP, F550) or organonitrogen metabolism (IPP, EHDP, F550). Our results suggest alternative FRs are neurodevelopmental toxicants in a hESC model of neurogenesis. They induce concentration-dependent toxicity and alter protein expression in DNT-relevant pathways. Future studies will examine the correlation between proteomic and transcriptomic FR signatures, and the functional relevance of proposed targets. *Supported by NIH/NIEHS R00ES023846.*

2071 Establishing Cell Painting for Morphological Studies of Toxicant Effects in Human Mammary Cells

A. Tapaswi, T. Thong, K. Polemi, E. Hill, C. Forte, and J. A. Colacino. *University of Michigan, Ann Arbor, MI.*

High Content Imaging (HCI) uses phenotypic screening to study whole cells and cellular components by simultaneously assessing multiple phenotypes in complex cell populations. Cell Painting, a phenotypic HCI assay, uses automated fluorescence microscopy to simultaneously measure 8 cellular components via six fluorescent stains which are imaged in 5 channels. The cellular components include DNA, RNA, endoplasmic reticulum, mitochondria, F-actin, golgi apparatus, and plasma membrane. Cell Painting was shown to be effective in quantifying subtle perturbations in cellular and sub-cellular features to identify mode of action for drugs and chemical stressors and to find genes implicated in disease onset and development. The goal of this project was to establish the Cell Painting method to study the effects of environmental toxicants on human mammary cells to assess potential carcinogens and stem cell toxicants. As a proof of principle, we tested the effects of cadmium on the non-tumorigenic human mammary cell line MCF10A. Cadmium is a putative metalloestrogen which dysregulates mammary stem cell biology at physiologically relevant doses. MCF10A cells were treated with cadmium doses ranging from 20nM to 10uM for 48 hours, subjected to Cell Painting, and images were captured via a CellInsight CX5 HCI microscope. Image data were quantified in an unbiased manner using CellProfiler software, which yielded approximately 3000 distinct morphological measurements per cell, including staining intensity, texture, and localization. Dose-response effects across various morphometric features were quantified in R and BMDExpress. CellProfiler analysis revealed dose-dependent alterations in cellular morphology, both nuclear and cytoplasmic. BMDExpress analysis identified multiple changes in granularity and intensity of DNA staining and granularity of cytoplasmic golgi and actin staining between 750 nM and 1 uM cadmium exposure. Ongoing work is quantifying alterations in cell morphology across a range of chemical exposures at the single cell level to understand cellular heterogeneity in response to toxicant effects. Cell Painting is a cost-effective, easily customizable technique that can identify the morphological effects of environmental toxicants and could aid in deducing modes of action and pathways involved in development of breast cancer.

2072 Hepatocytes Derived from NASH iPSC Donors Provide a Valuable Platform for Disease Modeling and Drug Discovery

I. Gurevich, S. Burton, M. Ohshima, C. Munn, M. Goedland, K. Czysz, and D. Rajesh. *Fujifilm Cellular Dynamics Inc., Madison, WI.* Sponsor: L. Alexunes

Non-alcoholic fatty liver disease (NAFLD) affects 30 to 40% of adults and about 10% of children in the US. About 20% of people with NAFLD develop non-alcoholic steatohepatitis (NASH), which may lead to cirrhosis, onset of hepatocellular carcinoma and is expected to become the leading cause of liver transplantation in the near future. Development of NASH may be exacerbated by toxic insults to the liver. Human induced pluripotent stem cells (iPSCs) derived from NASH patients are a valuable tool for studying NASH pathobiology at the cellular and molecular level and to improve drug target screening. We have developed a novel hybrid two dimensional/aggregate protocol to generate cryoperservable hepatocytes using a panel of iPSCs from NASH patients and healthy donors. iPSCs from both sets of donors demonstrated a rapid decline in pluripotency genes *POU5F1* and *NANOG* at the onset of definitive endoderm (DE) differentiation. End stage DE cells coexpress high levels of CXCR4 and CD117 and, when differentiated further along the hepatic lineage, developed >90% purity of hepatic markers alpha-1 antitrypsin (AAT), asiaglycoprotein 1 (ASGPR1). End stage hepatocytes also developed expression of albumin. Importantly, both cryopreserved DE and hepatoblasts also successfully differentiated to mature functional hepatocytes demonstrating ~2-fold induction of CYP3A4 activity in response to rifampicin. Additionally, hepatocytes from healthy and NASH donors demonstrated lipid accumulation upon fatty acid (FA) treatment. Interestingly, hepatocytes derived form one of the NASH donors demonstrated spontaneous lipidosis mimicking hallmarks of NASH hepatocytes. Co-culture of hepatocytes along with iPSC derived macrophages and mesenchymal stem cells from healthy and NASH donors will enable generation of liver organoids that would be considerably valuable for understanding NAFLD/NASH biology, identifying novel targets for treatment, and will improve safety assessments of the potential drugs aimed at treating the disease.

2073 High-Throughput Anisotropic Human iPSC-Derived Cardiomyocyte Cultures Display Differential Response to Chronic Oncology Compound-Related Toxicity

R. Contu, R. Padilla, C. Turori, B. Van Hese, and F. Zanella. *StemoniX, La Jolla, CA.*

Cardiac toxicity derived from chronic exposure of oncology treatments can be a concerning side effect of those therapies. The ability to better detect and dissect chronic cardiac toxicities in a human and tissue-specific *in vitro* high throughput system would enable a better understanding of the mechanisms underlying those toxicities, potentially leading to strategies to mitigate or eliminate them. Human induced Pluripotent Stem Cell-derived Cardiomyocytes (hiPSC-CMs) have been employed successfully in the detection of chronic cardiac toxicities arising from several independent oncology drugs. Nonetheless, current remaining challenges under consideration for the hiPSC-CM system are sub-ideal cardiomyocyte geometry, sub-cellular structural organization, and coherent contractile behavior in standard monolayer cultures. Independent Bioengineering approaches have shown improvements in aspects of hiPSC-CM physiology *in vitro*, however those approaches have limited scalability and thus are not amenable to high throughput screening. hiPSC-CMs cultures passively aligned on a high throughput platforms have been shown to display physiologically-relevant features, including more physiological cellular geometry, coherent unidirectional contraction, cardiac cell junction re-modeling, and improved calcium handling. To evaluate whether the changes induced by this platform translated into differential responses to compounds previously liked to chronic cardiotoxicity, high throughput calcium flux and viability assays were performed on hiPSC-CMs cultured in standard high throughput screening cell cultureware or anisotropic 384-well plates. hiPS-CMs were interrogated with 14 compounds previously linked to chronic cardiotoxicity across a 7-point concentration range. Interestingly, compounds like Doxorubicyn and Vandetanib displayed a differential response in anisotropic conditions, with more evident arrhythmic behavior detected at lower concentrations than in standard monolayer cultures. Additionally, Vandetanib induced the occurrence of severe early afterdepolarizations (EADs) that weren't observed in standard culture conditions aside from the highest doses tested. Simultaneously, no evident ab-

normal arrhythmogenic behavior or EADs were observed for vehicle control (DMSO) treatment or Aspirin, a negative control compound. Taken together, the observations from this study indicate that anisotropic high throughput hiPSC-CM cultures showed better sensitivity and resolution over the progression and severity of pro-arrhythmic events.

PS 2074 Investigating the Impact of Trisomy 21 on Xenobiotic Biotransformation Using Induced Pluripotent Stem Cell-Derived Hepatocyte-Like Cells

J. O. Marentette, A. Rauniyar, and J. Roede. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

Individuals with Down syndrome (DS, Trisomy 21) experience an array of comorbidities in addition to intellectual disabilities including type 1 diabetes, hypothyroidism, obesity, leukemia, inflammation and Alzheimer's disease. These comorbidities are of great relevance to this study due to the fact that genetics, disease states, and cofactor levels can greatly impact xenobiotic biotransformation. To investigate the impact of DS on xenobiotic biotransformation, we utilized hepatocyte-like cells (HLCs) derived from two isogenic induced pluripotent stem cell lines (iPSCs). These cell lines, C3 (CTRL) and C2 (DS) are ideally suited to investigate the impact of trisomy 21 on drug metabolism as they are derived from the same fibroblast cell line, AG06872; therefore, any differences observed from this study are exclusively due to the trisomy of chromosome 21. HLC phenotype was assessed by gene expression (i.e. HNF4α), glycogen synthesis and cytochrome P450 (CYP) activity. We then administered agonists for xenosensor transcription factors, like the aryl hydrocarbon receptor (AhR) and constitutive androgen receptor (CAR), and analyzed downstream drug metabolizing enzyme (DME) expression. HLCs were treated with benzo[a]pyrene (BaP, AhR agonist) for 24 hours to induce downstream Phase 1 DME (ALDH3A1, CYP1A1, CYP1B1) and Phase 2 DME (GSTA1) expression. After 24 hours of BaP (10μM) stimulation, we detected variations in DME gene expression in DS compared to CTRL with ALDH3A1 (1 to 1.9 fold change in CTRL vs DS), CYP1A1 (6.0 to 5.4), CYP1B1 (1.6 to 2.0) and GSTA1 (1.3 to 1.8). To induce downstream CAR gene expression, HLCs were treated with 6-(4-chlorophenyl)imidazo[2,1-b][1,3]thiazole-5-carbaldehydeO-(3,4-dichlorobenzyl)oxime (CITCO, CAR agonist) for 24h and Phase 1 DME (CYP3A4, CYP2B6) expression determined. Following 24 hours of CITCO (1μM) treatment, we saw a drastic increase in CYP3A4 in DS compared to CTRL (1.19 to 11.9 in CTRL vs DS). These studies highlight the inherent differences that having the presence of trisomy 21 has on xenobiotic biotransformation and induction of Phase 1 and 2 DME. Further, these data show that DS individuals do not metabolize xenobiotics in a manner similar to euploid, indicating that additional characterizations are necessary to effectively understand drug and toxicant metabolism in this unique genetic background.

PS 2075 Single Cell RNA Sequencing Reveals Differences in Transcriptomic Profiles of Normal Mammary Cells between African American and European American Women

T. Thong, M. D. Brooks, Y. Wang, L. Middleton, A. Tapaswi, K. Polemi, S. Rocco, C. Scott, E. Hill, L. Balzano, M. S. Wicha, and J. A. Colacino. *University of Michigan, Ann Arbor, MI.*

In the US, women of African ancestry have significantly worse breast cancer outcomes. In particular, African American women are two to three times more likely to develop the most aggressive subtype, triple negative breast cancer (TNBC). The biological basis for these disparities remain elusive. Mounting evidence points to an important role for stem cells in breast cancer, and studies have shown that normal mammary stem cell number is associated with genetic and environmental risk factors. These findings suggest that differences in stem cells may influence breast cancer incidence, survival, and even racial disparities in cancer. The goal of this study was to characterize differences in normal breast stem cell biology between women of African and European ancestry to provide insight into the potential role of stem cells in breast cancer disparities. Breast punch biopsy samples from healthy, nulliparous women were obtained from the Susan G. Komen normal tissue bank and matched on age, BMI, and days since last period. 8 African American (AA) and 8 European American (EA) tissues were successfully established in conditional reprogramming (CR) culture conditions which induce rapid expansion and dedifferentiation of primary cells. All established samples were profiled using single-cell RNA sequencing (drop-seq) in order to characterize differences in cell type proportions and cell states. Unbiased clustering revealed that post-CR, cells both mix and form distinct clusters by individual and by race. All samples retained luminal and myoepithelial mammary cell populations which varied greatly by individual, with AA samples having a higher overall proportion of myoepithelial cells. AA samples were enriched for an embryonic stem cell gene expression signature, particularly in the myoepithelial population. Comparing gene expression between AA and EA samples revealed 135 differentially expressed genes (DEGs) in the luminal population alone, 276 DEGs in the myoepithelial population alone, and 41 overlapping DEGs in both populations. Of particular note are *S100A11* and *KRT17*, found to be higher in AA myoepithelial cells and known to be involved in differentiation and proliferation. Ongoing work is assessing the response of these cells to environmental stressors. We report that normal mammary cells from AA and EA women have differences in cell type proportions, transcriptomic profiles, and stem cell gene expression. These findings provide new insights into how differences in normal stem cell biology may impact breast cancer disparities.

PS 2076 Generation of iPSC-Derived Basal Cells and Differentiation into a Pseudostratified Lung Airway Model on Air-Liquid Interface

I. Djidrovski, C. Brown, and L. Armstrong. *Newcells Biotech Limited/ Newcastle University, Newcastle upon Tyne, United Kingdom.*

The conducting airways of the lungs are constantly exposed to the damaging effects of pollutants, gasses and nanoparticles (NM) present in the atmosphere. Various chemical compounds used as medication can also have an adverse effect on the respiratory system. It is of particular interest to understand and model those interactions as part of risk assessment evaluations in the process of drug discovery. Current *in vitro* models rely on the availability of primary lung epithelial cells or the use of immortalized cell lines, which poorly represent human biology, highlighting the need for a better model system. In3 project (Marie Curie - ITN) is a collaboration between industry and academia with a common goal of development and utilisation of *in vitro* and *in silico* tools for human chemical and NM safety assessment. Our objective is to utilise iPSC technology and generate a conducting airway epithelium model that would then be used with the in3 chemical compound set for mechanistic and kinetic analysis. We have developed a new strategy to isolate iPSC-derived basal like cells of high purity from a mixed population of lung progenitors by integrating several approaches used in primary bronchial airway cell culture. Those cells are positive for lung basal cell markers cytokeratin 14, NGFR, Integrin alpha 6 and ΔNp63 and can be expanded for several passages while maintaining their multipotency. When those cells were differentiated on an air-liquid interface, they formed tight junctions and a structured pseudostratified epithelium, strikingly similar to *in vivo* like airway. The iPSC derived airway-contained functional basal cells, goblet cells, club cells and ciliated cells, confirmed by immunohistochemistry. A mucus layer was formed on the apical side and beating cilia could be observed on bright field microscopy. Preliminary exposure to chemicals relevant for inhalation toxicology gave us encouraging results: the cells were treated with chemicals such as cigarette smoke condensate, cerium oxide nanoparticles, busulfan and others for 24h and the activation of toxicological pathways was assessed by qPCR. This is the first functional iPSC derived lung airway model on an air-liquid interface, which offers many advantages over the alternative existing models which is very exciting, further characterisation will help us understand the full potential of the model for toxicology and drug discovery.

PS 2077 An *In Vitro* Bronchosphere Model to Assess Respiratory Toxicity

W. Liu[1,2], X. Mei[1], A. Crews[2], K. Cheng[2], and K. B. Adler[2]. [1]*Dalian University of Technology, Dalian, China; and* [2]*North Carolina State University, Raleigh, NC.*

In vitro model systems to assess potential toxicity of pollutants such as diesel exhaust and nanoparticles in the respiratory tract are limited to primary airway or lung epithelial cells and non-differentiated, often cancer-derived, cell lines. The purpose of the studies described here was to develop a more representative model of human airways utilizing airway basal cells which take on a 3D structure, called "bronchospheres" when maintained in a gel matrix, allowing for high throughput toxicity screening of chemicals/particles. Furthermore, the culture conditions were optimized to improve the differentiation of basal cells to goblet/ciliated cells, which is crucial for unraveling the adverse effects of pollutants on the resiliency and homeostasis of the lung airway. Normal human bronchial epithelial basal cells were purchased and cultured/expanded through 3 passages using standard methods. Passage 2/3 cells were seeded in Matrigel® with medium optimized for their differentiation. After 14 days, these cells formed spheroids with a clearly-observable lumen, accompanied by the apoptosis of cells in spheroid interior. Furthermore, gene expression of markers for goblet cells, *MUC5B*, and that for ciliated cells, *FOXJ1*, were detected in Day 14 bronchospheres, with their absence of expression in the basal cells. Passage 2 and 3 cells had similar if not identical responses to these conditions, with number and size of the bronchospheres essentially identical for each. Initial seeding density of the cells was optimized at 2400

cells/cm^2. These bronchospheres, with a 3D structure, could represent an improved *in vitro* model system to more accurately reflect the *in vivo* responses of these cells to inhaled deleterious substances. When further developed and validated, they could provide a robust high throughput method for screening for toxicity of chemicals/particles, as well as for facilitating mechanistic study on the association between environmental pollution and lung disease, and eventually reduce/replace the use of *in vivo* animal studies for such testing.

2078 Human Induced Pluripotent Stem Cell (hiPSC)-Derived Retinal Model Containing Microglial Cells as a Platform for Toxicology Studies

V. Chichagova[1], M. Georgiou[2], M. Carter[2], B. Dorgau[1], C. Brown[1], E. Sernagor[2], L. Armstrong[1], and M. Lako[2]. *[1]Newcells Biotech Limited/ Newcastle University, Newcastle, United Kingdom; and [2]Newcastle University, Newcastle, United Kingdom.* Sponsor: C. Brown, International Society for the Study of Xenobiotics

Microglia (MG) are the primary tissue resident immune cells in the retina. They are essential for normal development by regulating neuronal survival and synaptic pruning. In the adult retina, they regulate homeostasis by maintaining synaptic structure and function. Under pathological conditions, MG can mediate adaptive responses within the retina following injury. In addition, MG can trigger neurodegeneration exacerbating the effect of the disease making it a potential therapeutic target. Retinal organoids (RO) derived from hiPSCs provide a human physiologically relevant platform to study retinal development, disease modelling and compound screening. However, due to the differences in their developmental origins, MG and retina do not arise under the same differentiation conditions. We developed a differentiation protocol for deriving MG from hiPSCs. The cells expressed key developmental markers CX3CR1 and IBA1. In addition, they were functional with >90% of cells phagocytosing fluorescent beads. In parallel, we differentiated hiPSCs to RO using our established protocol. We assessed their development by confirming the expression of key markers, including Recoverin, HuC/D, AP2α and Prox1. To enhance our retinal model, we incorporated hiPSC-derived MG and tested their retinal invasion capacity and function in response to agents causing retinal degeneration, namely chloroquine and moxifloxacin; and lipopolysaccharide (LPS) that is known to initiate pro-inflammatory response. Our results showed that LPS and chloroquine treatment led to an increased secretion of pro-inflammatory and chemotactic factors. LPS increased secretion of IP-10 from 59.2 ± 1.5 to 108.4 ± 5.05; MIP-1α from 37.0 ± 1.9 to 129.6 ± 1.4; MIP-1β from 83.6 ± 2.3 to 170.5 ± 11.6; and IL-6 from 1.4 ± 0.1 to 4.3 ± 0.2 (pg/ml). Treatment with chloroquine increased secretion of MIP-1α from 37.0 ± 1.9 to 82.6 ± 6.6 and MIP-1β from 83.6 ± 2.3 to 121.9 ± 4.7 (pg/ml). Moxifloxacin treatment did not induce an increase in cytokine release which is in line with its role in reducing MG activation and having an anti-inflammatory effect. Our results confirmed that MG cells co-cultured with RO are able to respond to known toxins and stimulants thereby providing a tissue structure with greater physiological relevance to the *in vivo* human retina which can be used for compound screening and disease modelling.

2079 Highly Prescribed Antipsychotics Perturb Cholesterol Biosynthesis in hiPSC-Derived Human Cortical and Dopaminergic Neural Precursors

J. Kim, H. Kim, K. Tallman, M. D. Neely, and N. Porter. *Vanderbilt University, Nashville, TN.*

Smith-Lemli-Opitz syndrome (SLOS) is a rare, autosomal recessive developmental disorder whose phenotype encompasses a wide spectrum from craniofacial malformations to severe intellectual disability. SLOS patients carry mutations in the gene that codes for 7-Dehydrocholesterol reductase (DHCR7), an enzyme that converts the highly oxidizable lipid 7-dehydrocholesterol (7-DHC) to cholesterol, and thus these patients present with elevated 7-DHC/Cholesterol serum ratios. Both preclinical and clinical evidence has established unimpaired DHCR7 function as essential for proper neurodevelopment, as an accumulation of 7-DHC has been reported to negatively affect neuronal differentiation, proliferation, and viability. Recent studies have demonstrated that highly prescribed antipsychotics such as Aripiprazole and Cariprazine have off-target inhibitory effects on DHCR7 and lead to elevated 7-DHC levels *in vitro* models and in sera of patients on these medications. To determine the impact of these and similar compounds on early human neurodevelopment, we assessed their effects on cholesterol biosynthesis precursor profiles in human-induced pluripotent stem cell (hiPSC)-derived neural precursors (NPCs). hiPSC-derived day 13 cortical and dopaminergic NPCs were exposed to increasing concentrations (1-1000 nM) of Aripiprazole and Cariprazine for 48 hours. Lipid extracts were analyzed via Liquid Chromatography-tandem Mass Spectrometry (LC-MS-MS). Both cortical and dopaminergic cultures exposed to Aripiprazole and Cariprazine demonstrated a dose-dependent increase in DHCR7 substrates and a corresponding decrease in DHCR7 products. Cariprazine potently inhibited DHCR7 at the lowest dosage (1 nM), a significant finding as plasma concentrations of the drug and its metabolites can persist above 100 nM for many months in humans. Interestingly, while the small molecule inhibitors dramatically altered sterol profiles, no cytotoxicity was observed at any dosage. These findings support the hypothesis that perturbed cholesterol biosynthesis may mediate the teratogenic effects of prenatal exposures to antipsychotics, especially as similar cholesterol precursor profiles are observed in SLOS, a developmental disorder affecting the very same enzyme.

2080 Assessing DDT/DDE in Alzheimer's Disease Pathways in Human Stem Cell-Derived Neurons Carrying APOE Gene Variants

A. D. Morris[1], A. Eid[2], J. R. Richardson[2], and R. P. Hart[1]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; and [2]Florida International University, Miami, FL.*

The E4 allele of the Apolipoprotein E (*APOE*) gene contributes the greatest single genetic risk for late-onset Alzheimer's disease (LOAD), but it is also affected by factors including age and environmental exposure. The pesticide dichlorodiphenyltrichloroethane (DDT) has been identified as a risk factor for LOAD due to its persistent bioaccumulation and elevated serum levels of the DDT metabolite, dichlorodiphenyldichloroethylene (DDE) of AD patients even after it was banned in the US over forty years ago. Previous results found that there were significant interactions between serum DDE levels, *APOE* genotype and cognitive dysfunction, with *APOE* E4 genotype and higher DDE levels being associated with worsened cognitive function. Mechanistically, our previous experiments found significant increases in amyloid precursor protein (APP) levels in differentiated SH-SY5H cells and primary mouse hippocampal neurons after DDT/DDE exposure. To quantify this relationship in human neurons, an appropriate model system needs to be generated. We prepared induced excitatory neurons (iNs) by reprogramming two isogenic induced pluripotent stem cell (iPSC) lines, a heterozygous APOE E3/E4 and an engineered line carrying frameshift mutations in both alleles (APOE-null). A 24 hour treatment of APOE-null neurons with 1 μM DDT increases APP levels on Western blots by approximately 50% compared with vehicle control. To test interaction with APOE, neurons will be cultured in the presence of conditioned medium containing APOE-e2, e3, or e4 and/or oligomeric amyloid beta collected from lentiviral-transduced HEK293 cell lines to mimic conditions of Alzheimer's disease. Utilizing this novel human neuron model, we examine direct effects of DDT and DDE on neuronal function and indirect effects on AD markers. The combination of electrophysiologically-mature human neurons, addition of APOE and/or amyloid toxic signals, and environmental toxicants such as DDT/DDE represents a novel approach to modeling AD.

2081 Development of a Workflow for Multi-Modal Assessment of Functionally Matured Human iPSC-Derived Cardiomyocytes Using Calcium Imaging and Impedance Readout

X. Zhang, M. Hong, and Y. A. Abassi. *Agilent Technologies Inc., San Diego, CA.*

Non-cardiac drug induced functional changes in cardiomyocytes are one of the common causes of attrition during preclinical and clinical drug development. Therefore, understanding drug-mediated modulation of cardiac electrophysiology and contractility, which are important hallmarks of cardiomyocyte function are critical from both a therapeutic as well as safety/toxicity angle. Even though human iPSC-derived cardiomyocytes (hiPSC-CMs) have been validated as a suitable model for assessment of contraction (Scott C. et al, 2013), their fetal-like phenotypes, such as immature contractile apparatus and the calcium handling mechanisms have hampered full utilization. In order to address this limitation, we developed a workflow where long-term electrical pacing was applied using the xCELLigence RTCA e*Pacer* to enhance functional maturity of hiPSC-CM (paced cardiomyocytes), as assessed by reversal of negative force-frequency relationship, a hallmark of immature phenotype of hiPSC-CMs. The paced cardiomyocytes were then treated with a panel of contractile modulators, including both positive and negative inotropic compounds with different mechanisms of action and assessed for calcium dynamics via calcium sensitive dye and for contractility via impedance, respectively. Our data shows that isoproterenol, milrinone and BayK 8644, which are positive inotropic compounds increased the force of contraction by mobilizing calcium and significantly increasing the amplitude of calcium transient (Ca-Amp) and impedance/beating amplitude (B-Amp) in paced car-

diomyocytes but not in non-paced (CTRL) cells. Omecamtiv mecarbil (OM), a positive inotrope increased cardiac contractility as measured by impedance but did not show any impact on intracellular calcium concentration in both paced and non-paced cardiomyocyte. Isradipine, a L-type calcium channel blocker and negative inotrope, decreased both Ca-Amp and B-Amp in both paced and non-paced cells. In summary, our data suggests that chronically paced hiPSC-CMs could be a more improved model system for cardiac contraction assessment compared to standard (non-paced) hiPSC-CMs. The combination of calcium transient and impedance readout for cardiac contractile assessment can provide more mechanistic insights for drug induced changes to cardiomyocyte function.

PS 2082 Toxicological Assessment to Pain-Related Compounds in Cultured Human iPS Cell-Derived Sensory Neurons Using CMOS-MEA System

A. Odawara, N. Matsuda, Y. Ishibashi, and I. Suzuki. *Tohoku Institute of Technology, Miyagi, Sendai, Japan.*

Electrophysiological assessment using human induced pluripotent stem cell (hiPSC)-derived sensory neurons are expected to predict the pain-related toxicity of drugs and the *in vitro* alternatives to reduce the number of animal tests. In this study, we aimed to evaluate the electrophysiological responses against pain-related molecules including anti-cancer drugs in cultured hiPSC-derived sensory neurons using multi-electrode array (MEA) and CMOS-MEA with high temporal and spatial resolution, in which is possible to measure axon and dendrite conduction velocity of single neuron. hiPSC-derived sensory neurons were cultured on MEA and CMOS-MEA chips, and the electrophysiological evoked responses against capsaicin, menthol, AITC, anti-cancer drug oxaliplatin were detected dose dependently. We also confirmed that these responses are the responses via TRPV1, TRPM8, and TRPA1 receptors. The responses to oxaliplatin are consistent with *in vivo* report. We also detected the change of axon conduction velocity and identify the neurons having high sensitivity reaction. MEA and CMOS-MEA measurement coupled with hiPSC-derived sensory neurons is useful to assessment to pain-related compounds.

PS 2083 Prediction Methods for Seizure Liability and MoA of Drugs Based on the Electrophysiological Activities of hiPS Cell-Derived Neurons

Y. Ishibashi, N. Matsuda, A. Odawara, R. Yokoi, and I. Suzuki. *Tohoku Institute of Technology, Sendai, Miyagi, Japan.*

Human iPSC-derived neurons are expected to be applied to toxicity evaluations in nonclinical studies and drug screening. Microelectrode array (MEA) measurement system is suitable to evaluate the neuronal electrophysiological responses to drugs. We have previously reported the electrophysiological responses to convulsants using MEA in cultured hiPSC-derived neurons. In this study, we aimed to develop an analytical method enabling the evaluation of toxicity and the classification of MoA of convulsants using multivariate analysis and deep learning. hiPSC-derived cerebral cortical neurons were cultured on Micro-electrode array (MEA) plate, and the pharmacological responses over 10 drugs in spontaneous firings were obtained. We identified the parameter sets that can separate the responses between convulsive and negative control drugs, and the responses among the several convulsants with different action mechanism using principal component analysis. In principal component analysis and clustering method using the identified parameter set method will be effective for detecting convulsive response and predicting MoA of convulsive drugs. We also constructed the raster plots of spontaneous firing and the divided image data. The 4096 feature vectors of the divvied image data in raster plots were extracted by pre-trained model. Next, CNN model was trained with feature vectors each drug name. Using this trained CNN model, we have succeeded in separating the responses between non-convulsive drugs and convulsants, and classifying the MoA of convulsants. These multivariate analysis and deep learning methods are useful for the prediction of seizure liability and the classification of MoA of new drugs.

PS 2084 Altered AhR Signaling Disrupts the Expansion and Differentiation of Hematopoietic Stem and Progenitor Cells

K. L. Vaughan, A. M. Franchini, H. G. Kern, and B. Lawrence. *University of Rochester, Rochester, NY.*

Hematopoietic stem cells (HSCs) give rise to all the cells of the blood and immune system. HSCs balance between self-renewal and differentiation in order to not only sustain homeostatic cell production, but also respond to stressors such as infection or injury. In response to environmental signals, HSCs proliferate and differentiate into multipotent progenitors (MPPs), with different MPP subtypes biased toward particular lineages. Yet, how environmental signals direct HSC transition to MPPs and influence lineage biasing are not fully understood. Growing evidence indicates that the aryl hydrocarbon receptor (AhR), an environment sensing transcription factor, regulates HSCs. For instance, HSCs from mice lacking AhR have an increased rate of proliferation. Additionally, mice lacking AhR have a greater proportion of mature myeloid cells. We hypothesize that the AhR regulates hematopoiesis by controlling HSC self-renewal, and also directs differentiation towards specific lineage-biased progenitors. We show that *in vivo* antagonism of AhR in mice using CH-223191 decreased the proportion of HSCs. Treatment with CH-223191 also increased the proportion of myeloid-biased MPPs (MPP3s). Using *ex vivo* colony forming unit (CFU) assays, *in vivo* treatment with CH-223191 promoted greater myeloid biased differentiation. Concomitant with HSC proliferation in response to stressors, *AhR* expression is downregulated. To further define the role of *AhR* downregulation, we utilized inducible global AhR knockout mice and found that they had a greater frequency of HSCs and MPP3s. In addition to signals from the hematopoietic compartment, hematopoiesis is regulated by bone marrow niche cells. To determine if the AhR affects HSCs and MPPs intrinsically or via signals from non-hematopoietic cells we utilized hematopoietic-specific conditional AhR knockout mice. Mice lacking AhR in the hematopoietic compartment had a greater frequency of HSCs and also a significant increase in myeloid biased progenitors. These findings indicate that the effects observed were due to changes intrinsic to the hematopoietic compartment. These findings implicate the AhR in the regulation of hematopoiesis by controlling HSC expansion and lineage biasing. This provides further insight into the factors that control steady state hematopoiesis and how hematopoietic stem and progenitor cells respond to environmental factors.

PS 2085 Deconvolution Algorithm Applied to RNA-seq Data Reveals Genetic Heterogeneity in the Differentiation of Induced Pluripotent Stem Cells (iPSC) Derived from Collaborative Cross Recombinant Inbred (CCRI) Mice into Fetal Liver

D. Botta[1], L. Wang[1], L. A. Lewis[2], C. C. White[1], P. L. Stapleton[1], J. L. Popp[2], L. C. Farris[2], R. M. Lynch[2], T. K. Bammler[1], E. M. Faustman[1], I. Rusyn[2], D. W. Threadgill[2], and T. J. Kavanagh[1]. *[1]University of Washington, Seattle, WA; and [2]Texas A&M University, College Station, TX.*

Hepatocyte-like cells (iHeps) can be differentiated in culture from induced pluripotent stem cells (iPSCs) providing a useful tool for investigating a wide variety of liver associated pathologies. Since genetic differences in the population complicate the interpretation of toxicological study results we chose to use the Collaborative Cross (CC) mouse resource. Composed of 8 genetically extant founder lines that have been intercrossed for multiple generations to derive recombinant inbred (CCRI) mouse lines that breed true, CCRI iPSCs provide the opportunity to conduct genetically diverse studies *in vitro*. We previously showed that 3 independent CCRI iPSC lines differentiated to iHeps showed significant heterogeneity in phenotype and gene expression. Transcriptomes of these lines were analyzed at 3 time points during their differentiation using RNAseq with RT-PCR validation of selected genes. To further elucidate differentiation trajectories, we applied the multi-subject single cell deconvolution (MuSiC) algorithm and the mouse organogenesis single cell atlas (MOCA) to determine which cell types and trajectories were likely present in our cultures. For purposes of comparison, we focused on three cluster types in the MOCA data set: main cell types, main trajectories, and sub-trajectories, to estimate the proportions of each of these cluster types found in CCRI iHep bulk RNAseq data. Five main cell types were identified: stromal, erythroid, endothelial, and to a much lesser extent, hepatocytes. Trajectories recognized were haematopoiesis, endothelial, epithelial, hepatic, early developmental mesenchyme and glial neural crest. Although all three iPSC cell lines follow the same differentiation patterns there is variation among them especially in the haematopoiesis trajectory. These results suggest that this is a model for early fetal liver differentiation that includes blood forming elements naturally present in fetal liver. This CCRI iHep model system will be

useful for investigating the genetic bases of xenobiotic-induced fetal liver damage, including the genesis of blood disorders and potentially, childhood leukemia. *Supported by NIH P30ES007033, P30ES029067 and R01ES029911.*

2086 Development of a Murine Liquid Culture Bone Marrow Assay Using a High Content Analysis Platform

J. Price, D. Bounous, and M. Davis. *Bristol-Myers Squibb Company, Princeton, NJ.*

Adverse hematological effects are frequently encountered and dose limiting for many drug therapies. The colony forming assay is valuable tool to assess and evaluate the hematopoietic adverse effects of compounds on bone marrow. The assay makes it possible to study both the proliferation and differentiation of hematopoietic stem cells and their progenitor cells however it is time and resource consuming. The murine CFU-GM assay has been validated to predict a drug candidate's potential toxicity, exposure levels & dose limitations in humans. The aim of the study was to develop a liquid culture based high throughput assay using the Thermo Scientific CellInsight CX7 High-Content Screening Platform to enable the study of both proliferation and differentiation. 17 compounds with in-house and/or published murine CFU-GM results were chosen for validation. Hydroxyurea, Didox, Busulfan, Bleomycin, Camptothecin, Topotecan, Zidovudine (AZT), Doxorubicin, Bortezomib, Paclitaxel (Taxol), 5-Fluorouracil, Melphalan, Etoposide, Cisplatin, Sunitinib, Flavopiridol and Clozapine. Characterization and optimization of the culture was further assessed using DAPI, F4/80, GR-1 (Ly-6G/Ly-6C), CD11b and/or C-kit. The assay was validated using the CX7 platform with a live/dead cell endpoint. IC50 values were obtained by using the CX7 spot detector protocol on the green (live) channel. IC50 values were calculated with GraphPad using a four parameter logistic regression model. Pearson correlation coefficient (r) and p values were calculated for all compounds. There is a strong positive (r values >0.8) correlation relationship between the published/in-house CFU assay and the liquid culture endpoint. The liquid culture assay is a suitable high throughput alternative to the resource consuming CFU assay in identifying bone marrow liabilities.

2087 Developing a Human Embryonic Stem Cell-Based High-Throughput Platform to Screen for Developmental Toxicants

Y. Chen[1], E. J. Tokar[1], and S. Birla[2]. *[1]NIEHS/DNTP, Research Triangle Park, NC; and [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Every year, millions of infants worldwide are born with a serious birth defect, which raises the risk for lifelong disabilities to those who survive and increases the economic burden to their families and society. Besides genetic or hereditary factors, many of these defects can be caused by environmental chemical exposure, such as alcohol, smoking, and drugs. While there are over 80,000 chemicals registered for use in the United States, many of them have undergone little safety testing. Therefore, a rapid and accurate method for predicting developmental toxicants in the environment to humans is strongly desired. Pluripotent human embryonic stem cells (hESCs) possess the capacity to differentiate into any cell type which makes them an ideal *in vitro* model to investigate developmental toxicity. In this study, we aim to develop a transcriptomic-based high-throughput platform using hESCs to screen for environmental teratogens. Three-dimensional embryoid bodies (EBs) formed from hESCs were used as the model since its formation recapitulates many early embryogenic processes. 108 selected chemicals were first administered to EBs for 7 days to evaluate their toxicities. As the result, 64 impaired EB cell viability in a dose-dependent manner, 7 increased cell viability at high concentrations, while the remaining 37 showed no effect on EB formation within the tested concentration range. Next, the impacts of 23 chemicals on key embryogenesis signaling pathways and germ layer formation were investigated by measuring the expression of 37 hallmark genes of these processes. Hierarchical cluster analysis based on the transcriptional response change showed the ability to group chemicals with similar toxicity. For a more accurate categorization, a machine learning based prediction model was built. 10 chemicals with confirmed teratogenicity from TERIS (Teratogen Information System) were selected as the training controls. With recursive feature elimination, our model showed a high accuracy (mean: 0.82) and reliability (mean: 0.70) and the prediction results for the other 13 tested chemicals were similar with the findings from existing studies, with few discrepancies. Together, these results indicate that our screening platform could be successfully applied for identifying developmental toxicants and understanding their etiology.

2088 Capturing Drug-Induced Structural Changes in Images of Live Cells Using a Novel Deep Learning Method

M. Maddah[1], K. Dame[2], K. Loewke[1], and A. Ribeiro[2]. *[1]Dana Solutions LLC, Palo Alto, CA; and [2]US FDA, Silver Spring, MD.* Sponsor: R. Rouse

There has been significant progress in using cells differentiated from human induced pluripotent stem cells (hiPSCs) for modeling of human disease and for screening drug toxicity and efficacy. hiPSCs differentiated into specific lineages can represent human- and organ-specific properties for preclinical predictions of drug effects, including toxicity. To predict structural toxicity *in vitro*, cellular structures can be imaged using high-content microscopy, and image analysis algorithms used to generate quantitative measurements that relate to cell degradation or death, such as change in signal intensity or nuclear count. Such measurements do not typically capture subtle structural changes that are not easily visualized or are too complex to formulate with traditional image analysis and are rarely amenable to live-cell brightfield imaging. We have developed a novel method, PhenoTox, that uses deep learning for quantifying structural changes in cell-based models. The inputs are a collection of cellular images captured at multiple doses for the drugs of interest and a reference set of images with only the vehicle applied. Through the process of training 2-class deep neural networks, the system learns on its own what features within the images, if any, reflect structural changes. The output is a metric of structural change for each drug dose relative to the reference. Our technology introduces a new approach for structural toxicity testing that provides a high level of sensitivity that has not previously been possible. Our proposed method is agnostic to imaging modality and works for fluorescence images as well as bright-field images, enabling drug testing in live cell cultures. We present data from experiments using hepatocytes differentiated from hiPSCs in live cell cultures. Multiple doses of tamoxifen and doxorubicin (hepatotoxins) as well as aspirin and acetylcysteine (negative controls) were applied. Brightfield images were captured every 3 hours for 2 days using the IncuCyte imaging system. The time-lapse imaging data was analyzed with PhenoTox. Our method detected dose-dependent morphological changes caused by tamoxifen and doxorubicin over time and showed better sensitivity than a caspase-3/7 apoptosis assay. No significant structural change was detected for either aspirin or acetylcysteine.

2089 Human Induced Pluripotent Stem Cell Fluorescent Protein Reporter Lines for Dissecting Lineage-Specific Cellular Stress Response Dynamics Using High Content Imaging

K. E. Snijders[1], B. ter Braak[1], L. van den Berk[1], M. Niemeijer[1], A. Fehér[2], J. Kobolák[2], M. Kumar[3], R. Van Rossom[3], A. Wilmes[4], P. Jennings[4], C. Verfaillie[3], A. Dinnyés[2], and B. van de Water[1]. *[1]Universiteit Leiden, Leiden, Netherlands; [2]BioTalentum Ltd., Gödöllő, Hungary; [3]Katholieke Universiteit Leuven, Leuven, Belgium; and [4]Vrije Universiteit Amsterdam, Amsterdam, Netherlands.*

Cellular stress responses are critical for the repair of injured cells during diverse types of tissue damage, under pathological conditions as well as adverse responses to drug exposures. Targeting cellular stress response activation can contribute to cellular fitness and resilience to stress conditions. We established a reporter platform using fluorescent tagging of human induced pluripotent stem cells (hiPSCs) to visualize the dynamics of various cellular stress pathways on a single cell level. Both endogenous and scar free tagging was achieved using CRISPR/Cas9 technology, resulting in the maintenance of a representative cellular stress response *in vitro*. HiPSCs are an excellent model for *in vitro* safety screening since they rapidly divide, have undisrupted metabolic activity and can be differentiated into a whole range of cell types. This overcomes many of the limitations found in current *in vitro* models such as availability, inter-donor variability and stability. In order to dissect lineage specific oxidative stress response dynamics upon chemical exposure we differentiated oxidative stress hiPSC reporters, HMOX1-GFP and SRXN1-GFP, into different lineages including hepatocytes, cardiomyocytes, neuronal cells and kidney cells. The various differentiated cells were exposed to different oxidative stressors, CDDO-Me, diethyl maleate and paraquat followed by live cell imaging of the reporter activation using automated high content confocal imaging (HCI). We found large cell type dependent differences in amplitude of the oxidative stress response as well as the dynamic profile as a whole. This provides insights into organ specific sensitivity and dynamics towards chemically-induced oxidative stress response signaling. We anticipate that our hiPSC cellular stress response reporters in combination with HCI may play a key role for refined understanding of the dynamic stress response signaling in diverse target tissues under adverse drug reactions.

2090 Concentration-Dependent Toxicogenomic Changes of Silver Nanoparticles in Hepatocyte-Like Cells Derived from Human-Induced Pluripotent Stem Cells

X. Gao, R. Li, R. L. Sprando, and J. J. Yourick. *US FDA, Laurel, MD.*

The widespread application of silver nanoparticles (AgNPs) has raised public concerns about their adverse effects on human health. However, information on their potential toxicity is still limited and sometimes controversial. Liver is one of the major organs where AgNPs accumulate after entering the blood stream. Therefore, *in vitro* models capable of accurately predicting hepatotoxicity of AgNPs are much needed. Primary human hepatocytes (PHHs) and hepatoma cell lines (HCLs) have mainly been employed in the past for *in vitro* hepatotoxicity assessment of AgNPs. The recent advent of hepatocyte-like cells (HLCs) derived from human induced pluripotent stem cells (iPSCs) represents an attractive alternative *in vitro* liver model. Yet, the use of iPSC-derived HLCs for the study of nanoparticle toxicity has not been reported so far. In this study, we characterized transcriptomic changes induced by varying concentrations (5-25 µg/ml) of AgNPs in HLCs after 24 h exposure. AgNPs caused concentration-dependent gene expression changes in HLCs with increasing numbers of differentially expressed genes (DEGs) at higher concentrations. A total of 179 DEGs was identified at 5 µg/ml; the number increased to 936, 2859, and 4265 at 10, 20 and 25 µg/ml respectively. In all cases, members of the metallothionein (MT) and the heat shock protein (HSP) family were the dominating upregulated genes, suggesting that AgNP exposure induced cellular stresses and elicited cellular protective responses in HLCs. Functional analysis showed that the DEGs were majorly involved in the biological processes of metabolism, response to stress, and cell organization and biogenesis. Ingenuity Pathway Analysis revealed that cancer was at the top of diseases and disorders associated with the DEGs at all concentrations; hepatocellular carcinoma and liver hyperplasia/hyperproliferation were the leading hepatotoxicity responses. These results were in accordance with those reported previously on PHHs and HCLs. Considering the advantages HLCs have over PHHs and HCLs in terms of unlimited supply, consistency in quality, and sustainability of function in long-term culture, the results of the current study suggest that iPSC-derived HLCs may serve as a better *in vitro* model for liver nanotoxicology.

2091 Development of Assay-Ready iPSC-Derived CD34$^+$ Cells, Monocytes, and Mesenchymal Stem Cells

D. Yin, S. P. Jacob, H. Desai, and M. Spencer. *ATCC, Gaithersburg, MD.*

There is an unmet need for highly characterized and reproducible cell models for a wide range of applications including mechanisms of action, drug development, and toxicity testing. Human induced pluripotent stem cells (iPSCs) have the potential to differentiate into all somatic cell types and therefore hold great promise for development into cell models for variety of toxicity applications. Herein, we have developed processes for the scalable generation of iPSC-derived CD34$^+$ cells, monocytes, and mesenchymal stem cells (MSCs). It is well documented that starting cell types and donor background play an important role in the efficiency of iPSCs to terminally differentiated cells. We screened four iPSC lines, three from bone marrow CD34$^+$ cells and one foreskin fibroblast-derived iPSC line, for differentiation into CD34$^+$, monocytes, or MSCs. All CD34$^+$ cell-derived iPSC lines exhibited high efficiency for differentiation into CD34$^+$ cells and MSCs, while the fibroblast-derived iPSC line favored differentiation into monocytes. To assess the differentiation potential of the iPSCs-derived cells, we demonstrated that CD34$^+$ cells could be differentiated into erythroid cells, myeloid cells, and megakaryocytes while monocytes were capable of differentiating into dendritic cells and functionally active macrophages. Compared to primary MSCs, iPSC-derived MSCs exhibited similar immunophenotypes and T-cell suppression properties as well as the ability to differentiate into adipocytes, osteoblasts, and chondrocytes. It can be problematic to obtain sufficient quantities of certain cell types, including CD34$^+$ cells, for high throughput drug screenings. To address cell availability and donor variation issues, we have developed processes for the scalable and reproducible generation of highly pure, functionally active, assay-ready iPSC-derived CD34$^+$ cells, monocytes, and MSCs. Furthermore, we have validated iPSC-derived monocytes for conducting the monocyte activation assay, which can be used as an alternative to the rabbit pyrogen test for biologic drugs. Utilization of CFU-GM assays for myelotoxicity screening is hampered by the low throughput of the assay. We have explored the potential of using iPSC-derived CD34$^+$ for *in vitro* assessment of anticancer drug-induced myelotoxicity. This assay further enhances the wide variety of applications. These highly characterized iPSC-derived cells provide as powerful tools for drug screening and toxicity testing.

2092 Effects of Electrical Stimulation on hiPSC-CMs Responses to Classic Ion Channel Blockers

F. Wei[1], D. Strauss[2], N. Stockbridge[2], and L. Pang[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]US FDA/CDER, Silver Spring, MD.*

Human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) have been widely used to assess the cardiac safety profiles of new drug candidates and hold great potential for personalized cardiac safety prediction, particularly for drug-induced proarrhythmia. However, hiPSC-CMs fire spontaneously, thus, the variable beating rates can be a confounding factor that interferes with data interpretation. Moreover, batch variations of hiPSC-CMs hamper their application for precision medicine. Controlling beating rates with electrical stimulation (E-pacing) or optogenetic pacing may reduce batch and assay variations, enable evaluation of rate-dependent drug effects, and facilitate the comparison of results obtained from hiPSC-CMs with results from adult human cardiomyocytes (CMs). As E-pacing of hiPSC-CMs has not yet been validated with high-throughput assays, herein, we compared the responses of hiPSC-CMs to the challenges of classic cardiac ion channel blockers under spontaneous beating and E-pacing conditions, utilizing the Axion Maestro Microelectrode Array (MEA). The rate-dependent drug effects were examined. Effects of E-pacing on different batches of hiPSC-CMs responses to I_{Kr} channel blockades were also evaluated. We found that compared to spontaneous beating hiPSC-CMs, E-pacing 1) reduced well-to-well, plate-to-plate, and batch-to-batch variabilities; 2) showed limited changes of FPD to I_f blocking; 3) revealed reverse rate-dependence of the responses to I_{Kr}, I_{Ks}, and I_{CaL} channel blockers in repolarization timing; and 4) eliminated effects of I_{Na} blocking on depolarization spike amplitude and spike slope due to the software defect. Optogenetic pacing of hiPSC-CMs showed use-dependent block of I_{Na} as found in adult CMs. In conclusion, pacing reduced batch and assay variations. Analyzing the responses of hiPSC-CMs in both spontaneous beating and pacing conditions may help better assess the effects of test compounds on cardiac electrophysiology and weigh the value of the hiPSC-CMs model for cardiac safety assessment.

2093 Simultaneous Assessment of Oncology Compound Efficacy and Toxicity in a Neuronal Human Induced Pluripotent Stem Cell and Glioblastoma-Based High-Throughput Screening Platform

R. Padilla, A. Fanton, C. Carromeu, O. Guicherit, C. Andersen, and F. Zanella. *StemoniX, La Jolla, CA.*

Glioblastoma Multiforme (GBM) are aggressive brain tumors with poor prognosis. Therapeutic management for GBM is currently limited; with Temozolomide currently being the standard of treatment for GBM. However, even when combined with radiotherapy only up to 20 percent of patients show favorable response to Temozolomide. Importantly, due to their requirements for potency and efficacy, oncology drugs often display appreciable toxicity profiles. In this study, the U87 GBM cell line was tagged with mCherry to serve as a traceable model for GBM. To study their growth behavior in a physiologically relevant system amenable to drug discovery, U87-mCherry cells were co-cultured with human induced pluripotent stem cell-derived cortical neurospheroids in a high throughput based screening platform. The neurospheroids are composed of a balanced co-culture of cortical neurons and astrocytes with mature functional neuronal circuitry evidenced by spontaneous calcium oscillations. Previously, this neurospheroid model has been successfully utilized in independent neurotoxicity and drug discovery studies. Thus, by combining U87-mCherry and the high throughput neurospheroids, the proliferation and infiltration patterns of the GBM cells as well as the preservation of cortical functionality can be analyzed within the same high throughput platform. Proof-of-principle studies focused on Temozolomide, Carmustin, Paclitaxel and Cisplatin to identify and profile compound efficacy versus their toxicity with the ultimate goal of providing a platform that can separate safe and effective compounds from those that have minimal efficacy and deleterious toxicity. Interestingly, Cisplatin seemed able to impact the proliferation and survival of the GBM cells, however it did cause detectable toxicity seen as impact in neuronal functionality. Tomozolomide did not cause neurotoxic effects, however it also did not impact the proliferative and invasive behavior of the GBM cells. The effects of Carmustine and Paclitaxel were unremarkable at the concentration ranges tested in this study. In summary, the work described herein suggests a novel framework approach for combining human induced pluripotent stem cell-derived cortical neurospheres with GBM, enabling more streamlined drug discovery of compounds against aggressive brain cancers.

2094 Validation of a qPCR Assay for Human Cell Biodistribution Assessment in Rat Tissues

A. Rogue[1], M. Glaran[1], P. Singh[1], P. Ancian[1], and M. Koga[2]. [1]*Charles River, Evreux, France; and* [2]*KM Pharmaceutical Consulting LLC, Washington, DC.*

Cell therapies today hold enormous promise for treating many diseases. Determination of the fate of the human cells following administration in a nonclinical species can contribute to the assessment of its safety profile for investigational cell therapies. This can be achieved using quantitative polymerase chain reaction (qPCR). Successful qPCR assay validation requires careful scientific support as no regulatory guidance exists for the analytical validation for this assay type. We validated a qPCR assay based on specific detection of the human AluY repeat sequence corresponding to primate-specific short interspersed elements that represents 6-13% of the haploid genome. A fit-for-purpose assay validation approach was thus used, taking into account the validation parameters in the bioanalytical method validation guideline. Assuming that a human cell contains 7.0 pg of DNA, the calibration curve ranged from 1 to 2857 human genomes per µg of rat DNA, corresponding to ~1.5×10^5 rat genomes. The maximal CV% values of the within- and between-run precision were 9.9 and 7.7%, respectively. The qPCR assay displayed high accuracy with maximal RE% of 14.8%, and a very low limit of detection (6.5×10^{-3} human genomes per µg of rat DNA). The qPCR assay was linear, with a range from 0.02 to 1 µg of rat DNA. Assay selectivity, specificity and matrix effect were evaluated in a series of qPCR experiments on rodent genomic DNA spiked or not with known amounts of human reference genomic DNA. The qPCR detection assay was found to be selective and specific in DNA from rat tissue and without a significant matrix effect. DNA extraction yield and stability in homogenates from rodent tissues were also evaluated. The DNA extraction process was considered as acceptable, except for blood and testes (sub-optimal yields). Cell stability in blood and tissue homogenates was demonstrated for up to 27 weeks at -80°C. This fit-for-purpose assay validation demonstrated that this qPCR assay displays adequate performance and a high sensitivity for quantitation of human cells in rodent tissues within the framework of a cell therapy biodistribution study.

2095 Statistical Modeling for Predicting Subacute Hepatotoxicity Induced by Distinct Surface Charged ZnO Nanoparticles in a Swiss Albino Murine Model

N. Dhiman[1,2], A. K. Srivastav[1], S. K. Mishra[1], M. Kumar[1], D. Ghosh[1], and S. Patnaik[1]. [1]*CSIR-Indian Institute of Toxicology, Lucknow, India; and* [2]*AcSIR, Lucknow, India.* Sponsor: S. Yadav

Nanoparticles (NPs) interacts with biological molecules such as proteins, cell membranes, and nuclear material in a multi-pronged interfaces dictating their biological outcomes. This NPs/biological interfaces predominantly depends on colloidal forces as well as dynamic physico-chemical properties of NPs. These interactions were governed by size, solubility, shape, surface area, and surface chemistry of the NPs. In present study, we examined the role of surface charge to elicit the charge dependent hepatotoxicity of commercial zinc oxide NPs (ZnO) in murine model, Swiss Albino mice to probe the mechanistic role of surface charges of NPs on its toxicity outcome. Three specific ZnO NPs,neutral, positive and negatively charged particles were prepared by suitable coating with natural polymers (guar gum, chitosan and alginate respectively). These engineered ZnO NPs were characterized by advance spectroscopic and microscopic tools. NPs ionization study was performed in Milli Q, neutral PBS, gastric pH, lysosomal pH, and FBS to assess the impact of medium on degree ionization. The induced hepatotoxicity and bio-availability of different surface coated ZnO NPs have been tested in the mice model at dose level of 10, 50 and 300 mg/kg after sub-acute oral treatment. The dose, surface charges and time dependent hepatotoxicity of NPs based on biochemical parameters (AST and ALT) were evaluated by using multivariate optimizing Response Surface Methodology (RSM). ANOVA indicated appropriateness of the model for predication of hepatotoxicity owing to "Prob. >F" less than 0.05 for variable parameters. At RSM predicted optimal condition, positive charged NPs at the dose of 300 mg/kg showed higher toxicity than other groups. RSM models were validated using the method of cross-validation. Additionally the induction of ROS and histopathological lesions in liver were also support the RSM prediction.

2096 Inhalation Exposure to Cellulose Nanocrystals: Study of Pulmonary and Reproductive Outcomes in Male Mice

A. A. Shvedova[1,2], E. R. Kisin[1], N. Yanamala[1], M. Farcas[1], S. Guppi[1], W. McKinney[1], D. Gutkin[3], M. R. Shurin[3], and V. E. Kagan[3]. [1]*NIOSH, Morgantown, WV;* [2]*West Virginia University, Morgantown, WV; and* [3]*University of Pittsburgh, Pittsburgh, PA.*

Cellulose(s) are bio-based lightweight natural materials with high aspect ratios, excellent physical strength, transparency and chemical resistance. Crystalline nanocelluloses (CNC) have better electrical, optical, and mechanical properties compared to non-nanosized original forms. These features are very desirable for a number of novel applications. Eco-friendly technology and sustainability along with biodegradable nature made CNCs very attractive for manufacturing and high demand in industrial world market. We investigated adverse pulmonary and reproductive outcome caused by inhalation exposure to CNC aerosol generated from a bulk supply of wood pulp derived cellulose nanocrystals (freeze dried powder, FPL, USFS). C57BL6/J male mice were exposed to precise concentration of dispersed airborne CNC (5 mg/m^3, 5 h/day, 5 days/week for 3 weeks). Measurements of pulmonary functions in mice were conducted prior to bronchoalveolar lavage (BAL), lungs and testes collection for histopathology, and measurements of oxidative stress, inflammation, and effects on male reproductive functions at 24 h, 2-, 6- and 12-months post exposure. Exposure to CNC significantly increased airway responsiveness to methacholine and decreased tidal volume at 12 months of recovery as compared to air-control group. Hierarchical clustering analysis of the inflammatory cytokine responses revealed a shift in inflammatory responses from a Th1 type at early recovery time points to a Th2 response at the later stages. Similarly, BAL cytology indicated the preferential accumulation of polymorphonuclear neutrophils (PMNs) or eosinophils, respectively, at 24h and 12 months post exposure. Moreover, CNC inhalation resulted in the prominent perivascular lymphoid aggregates along with stronger peribronchial and perivascular fibrosis in the lungs (6-12 months of recovery). Histological analysis of testes showed pathological manifestations suggestive of abnormal sperm functions and production at the later time points of recovery. Inhalation exposure was associated with sperm DNA damage, changes in sperm motility and morphology. Accumulation of oxidative damage was observed as evidenced by elevated contents of oxidatively modified protein carbonyls in the testes. In conclusion: Exposure of C57BL6 mice to respirable CNC caused pulmonary and male reproductive toxicity observed up to 12 months post inhalation.

2097 Molecular-Level Insight into Adverse Outcome Pathway for Complex Metal Oxide Nanomaterial Exposure Using *Chironomus riparius*

N. J. Niemuth[1], Y. Zhang[2], A. Mohaimani[1], E. D. Laudadio[2], R. J. Hamers[2], and R. D. Klaper[1]. [1]*University of Wisconsin–Milwaukee, Milwaukee, WI; and* [2]*University of Wisconsin–Madison, Madison, WI.* Sponsor: M. Carvan

Lithium cobalt oxide (LCO) nanomaterials, contained in the cathode material of lithium ion batteries (LIBs), comprise a growing category of industrial production and commercial waste, with LIB waste from electric vehicles alone expected to reach 200 kilotons annually by 2025. A mechanistic understanding of the toxicology of this material will be important for understanding the implications of exposure to this material, including for the environment. In aqueous media, this material can aggregate and settle, concentrating at the bottom of the water column, which would create particularly high exposures for benthic organisms. A model for such exposure is the midge larvae *Chironomus riparius*. Exposure of *C. riparius* larvae to LCO concentrations as low as 10 mg/L cause reductions in size, lower levels of hemoglobin, and delays in development. Molecular studies by qPCR, RNA-Seq, enzyme assay, and electron paramagnetic resonance reveal negative impacts of LCO on Fe-S centers of proteins important for metabolism and regulation of heme production. These findings inform an Adverse Outcome Pathway for LCO exposure, whereby LCO impacts on protein Fe-S centers cause metabolic impairments that result in stunted growth and delayed development.

2098 Sex Differences in Acute and Chronic Lung Inflammatory Responses to Nickel Nanoparticles

D. J. You, H. Lee, A. J. Taylor-Just, and J. C. Bonner. *North Carolina State University, Raleigh, NC.*

Nickel nanoparticles (NiNPs) are widely used in various technological applications. A strong association between nickel inhalation exposure and asthma, pulmonary fibrosis, and lung cancer has been established in humans. In general, epidemiology studies show that women are more susceptible than men to chronic lung inflammation, while men are more susceptible to acute inflammation. Therefore, we hypothesized that male mice would be more susceptible to acute lung inflammation, whereas female mice would be more susceptible to chronic lung inflammation when exposed to LPS or/and NiNPs. The goal of this study is to explore mechanisms of susceptibility between male and female mice to acute and chronic lung inflammation after NiNP exposure. Methods**:** For the acute study, C57BL/6J male and female mice were treated by oropharyngeal aspiration with vehicle (0.1% Pluronic in PBS), LPS (5 µg/kg), NiNPs (4 mg/kg), or both, and sacrificed 24 hrs post-exposure. For the chronic study, mice were exposed to vehicle, LPS (0.83 µg/kg), NiNPs (0.67 mg/kg), or both at day 1, 3, 5, 15, 17, and 19, and sacrificed 24 days post initial exposure to the stimulants. Bronchoalveolar lavage fluid (BALF) was collected from the lungs for analysis of inflammatory markers. The lungs and other organs were collected for RNA and protein analysis or histopathology. Results: The acute study showed that male mice had higher IL-6 and neutrophils in their BALF after NiNP or LPS/NiNP treatment. Although total STAT3 levels measured by Western blot were similar, NiNP-induced STAT3 phosphorylation was significantly higher in male mice. This could be due to the inhibitory action of estradiol on IL-6 production, the main activator of STAT3. For the chronic study, we observed increased numbers of monocytes in the BALF of male mice after NiNP or LPS/NiNP exposure. Male mice also had higher levels of CCL2 in their lung lysates compared to the female mice. We suggest that the mechanism of male susceptibility to acute NiNP-induced lung inflammation involves increased neutrophilic infiltration regulated by IL-6/STAT3, whereas male susceptibility to chronic NiNP-induced lung inflammation involves monocytic infiltration regulated by CCL2. Overall, these findings suggest that human acute or chronic exposure to NiNPs and/or LPS would result in more severe lung inflammation or the inefficient resolution of inflammation in males. *Funding: Supported by NIEHS grant R01-ES020897 and NIEHS grant T32-ES007046.*

2099 Potential Toxicity of Graphene Oxide Nanomaterial to Japanese Medaka Fish

A. K. Dasmahapatra, D. K. Powe, S. T. Dasari, and P. B. Tchounwou. *Jackson State University, Jackson, MS.*

Due to unique physico-chemical properties, graphene oxide (GO) has shown great potential for biomedical, energy and electronic applications. As a result, release of GO into the ecosystem especially into the aquatic environment is inevitable; however, the potential risks on aquatic life are almost unknown. We have evaluated the toxic potential of GO on Japanese medaka fish (*Oryzias latipes*) adults. Reproductively active male and female medaka fish were intraperitoneally injected with GO (25-200 µg/g; single injection). The exposed fish were paired and allowed normal breeding for three weeks. The laid eggs were evaluated for hatching, fertility and developmental abnormalities. Males were more sensitive to GO toxicity than females; the calculated EC_{50} values were 172.9 µg/g and 1766 µg/g for males and females, respectively. Histological evaluation of the gonads (testis and ovary), liver and kidney of fish three weeks post injection showed that GO agglomerated in the peritoneum and accumulated in different organs including ovary, even though the fish were able to maintain normal breeding. The embryos were able to maintain normal development with occasional cardiac and yolk edema. GO accumulation produced organ damage including fibrosis of the ovary and interstitial cell hyperplasia of the kidney (especially in males). Taken together, our data indicate that GO is toxic to Japanese medaka fish, and the males being more sensitive than females. GO also accumulated in different organs and produced an oxidative damage that may initiate aggregation of macrophages in the damaged sites leading to necrosis and/or granulomatous inflammation. *Supported by NIMHD grant # G12MD007581and NSF grant #HRD 1547754.*

2100 Chronic Exposure to the Food Additive Silicon Dioxide (E551) at a Human-Relevant Dose Blocks Oral Tolerance Induction and Induce Food Intolerance in Mice

N. Breyner, P. Leitao, C. Ollivier, T. Parera, A. Guillard, E. Gaultier, C. Cartier, B. Lamas, and E. Houdeau. *Toxalim (Research Centre in Food Toxicology), Team Enterisk, INRA/ENVT/Paul Sabatier University, Toulouse, France.* Sponsor: D. Zalko

Food-grade SiO_2 (E551 in EU), composed of aggregated nanoparticles (NPs), is used as an anticaking and antifoaming agent in powdered foods, with chronic dietary exposure in humans (0.8-74 mg/kg/day). In mice, SiO_2-NP models block induction of oral tolerance (OT) to dietary antigens. The current study in mice aimed at evaluating the effect of chronic exposure to E551 at a human-relevant dose, added to a solid food matrix or in liquid suspension, on OT induction to the food antigen model ovalbumin (OVA). Mice were daily treated for 60 days without (controls) or with E551 (10mg/kg/day) in water suspension (gastric gavage) or incorporated into food pellets (solid matrix). Food intake was controlled. At day 41, OVA (20mg/mouse; OVA-tolerized mice) or PBS vehicle was orally administered for 3 days in each group. All mice were subsequently immunized by subcutaneous injection of OVA (100µg/mouse) on day 48. Blood was collected 1 week after for anti-OVA IgG serum titers to evaluate OT induction in OVA-tolerized mice exposed or not to E551. In all groups, to further assess OT to food antigens, mice were orally challenged by OVA (25µg/mouse) for 5 days before sacrifice. Isolated immune cells from mesenteric lymph nodes (MLN) were activated by PMA/ionomycin to assess pro- (IFNγ) and anti-inflammatory (IL-10, TGFβ) cytokine secretion by ELISA. Fecal lipocalin (Lcn)-2 level was used as a global marker of gut inflammation. In control mice, OVA tolerance protocol (oral OVA) lowered by 87% circulating anti-OVA IgG levels ($p<0.0001$) compared to oral PBS group, showing OT induction to OVA. In contrast, anti-OVA IgG titers did not decrease in OVA-tolerized mice chronically exposed to E551 regardless of the vehicle, showing blockade of OT to food antigens. In OVA-tolerized mice exposed to E551 through food pellets, *de novo* oral challenge with OVA led to an increase ($p<0.05$) of fecal Lcn-2 levels (+131%) and IFNγ (+139%) production by MLN cells, together with a drop ($p<0.05$) of TGFβ (-46%) and IL10 (-46%) when compared to OVA-tolerized controls, demonstrating gut inflammation. These results showed that chronic E551 exposure at human dietary levels in solid or liquid matrix impairs OT to dietary antigens, and promotes intestinal inflammation supporting food intolerance.

2101 Silver Nanoparticle-Induced Differential Biodistribution and Inflammatory Responses in Healthy and Obese Models

L. Kobos, S. Alqatani, L. Xia, V. Coltellino, R. Kishman, and J. Shannahan. *Purdue University, West Lafayette, IN.*

Silver nanoparticles (AgNPs) are proposed as an antibacterial agent in many biomedical applications, including surgical devices and implants. While research regarding their toxicity has primarily been performed in healthy models, the evaluation of AgNP toxicity in diseased conditions is of critical importance, as a substantial and growing proportion of the population suffers from a pre-existing condition. Specifically, approximately 40% of adults and 20% of children in the United States are obese. Our current evaluation utilized both healthy and obese mouse models to determine potential variations in AgNP toxicity. We hypothesized that obesity would alter inflammatory responses due to differential AgNP biodistribution. Healthy and obese C57BL6 mice were injected via tail vein with 2mg/kg AgNPs. After 24 h, the organs were collected and assessed for Ag content by atomic absorption spectroscopy and expression of inflammatory genes including IL-6, TNF-α, CXCL1, CXCL2, CCL2, TGF-β, IL-1β, HO-1 and others via real-time rtPCR. AgNPs induced differential total and relative inflammatory responses in healthy and obese mice. While AgNP exposure consistently caused an increase in the expression of inflammatory genes (IL-6, TNF-α, CXCL1, CCL2, TGF-β, IL-1β, HO-1) within the spleen of healthy mice, obese mice demonstrated decreased gene expression of CXCL1, CCL2, TGF-β, and IL-1β. Both healthy and obese mice exhibited similar inflammatory responses to one another within the liver. AgNPs localized primarily to the liver and the spleen, though Ag was present in all organs that were tested, including the brain, kidney, aorta, intestines, heart, lung, and serum. Biodistribution differences were observed between models. More Ag was deposited within the liver, kidney, heart, and serum of the obese mice compared to healthy. For the intestines and lungs, more Ag was detected in the healthy than the obese. The aorta, spleen, and brain contained the same amount of Ag between groups. Induction of inflammatory genes was not determined to correspond with biodistribution, suggesting disease-related variations in AgNP-induced toxicological responses. Together, these findings indicate that prevalent underlying diseases may impact the clinical application of NPs by influencing biodistribution and immune responses.

2102 Oral-Administered TiO_2 Nanoparticles Impact Basic Neurobehavioral and Cardiac Assessments and Biochemical Profiles in Rat Pups

N. P. Mortensen[1], M. Moreno Caffaro[1], R. W. Snyder[1], S. L. Watson[1], P. R. Patel[1], S. Aravamudhan[2], S. J. Sumner[3], and T. R. Fennell[1]. *[1]RTI International, Research Triangle Park, NC; [2]North Carolina A&T State University Joint School of Nanoscience and Nanoengineering,, Greensboro, NC; and [3]University of North Carolina Nutrition Research Institute, Kannapolis, NC.*

Titanium dioxide (TiO_2) is one of the most prevalent nanoparticles (NP) used as a food additive, and is found in baby formula, baked goods, candy, dairy products, etc., making ingestion unavoidable. Little is known about biological responses to NP exposure during infancy when both the intestinal tract and brain is still undergoing considerable development. In the study presented here male and female rat pups received four oral doses of 10 mg/kg TiO_2 P25 NP between postnatal day (PND) 2-5, 7-10, or 17-20, and were sacrificed at PND 21. Basic neurobehavioral (acoustic startle response, locomotor activity, and rotarod) assessments were performed at PND 20. Cardiac assessment (ECGenie) was conducted on PND 14 and 20. Six neurotransmitters/metabolites were quantified in brain by UPLC with electrochemical detection. Plasma metabolites (n = 181) were quantified using AbsoluteIDQ® p180Kits (Biocrates) analyzed by LC-MS. TiO_2 administered between PND 17-20 caused a decrease in locomotor activity ($P<0.05$). Dosing between PND 7-10 resulted in a decrease in heart rate in both male and female pups, however when dosed between PND 17-20 only female pups had a significantly decreased heart rate. Neurotransmitters/metabolites analyses show dopamine (DA), dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), and norepinephrine (NE) were impacted in an age- and gender-specific manner: DA was increased for male and female pups dosed between PND 2-5 but decreased for males dosed PND 17-20. DOPAC was increased for male and female when dosed PND 7-10. HVA were decreased following administration at PND 7-10 and 17-20. NE were decreased for females dosed PND 17-20. Metabolomic analysis of plasma shows between 6-17 individual metabolites and metabolite ratios/sums were significantly different between exposure groups and vehicle controls. Our results show that the biological responses to orally dosed TiO_2 NP in early life happen in an age- and gender-specific manner. Our data suggest that TiO_2 NP may impact neurobehavioral and cardiac performance, neurotransmitter/metabolite concentrations in brain, as well as metabolite concentrations in plasma.

2103 Understanding the Variable Drivers of Toxicity for the Broad Class of Carbon Nanotubes and Nanofibers from US Facilities

K. Fraser[1], N. Yanamala[1], T. Boots[1], K. Siegrist[2], T. Eye[1], S. Foster[1], J. Hubczak[1], D. Lowry[1], S. Friend[1], L. Bishop[1], A. Stephaniak[1], M. Dahm[3], M. Schubauer-Berigan[4], E. Birch[3], D. Evans[3], T. Lersch[5], G. Casuccio[5], K. Bunker[5], M. Orandle[1], A. Hubbs[1], A. Bauer[2], L. Sargent[1], V. Kodali[1], and A. Erdely[1]. *[1]NIOSH, Morgantown, WV; [2]University of Colorado Boulder, Boulder, CO; [3]NIOSH, Cincinnati, OH; [4]IARC, Lyon, France; and [5]RJ Lee Group, Monroeville, PA.*

Pulmonary exposure to carbon nanotubes or nanofibers (CNT/F) is known to induce inflammation, toxicity, or tumorigenesis, and is a concern in the occupational setting. Previously, we established toxicity profiles from male C57BL6/J mice aged 8-10 weeks exposed to either 4 or 40 µg of one of nine different CNT/F via oropharyngeal aspiration as well as human epithelial BEAS-2B cells (0-24 µg/ml), differentiated THP-1 cells (0-120 µg/ml), and human fibroblasts (0-2 µg/ml) for four primary outcomes of genotoxicity, inflammation, pathology, and translocation. An overarching goal of our expansive study was to use machine learning to determine the relationship between particle physicochemical characteristics with respective toxicity outcomes and the relationship between those four primary outcomes. The nine materials had a wide range of characteristics including diameter (6-397 nm), length (0.1-50 µm), surface area (18-238 m^2/g), aspect ratio (2-1396), residual metal catalyst (0.3-6.2 %), density (0.007-0.220 g/cm^3), etc., to consider. Unsupervised approaches were used to identify and define subsets of materials with similar outcomes. Subsequently, supervised learning approaches were used to identify physicochemical characteristics that define these outcomes. While some physicochemical characteristics were determined to be key drivers of specific toxicity outcomes, different characteristics were essential when considering other toxicity endpoints. More specifically, drivers of inflammation and/or pathology were not the factors driving translocation and/or genotoxicity. No single characteristic could be used as a toxicity predictor, therefore, multifactorial processes, or combination of characteristics, were necessary for an accurate and effective prediction model for responses. The study identified physicochemical drivers of CNT/F toxicity using an integrated approach, combining experimental evidence with computational modeling, with potential for broad application.

2104 A Long-Term Whole-Body Inhalation Study of Multiwalled Carbon Nanotubes in Mice with an Improved Dispersion and Inhalation System

Y. Taquahashi[1], S. Yokota[1], K. Morita[1], M. Tsuji[1], M. Kuwagata[1], A. Hirose[1], and J. Kanno[2,1]. *[1]National Institute of Health Sciences, Kawasaki, Japan; and [2]Japan Bioassay Research Center, Hadano, Japan.*

Inhalation study is essential for assessment of general respiratory toxicity including non-cancerous endpoint of the nanomaterials (NMs). In designing inhalation studies for NMs, it is important to control the status of aggregate and agglomerates (AA) to be consistent with the human exposure. For example, a multi-wall carbon nanotube (MWCNT) such as Mitsui MWNT-7 is a mixture of single fibers (SF) and their AA. Human ambient air, in general, is less agitated; the AA may sediment away faster, SF may suspend longer in the air and to be inhaled by humans. On the other hand, the air for animal experiments is rigorously agitated in order to ensure the homogeneity of the aerosol; when the aerosol is a mixture of SF and AA, the AA could be trapped by the upper respiratory tract and impede the SF to reach the alveolar region consequently induce AA-specific lesions (e.g. granulomas) which are considered to block and/or mask the nature of toxicity induced by the SF. Taking all into account, we considered that it is essential to make a well-dispersed aerosol without AA for the human-relevant exposure scenario. To generate well-dispersed aerosol, we developed the "Taquann" dispersion method and a "direct injection" whole body inhalation system for the dispersed sample (designated as "Taquann System" J Toxicol Sci. 2013). In this study, we have conducted a long-term inhalation exposure study of MWCNT (MWNT-7, Mitsui) by using Taquann system. Male C57BL/6 mice, 12-week-old were exposed to MWCNT aerosol, 2.7 and 5.1 mg/m^3 in the low concentration group (LC) and in the high concentration group (HC), respectively. Duration of exposure was 6 hrs a day for 6 months every 4 weeks. MMAD on aerosol in the chamber was approx. 500 nm measured by MOUDI (Model125, Kanomax). Lung burden of the first time exposure were approx. 4 and 6 microgram per animal in the LC and in the HC, respectively. The fiber length recovered from the lungs was approx. 6.5 micrometer. Histologically, SF were found around terminal bronchioles to alveolar region. Macrophages surrounded and/or phagocytized cluster of SF. However, clear formations of granuloma were not observed. It is concluded that aerosol dispersibility should be considerations for risk assessment of NMs. *This work was supported by the Health and Labour Sciences Research Grant, Japan.*

2105 The Effect of Disease State and Age on the Biodistribution Profile of Injected Gold Nanoparticles

C. Wong, B. Gelein, G. Oberdörster, and A. Elder. *University of Rochester Medical Center, Rochester, NY.*

Many nanoparticle (NP) biodistribution studies focus on characteristics such as size, shape or dissolution that affect tissue accumulation and retention in healthy animals. However, little has been done to determine how factors such as disease state or age can alter barrier permeability and ultimately change NP biodistribution. Neuroinflammatory diseases, such as Alzheimer's disease (AD), often feature a compromised blood-brain barrier (BBB). Thus, we hypothesized that AD state and age would alter the biodistribution of blood-borne NPs, particularly to the brain. To study the effects of AD- and age-related changes in tissue NP accumulation, we used the 3xTgAD mouse model and varied age as a function of disease state. Young (3 mo) and aged (19 mo, 23 mo) 3xTgAD and non-transgenic (NTg) mice were injected intravenously with colloidal gold NPs (AuNPs, primary particle size 20 nm, 45-49 µg per mouse). Tissues were collected 24 hrs post-injection and processed by acid-assisted microwave digestion. Au tissue content was determined by atomic absorption spectrometry (liver, spleen) or inductively-coupled plasma mass spectrometry (kidneys, blood, microdissected brain). The total recovered Au dose in all tissues measured was higher in the aged mice as compared to young mice irrespective of genotype ($p=0.0012$). The biodistribution profile for both genotypes demonstrated that the livers accumulated the highest relative dose (65-85% of the recovered dose), followed by the spleen (14-33%), kidneys (2-3%), blood (<1%), then whole brain (<0.5%). Analysis of Au tissue concentrations in microdissected brain regions (olfactory bulb, hippocampus, striatum, frontal cortex, cerebellum) demonstrate regional differences in brain accumulation by age and genotype. When considering the brain as a whole, there was a significant interaction effect of age and genotype on Au accumulation ($p=0.006$), where elevated levels of Au were found with in-

creased disease progression. Levels of Au in blood filtering organs such as the liver, spleen, and kidneys demonstrated either no effect or decreased levels of Au with age. Overall, these findings suggest that the BBB is comparatively more permeable to blood-borne NP accumulation due to AD- and age-related changes as the liver, kidneys, and spleen did not show these same effects. *Funding Sources: ExxonMobil Biomedical Sciences, R01ES020332, T32ES007026, P30ES001247.*

PS 2106 Assessment of Chronic Inhalation Exposure of Thin and Long Multiwalled Carbon Nanotubes in Rats and Mice

N. J. Walker[1], N. L. South[2], S. T. Gibbs[2], A. Gupta[2], K. E. Elsass[2], B. R. Sparrow[2], J. S. Richey[2], G. L. Baker[2], M. F. Cesta[1], and M. D. Stout[1]. *[1]NIEHS/NTP, Durham, NC; and [2]Battelle Memorial Institute, Columbus, OH.*

Multiwalled carbon nanotubes (MWCNTs) are a diverse class of nanoscale materials with a broad range of industrial uses. While one type of MWCNTs with physical attributes of a nanoscale fiber has been classified as probably carcinogenic, MWCNTs as a class are currently unclassifiable regards their carcinogenic hazard due to a lack of available data. A relatively thin and long MWCNT (2.6 um long x 15 nm wide) with high purity (>99%, residual nickel present at 0.52%) was selected as a test material for long-term whole-body inhalation toxicology and carcinogenicity studies. Consistent with reports of MWCNT observed in occupational settings, this material existed as micrometer scale agglomerates in the bulk test material and also in the inhalation exposure atmospheres. Using this material, 30-day and 2-year toxicology and tissue burden studies were conducted in male and female Sprague Dawley (HSD: Sprague Dawley® SD®) rats and B6C3F1/N mice. In the 30-day studies, the higher exposure concentrations (3 and 10 mg/m^3) were associated with reduced pulmonary clearance, inflammation and hyperplasia. To aid in the design of a chronic study, the lung burden data were modeled to predict the exposure concentration that would result in pulmonary overload at 18 months of exposure at the highest exposure concentration. Based on this information, rats and mice were exposed to 0, 0.06, 0.2 or 0.6 mg/m^3 (6 hr/day, 5 days/week) by whole body inhalation for up to two years. In the 30-day study there was negligible pulmonary toxicity at the range of these concentrations selected for the chronic study. In the chronic study, at the 12 month interim assessment, in general there was no effect of exposure on terminal body weights. There were modest but significant increases in relative lung weights in both male and female rats, and male and female mice. Lung burdens of MWCNT increased with exposure concentration and duration. The increase in lung burdens was consistent with the exposure concentration dependent increase in severity of "foreign material" diagnosed in the lung of exposed rats. Increases were greater than proportional as exposure concentration increased indicating that MWCNT were not effectively being cleared from the lung at the higher concentrations and as a result did not reach steady state in either species.

PS 2107 Hepatotoxicity of OH-*f* MWCNTs in Wistar Rats

N. K. Nirmal, and P. J. John. *University of Rajasthan, Jaipur, India.* Sponsor: V. Kale

Carbon in nano-form is a superstar material for 21st century nano-scientists. Multiwalled carbon nanotubes (MWCNTs) have potential applications in the field of electronics, textiles, water purification, nanocomposites and biomedical applications such as targeted drug delivery, biosensors, tissue engineering among others. Toxicity and biocompatibility studies have become very important before these materials enter our daily life in a big way. In the present study, OH-functionalized MWCNTs (OH-*f* MWCNTs) were homogeneously suspended in autoclaved normal saline with 0.1% Tween-80 by probe sonication method. Adult Wistar rats were divided into four groups namely control group, low-dose group, mid-dose group and high-dose group (each group having 6 animals) and each group was administered intraperitoneal doses of 0.0 mg/kg BW, 0.4 mg/kg BW, 2.0 mg/kg BW and 10.0 mg/kg BW respectively. Autopsy was done after 15 alternate doses over a period of 30 days. Biochemical assays for alkaline phosphatase (ALP), aspartate transaminase (AST), alanine transaminase (ALT) and oxidative stress assays (catalase and malondialdehyde) were performed. Liver histopathology was carried out in hematoxylin-eosin stained sections. A dose-dependent hepatotoxicity pattern was observed post OH-*f* MWCNTs exposure. Feeding pattern, body weight and organ indices did not change significantly during the exposure period. Concentrations of ALP, AST and ALT were altered significantly in the sera of mid and high-dose treated rats. Catalase enzyme activity in liver tissue homogenates was lowered in mid-dose and high-dose group. Malondialdehyde levels increased in animals treated with 2.0 mg/kg BW and 10.0 mg/kg BW. Histological analysis of hepatic tissue revealed dose-dependent pathological changes in structure. Mid and high-dose groups exhibited several necrotic areas especially near the central vein. Inflammation was also observed around the central vein and portal veins. Many hepatocytes showed abnormal features such as degenerated nucleus, vacuolation, cell shape changes and cell swelling. These findings indicate that multiwalled carbon nanotubes damage the structure of hepatic tissue and impair function as well. Further studies are required to understand the mechanistic aspect of hepatotoxicity caused by MWCNTs.

PS 2108 Acute Pulmonary Toxicity of Aerosolized Zinc Oxide Engineered Nanomaterials in Rats

P. Upadhyay[1], R. Abarca[1], X. Luo[2], L. Van Winkle[1], and K. Pinkerton[1]. *[1]University of California Davis, Davis, CA; and [2]Nanjing University of Information Science and Technology, Nanjing, China.*

There are more than 1600 engineered nanomaterial (ENM)-based consumer products on the global market today with annual sales of $70 million in the US alone. Zinc Oxide (ZnO) nanoparticles are commercially used as antibacterial, antifungal, anti-corrosive and UV filtering agents. Increased consumer product use has created concerns for the potential of increased risk by inhalation of these nanoparticles during synthesis and commercial application. ZnO nanoparticles have been reported to cause toxic effects by dermal, ingestion and inhalation routes of exposure. The primary objective of this study is to determine if inhalation of ZnO nanoparticles induces inflammation in the lungs. Male Sprague Dawley rats were randomly assigned to sham control (n=19) or ZnO inhalation (n=26) groups. Rats were exposed to aerosolized 50 nm diameter ZnO (1mg/ml) for a single 6 hour period and examined at 0, 1, 7 and 21 days following inhalation. Bronchoalveolar lavage (BAL) was collected from the right lung to assess protein concentration, cell number, viability, and cell differentials. The left lung was inflation-fixed, embedded and sectioned for histopathological analysis. Particle aerosol was characterized by gravimetric measurement, x-ray fluorescence (XRF), cascade impactor and transmission electron microscopy (TEM). The generated ZnO aerosol mass was 4.23 +/- 1.27 mg/m^3. The concentration of Zn in the aerosol by XRF analysis was 2.5 +/- 0.2 mg/m^3. Mass median aerodynamic diameter of the aerosol was 3.57 µm, while the average median size of nanoparticles measured by TEM was 118 nm. TEM demonstrated limited agglomeration of ZnO nanoparticles following aerosolization ranging from 50 to 340 nm in size. Day 0, 1 and 7 post-exposure (PE) demonstrated a significant decrease in the percent of viable cells in BAL following ZnO exposure ($p<0.05$). Macrophages were significantly increased on day 0 PE compared to controls. Neutrophils were significantly higher following ZnO inhalation on day 0 and 1 PE ($p<0.05$). BAL protein on day 7 was higher compared to control. Histopathological lung assessment showed increased numbers of macrophages in the airways and pleural regions positively stained for HO-1, a marker of oxidative stress. These findings demonstrate ZnO can lead to short-term inflammation and decreased cell viability, suggesting ZnO nanoparticles are not completely innocuous when inhaled.

PS 2109 Investigating the Toxicology of Intramuscular Injected CNT-AB in Mice Followed by Microwave Hyperthermia

C. E. Clark, E. Gato, A. C. Mixson, R. Quirino, and V. Sittaramane. *Georgia Southern University, Statesboro, GA.*

The advent of carbon nanotubes (CNT's) has prompted a wide range of research in various fields but more specifically into cancer therapy for localized and site-specific treatment. Carbon nanotubes bound to tumor-specific antibodies (Ab) offer specific treatment for cancer cells without affecting the surrounding tissue. It is hypothesized that this treatment will make use of the infrared absorptive properties of nanotubes and will produce systemic effects that are indicative of abolished cancer cells. We seek to affirm the initial results of CNT in cancer therapy by investigating the toxicology in mice injected with CNT-Ab followed by microwave hypothermia. The toxicological results from the animal models will help guide the development of this treatment and potentially validate the method as a viable and effective form of cancer treatment for humans. After 2 weeks, blood was collected from the mice to analyze albumin, total protein, aspartate transferase (AST), and creatinine in blood serum. At the end of treatment, mice were sacrificed for examination of gene expression in liver, pancreatic, and brain tissues. Total protein concentration was varied across treatment groups. There were no significant changes in albumin levels as compared to the control group. The 0.125 mg/ml anti-PSMA-MWCNT (No Microwave) and 0.5 mg/ml anti-PSMA-MWCNT + Microwave treatment groups showed reduced total protein while the Microwave only and 0.125 mg/ml anti-PSMA-MWCNT + Microwave treatment groups showed elevated total protein levels compared to the control. With respect to AST results, Microwave only, 0.125 mg/ml anti-PSMA-MWCNT + Microwave, and 0.5 mg/ml plain MWCNT + Microwave treatment groups showed elevated

levels while the 0.125 mg/ml plain MWCNT + Microwave treatment group showed reduced levels. The majority of groups given microwave treatment had lower levels of creatinine. All treatment groups showed an upregulation of NFKB and TNF, while IL6 and PTSG2 were downregulated and IL1B was not expressed at all. Results showed minimal to no effects two weeks after a single injection in mice with CNT-Ab followed by microwave hypothermia. Study is still ongoing to examine histopathological data.

2110 A Toxicological Assessment of Crystalline Nano-Cellulose in Mice

T. M. Sager, and P. Joseph. *NIOSH, Morgantown, WV.*

Crystalline nanocellulose (CNC) is derived from the natural polymer, cellulose. Considering the numerous applications of CNC, a substantial number of workers could be exposed to CNC. This study investigates the time-course of onset, progression, and resolution, if any, of CNC-induced toxicity. For hazard ranking, the outcome of the CNC toxicity studies was compared to those induced by a larger-sized crystalline micro cellulose; CMC, and to a reference material, Mitsui multi-walled carbon nanotubes (MWCNT). Mice (male, C57BL/6J, 7 weeks old) were administered dispersion medium (DM) or DM containing CNC, CMC (50, 100, and 200 µg/mouse), or MWCNT (50 µg/mouse) as a single pharyngeal aspiration. At 1 day, 7 days, 1 month, 3 months, and 6 months post-exposure toxicity facilitated by exposure to the varying materials was assessed. Serum transaminases were measured to determine hepatotoxicity. Whole lung lavage was conducted to assess pulmonary toxicity (PMN number and LDH activity). Sperm counts and motility analyses were used to assess reproductive toxicity. All doses of CNC caused a significant increase in PMN number and LDH activity at 1- and 7-days post-exposure. For CMC, an increase in PMN number and LDH activity was also found at 1-day post-exposure, for all doses. However, the inflammatory response of CNC (number of infiltrating PMNs) was significantly greater when compared to the response facilitated by CMC. The 200 µg/mouse dose of CNC also caused significant increases in serum ALT and AST at 7-days post-exposure compared to controls. CMC exposure also facilitated a significant increase in serum AST at the 200 µg/mouse dose at 1-day post-exposure. MWCNT resulted in significant pulmonary inflammation. However, at 1-day post-exposure, CNC (50 µg/mouse) caused a 2-fold greater increase in PMN number compared to that by MWCNT. By 7-days post-exposure MWCNT caused a 3-fold greater increase in PMN number compared to CNC. Additionally, there was no treatment related changes in sperm count or motility for any dose/post-exposure time combination of CNC, CMC, or MWCNT. In conclusion, the physico-chemical properties, such as the enhanced surface area of the CNC, are likely driving the more robust pulmonary toxicity response as compared to the pulmonary toxicity caused by the larger micron-sized CMC. Furthermore, MWCNT-facilitated pulmonary inflammation that was more persistent than CNC.

2111 Pulmonary Responses to Subacute Cadmium Sulfide Nanoparticle Inhalation

N. J. Parizek, B. R. Steines, A. Adamcakova-Dodd, and P. S. Thorne. *University of Iowa, Iowa City, IA.*

The uses and applications of engineered nanomaterials (ENMs) are expanding at an astounding rate. One such application is the manufacturing of quantum dots using cadmium sulfide (CdS) nanoparticles. CdS quantum dots are semiconductors with a direct intermediate bandgap and excellent thermal stability and thus have shown strong potential for wide scale use in solar cells, light emitting diodes, and specialty lasers. Industrial scale manufacturing of CdS quantum dots requires bulk quantities of CdS nanoparticles. To evaluate toxic risk associated with industrial CdS nanoparticle use, we performed a sub-acute nose-only inhalation exposure (3.49 ± 0.49 mg/m^3) to CdS aerosol (geometric mean mobility diameter 41 nm, geometric standard deviation 1.8) using a murine model. Analysis of bronchoalveolar lavage (BAL) fluid showed a 12-fold increase in total BAL cells per mouse immediately after 2 wk exposure accompanied with inflammatory cell infiltration (41% of these cells were neutrophils) that persisted through 3 weeks of rest after exposure (the number of neutrophils decreased only to 29%). Histopathologic analysis of lung tissue confirmed the presence of inflammatory cell infiltration. Exposed mice demonstrated an increase in inflammatory cytokines in the BAL fluid. There was evidence of lipid peroxidation in both lung tissue and serum of exposed mice (TBARS assay). Our analysis shows that sub-acute inhalation of CdS nanoparticles leads to pulmonary inflammation and an increase in ROS. Determination of Cd in selected tissues to assess deposited and cleared Cd after exposure as well as evaluation of pulmonary mechanics parameters is in progress. *Supported by: NIH U01 ES027252 & NIH P30 ES005605.*

2112 Effects of Iron Oxide Nanoparticles (IONPs): Cytotoxicity and Genotoxicity in Wistar Rat Brain

P. J. John, K. Vyas, and D. Bhatt. *University of Rajasthan, Jaipur, India.* Sponsor: V. Kale

The utilization of iron oxide nanoparticles in several biomedical applications, has received much attention due to their unique properties, such as extremely small size, high surface-area-to-volume ratio, excellent magnetic properties and great biocompatibility. Although, the potential benefits of iron oxide nanoparticles are considerable, there is a distinct need to identify any potential risk associated with their usages. It has been demonstrated earlier that corpus striatum and hippocampus are the major sites of IONPs accumulation in brain. The high surface activity of these IONPs deposited for long term in brain may cause neurodegenerative disorders. Our study put forward a notion that in making of a perfect treatment vehicle, any nanoparticle has to pass through various parameters of cytotoxic and genotoxic evaluation. Thus, the present study was designed to evaluate the cytotoxic and genotoxic effects of iron oxide nanoparticles (IONPs) *in vivo*. In order to study the toxic effects, male Wistar rats (6-8 weeks old) were randomly divided into four groups, group I served as control, group II treated with 20.322 mg/kg body weight, group III treated with 40.644 mg/kg body weight and group IV treated with 81.288 mg/kg body weight. Animals of each group were intraperitoneally administered the selected dose daily for 28 days. They were sacrificed on post exposure day 7th, 14th and 28th and brains dissected out for various biochemical assays such as antioxidant enzymes activity glutathione-S-transferase (GST), glutathione peroxidase (GPX), and glutathione reductase (GR), and genotoxicity assessment through single cell gel electrophoresis assay, in the tissue homogenates of four brain sub regions namely, frontal cortex, corpus striatum, hippocampus and cerebellum. The results revealed that the activity of antioxidant enzymes (GST, GR, GPx) elevated in IONPs treated groups in dose-dependent manner but non-significantly, however, activity of GR and GPx on 14th day of investigation for group IV animals was found significant. The comet assay results indicate that IONPs did not induce any significant DNA damage following exposure of IONPs at various dose levels. The present study concluded that IONPs are safe to use under prescribed doses. But it can induce oxidative stress as well as genotoxicity at higher doses of the particles with or without coatings. Therefore, there is a considerable need to address biocompatibility and biosafety concerns associated with their usage to avoid the adverse side effects of nanoparticles when used as biomedical tools.

2113 Time Course of Pulmonary Toxicity and Biodistribution during and after Subacute Inhalation Exposure to Copper Oxide Nanoparticles in a Mouse Model

A. Adamcakova-Dodd, S. Areecheewakul, E. Haque, B. Steines, P. O'Shaughnessy, A. Salem, and P. Thorne. *University of Iowa, Iowa City, IA.*

Research interest in nanotoxicity has dramatically increased due to the exponential growth of nanomaterial applications and nanotechnology because of their unique physicochemical properties compared to bulk materials. Copper oxide nanoparticles (CuO NPs) have been widely used in many applications such as antimicrobial agents, solar cells, catalysts, and electronic products. CuO NPs are highly cytotoxic compared to other metal oxide NPs. The inhalation is potentially the most significant route for unintentionally exposure especially in occupational settings. Several murine studies demonstrated that inhalation exposure to CuO NPs induces pulmonary inflammation. However, available data on the CuO NPs biodistribution relating to their toxicity are still limited. The goal of this study was to investigate the pulmonary toxicity and biodistribution of inhaled CuO NPs during and after subacute exposure. The time course of CuO NPs biodistribution will increase our understanding of CuO NP toxicity particularly in the pulmonary region. In this study, female BALB/CJ mice were exposed to CuO NPs at 3.75 mg/m^3 (geometric mean of aerosolized CuO NPs was 77.6 nm) using a nose-only exposure system for 4 hr/day, 5 days/week over a 2-week period and were necropsied on days 0, 3, 7, 10, 12, 17, 22, and 27. Sera, bronchoalveolar lavage (BAL) fluid and lung tissue were collected to measure 23 cytokine/chemokines levels, numbers of inflammatory cells, and lactate dehydrogenase (LDH). Histopathology of lungs was also evaluated. Whole blood, lung, brain, heart, kidney, liver, and spleen were collected to measure copper concentration by inductively coupled plasma mass spectrometry (ICP-MS). The number of macrophages, lymphocytes and neutrophils in BAL fluid were gradually increasing with a culmination on day 22, 17 and 12, respectively. Rate of weight gain, and LDH levels in BAL fluid exhibited similar changes as neutrophils. Significantly higher concentrations of many cytokines/chemokines (IL-12 (p40), KC, MCP-1, MIP-1a) persisted several days after the end exposure. The amount of copper in the lung tissues of all exposure groups increased significantly compared to the control group with a gradual increase observed during exposure and a decline subsequent to exposure. However, the copper concentration in whole blood exhibited a

significant increase only on day 7 and 17 compared to the control group. The copper concentration in other remaining organs will be further measured to assess the copper translocation. *Funded by: NIH U01 ES027252.*

2114 Toxicity of Multiwalled Carbon Nanotubes in Rat and Human Intestinal Cell Models

T. D. Kodavanti[1], A. H. Tennant[2], and M. F. Hughes[2]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; and [2]US EPA/ORD, Research Triangle Park, NC.*

Multi-walled carbon nanotubes (MWCNTs) are several layers of one-atom thick sheets of carbon. MWCNTs are hollow cylinders with a large length to diameter ratio. MWCNTs can improve the mechanical, electrical and thermal conductivity of many products so they are used in a wide variety of applications. The manufacture and use of MWCNTs may result in their release in to the environment. Exposure to MWCNTs may occur following inhalation and ingestion of these nanomaterials. The purpose of this study was to assess the *in vitro* toxicity of several MWCNTs in a rat (IEC-6 cells) and human intestinal cell models. The outside diameter (OD) of the MWCNTs were < 8 nm, 13-18 nm, 20-30 nm, and >50 nm. Two other MWCNTs of OD 20-30 nm were functionalized with -OH or -COOH groups. The IEC-6 cells are a 2-dimensional monolayer of cells, whereas the human model is a 3-dimensional model with multiple cell types. IEC-6 cells were plated in 96-well plate with 60K cells/well for 24 h. MWCNTs suspended in Dulbecco's media, 10% fetal bovine serum (FBS) and 0.1% pluronic were probe sonicated for 15 min before dosing. Media with 10% FBS was the negative control and Triton X-100 (0.3%) was the positive control. Cells were then exposed to the MWCNTs at several concentrations (0.3-300 µg/mL) for 24 h. Following incubation, the cells were washed with media and the cytotoxicity was assessed using a cell-permeant dye, Calcein AM. This is a non-fluorescent compound that is converted to the green fluorescent Calcein in viable cells upon acetoxymethyl ester hydrolysis by intracellular esterases. Lethal concentration$_{50}$ of the MWCNTs were determined: < 8 and 20-30 nm -OH, 35 µg/mL; 20-30 nm, 50 µg/mL; 20-30 nm -COOH, 80 µg/mL; 13-18 nm, 105 µg/mL; 50 nm, 300 µg/mL. Cell viability measured in the 3-dimensional human intestinal model using the colorimetric MTT assay showed no cytotoxicity by the MWCNTs following a 24-h exposure. For the rat intestinal model, outside diameter and functionalization of MWCNTs appear to be important factors in the cytotoxicity of these nanomaterials. *This abstract does not represent US EPA policy.*

2115 Titanium Dioxide and Zinc Oxide Nanomaterials Change Lipid Order and Increase Permeability in Model Systems

M. J. Sydor, D. S. Anderson, H. B. Steele, J. Ross, and A. Holian. *University of Montana, Missoula, MT.*

The expanded use of nanotechnology has led to increased production and use of engineered nanomaterials (ENM), resulting in an increased risk of human exposure. ENM generated occupationally can be airborne and are taken-up by immune cells (macrophages) in the lung, where the ENM accumulate in phagolysosome organelles. Some ENM have been reported to be bioactive and to trigger a pro-inflammatory response when inhaled. Alveolar macrophages have been demonstrated to be responsible for this inflammatory response due to their release of the cytokine, IL-1β. A key step preceding and linked to IL-1β release is phagolysosomal membrane permeability (LMP). This suggests that ENM may interact directly with the lipid membrane of the phagolysosomes, disrupting their normal state, resulting in LMP. The way in which various ENM disrupt lipid membranes, is not fully understood. Time-resolved fluorescence anisotropy measurements, using suitable lipid probes, can measure changes in membrane characteristics, such as lipid order (Lo) and disorder (Ld). Using appropriate model systems can help to describe mechanisms of ENM0-induced lipid membrane permeability. In this work, 100 and 400 nm liposomes made of DOPC (1,2-dioleoyl-sn-glycero-3-phosphocholine), POPC (1-palmitoyl-2-oleoyl-glycero-3-phosphocholine) and DOPS (1,2-dioleoyl-sn-glycero-3-phospho-L-serine) were used as model systems to determine phospholipid interaction with ENM. These models were exposed to 25 and 100 µg/ml of titanium dioxide (TiO_2) or zinc oxide (ZnO) nanospheres for 2 hours at 37°C. The fluorescence membrane probe Di-4-ANEPPDHQ and a time-resolved fluorometer were used to determine the changes in lipid Lo/Ld of the liposomes by anisotropy. Liposome lysis was measured by a calcein leakage assay. Again, these liposomes were exposed to the same doses and incubation time as described above. Treatment with both ENM produced significant increases in calcein leakage at the 100 µg/ml dose. This happened in all three models tested. POPC liposomes exposed to 100 µg/ml TiO_2 had a decrease in lipid order, but no significant change was observed using DOPC or DOPS liposomes. ZnO exposure (100 µg/ml) to DOPS liposomes also showed a decrease in lipid order, but again there was no change using DOPC or POPC liposomes. These results indicate that there is a consistency in term of changes to the order of the membranes, in which there is increased order around the probe. These results also demonstrate that both of these ENM are able to cause leakage of the small molecule calcein from inside the liposomes. *Funding: NSF MRI CHE-1531520 M.J. Murdock Charitable Trust, NIH R01ES023209, 1F32ES027324, P20GM103546 and P30GM103338.*

2116 Oxygen Mediates the Toxicity of Silver Nanoparticles in Human Liver Cells

F. Zhang, and E. D. Bruce. *Baylor University, Waco, TX.*

Due to the increasing concern of their hazard effects, there has been a rapid progress in characterizing the toxicological profiles of nanosilver (nAg). The current knowledge of the toxic effects, however, was mainly gained in the normoxic experimental condition, and only limited information is available on the effects of nAg in hypoxic conditions. Hypoxia is commonly found in humans in various clinical conditions, such as stroke, chronic injury, chronic wounds and solid tumors. There are several known scenarios where nAg exposure and hypoxia occur concurrently, such as nAg treated wound sites, nAg incorporated cancer therapy, and nAg administration to chronically diseased tissue. Therefore, investigating the effects of nAg in combination with hypoxia, addresses the toxicity concern in close mimic of these conditions. Such investigation also adds additional information to the overall understanding of nAg potential adverse effects in general. In this work, cytotoxicity, proliferative activity, oxidative stress and apoptotic potential of silver nanoparticles (AgNPs), were evaluated under both hypoxic (2% O_2) and normoxic (21% O_2) conditions. Two human liver cell types, including cancer cells (HepG2) and non-cancer cells (THLE-3) were tested. Results revealed that the toxicity of AgNPs was dependent on both O_2 level and cell type. AgNPs were more toxic to cancer cells in normoxia, whereas it's the opposite to non-cancer cells. AgNPs were only toxic to HepG2 above 5 mg/L during 24-hour exposure regardless of O_2 availability. At 20 mg/L AgNPs in normoxia, 1) cells were 50% less viable, 2) AgNPs exerted up to a 3-fold response in oxidative stress and 3) 20% more apoptotic cells compared to hypoxia condition. THLE-3 cells, on the contrary, were severely damaged in addition to insufficient O_2. At 1 mg/L AgNPs and 2% O_2, 1) cells were 30% less viable, 2) 20% fewer in population, and 3) showed non-significant increased apoptosis. Meanwhile, cellular uptake is being evaluated to study the link between toxicity and uptake amount. The protein expression of hypoxia-inducible factor (HIF-1α), an oxygen-sensitive transcription factor, will also be measured in the presence and absence of AgNPs under both O_2 conditions, to elucidate the underlying mechanism of hypoxia on AgNPs-induced toxicity. Overall, toxicity of AgNPs to human liver cells is mediated by O_2 level at which the exposure occurs. Hypoxia ameliorates AgNPs toxicity to cancer cells, while exacerbating it to non-cancer cells.

2117 The Effects of Genotype × Phenotype Interactions on Transcriptional Response to Silver Nanoparticle Toxicity in Organotypic Cultures of Murine Tracheal Epithelial Cells

T. P. Nicholas[1,2,3], A. K. Haick[4], T. K. Bammler[1], T. W. Workman[1], T. J. Kavanagh[1,2], E. M. Faustman[1], S. A. Gharib[2], and W. A. Altemeier[2]. *[1]University of Washington School of Public Health, Seattle, WA; [2]University of Washington School of Medicine, Seattle, WA; [3]Health Sciences Practice, Exponent (Current Location), Alexandria, VA; and [4]Fred Hutchinson Cancer Research Center, Seattle, WA.*

The airway epithelium is critical for maintaining innate and adaptive immune responses, and occupational exposures that disrupt its immune homeostasis may initiate and amplify airway inflammation. We have demonstrated that silver nanoparticles (AgNP), which are used in multiple applications including many antimicrobial products, induce toxicity in organotypic cultures derived from murine tracheal epithelial cells (MTEC). Those cells differentiated toward a "Type 2 [T2]-Skewed" phenotype experienced an increased sensitivity to AgNP toxicity, suggesting that asthmatics could be a sensitive population to AgNP exposures in occupational settings. However, the mechanistic basis for this genotype × phenotype (G×P) interaction has yet to be defined. In this study, we conducted transcriptional profiling using RNA-sequencing to predict the enrichment of specific canonical pathways and upstream transcriptional regulators to assist in defining a mechanistic basis for G×P effects on AgNP toxicity. Organotypic cultures were derived from MTEC across 2 genetically inbred mouse strains (A/J and C57BL/6J mice), 2 phenotypes ("Normal" and "T2-Skewed"), and 1 AgNP exposure (an acute 24 h exposure) to assess G×P effects on transcriptional response to AgNP toxicity. The "T2-Skewed" phenotype was marked by increased pro-inflammatory T17 responses to AgNP toxicity, which are significant predictors of neutrophilic/difficult-to-control asthma and is compatible with our hypothesis. This study

highlights the importance of considering G×P effects when identifying sensitive populations, whose underlying genetics or diseases could directly modify their response to AgNP exposures.

2118 The Yin-Yang of Inflammation: Is There a Balance during Nanoparticle Toxicity?

S. Rudraiah[1], S. Berman[1], P. Chilakamarri[1], S. Ninan[1], N. Haque[1], and S. G. Kumbar[2]. *[1]University of Saint Joseph, Hartford, CT; and [2]University of Connecticut Health, Farmington, CT.*

Nanoparticle exposure is rising due to their versatile utility as drug carriers, mechanical property enhancers in medical devices, consumer products, and food excipients. To name a few multiwalled carbon nanotubes (MWCNT), cobalt oxide (cancer therapy), silver (antibacterial composition), titanium oxide (sunscreen), are routinely used in a variety of formulations. Nanoparticles can accumulate in tissues due to their extremely small size and elicit toxic effects. Despite the tremendous benefit presented, common pitfalls of this technology are its potential short and long-term effects on the human body. High mobility group box-1 (HMGB1) acts as a damage-associated molecular pattern and can work as a necrosis signal for the immune cell activation through the toll-like receptor (TLR). HMGB1 can bind to multiple receptors including TLRs in liver diseases. Our previous differential HMGB1 expression analysis following TiO_2 or MWCNT exposure showed an increase in HMGB1 protein expression in the hepatocyte cell line, HC-04. Tumor necrosis factor α induced protein 3-interacting protein 1 (TNIP1), a cytoplasmic protein, inhibits signaling mediated by numerous trans-membrane receptors, such as TLRs, thus acting as a negative regulator of TLR signaling. Both HMGB1 and TNIP1 converge at TLR signaling: where HMGB1 activates TLRs producing an inflammatory response and TNIP1 restricts TLR mediated inflammation. Thus, in this analysis, our goal was to evaluate the relationship between HMGB1 expression and TNIP1 expression in HC-04 cells exposed to nanoparticles. Interestingly, we evidenced an inverse relation between HMGB1 and TNIP1 protein expression. Hepatotoxicants such as acetaminophen (APAP) and ethanol (EtOH) have been shown to induce HMGB1 expression in the liver. In HC-04 cells, HMGB1 expression also increased due to APAP and EtOH whereas TNIP1 expression decreased. For the first time, we could demonstrate the changes in TNIP1 expression after a xenobiotic exposure and its relationship with a pro-inflammatory signal. In summary, the results suggest that nanoparticle exposure results in an increase in the inflammatory ligand, which in combination with decreased inhibitory control on inflammatory signaling may predispose cells to the inflammatory response to otherwise less toxic xenobiotic exposure.

2119 Formation of Low Molecular Weight Products during Environmental Transformation of Graphene Oxide Modulates Toxicity in Aquatic Species

W. M. Henderson[1], J. C. Spear[2], R. F. Seim[2], R. G. Zepp[1], B. W. Acrey[1], and D. Bouchard[1]. *[1]US EPA/ORD, Athens, GA; and [2]Grantee to US EPA via Oak Ridge Institute of Science and Education, Athens, GA.*

Carbon-based nanoparticles (CNPs) are used extensively in industrial, consumer, and mechanical applications. Their unique structural properties provide novel opportunities to develop more robust and innovative commercial products including paints, fabrics, cosmetics and electronics. With increasing commercial use of CNPs, environmental exposure is growing increasingly common. Specifically, graphene oxide (GO) has been shown to compromise cell integrity via interactions with lipid membranes and subsequent induction of oxidative stress *in vitro*. An understanding of GO-membrane interactions and resulting potential of GO to perturb biological systems are crucial for estimating risk. To assess the exposure and toxicological implications of environmental transformations of GO in aquatic species, GO suspensions were photo-irradiated by simulated sunlight for up to 490 hrs. Fathead minnow (FHM) epithelial cells were exposed to both GO/reduced (rGO) suspensions as well as their filtrates. The formation of low molecular weight products (LMWPs) was assessed by mass spectrometry and metabolomic profiling was used to investigate the biological response in this ecologically relevant cell line. GO readily undergoes both direct and indirect photo-transformation processes and increasing time of irradiation increases the biological response of FHM cells. Both decreased size of GO (or rGO formation) as well as the formation of LMWPs are likely contributing to this cellular response. In FHM cells, GO induced changes in numerous markers of oxidative stress. Most biological pathways affected included perturbations in the citric acid cycle, glycolysis and amino acid metabolism. Removal of suspended GO/rGO via filtration still elicited a biological response in our test system. Mass spectral identification of the LMWPs suggested that the photo-production of polycyclic aromatic hydrocarbon (PAH)-like derivatives facilitate the measured response in FHM cells. Ultimately, identifying potential biomarkers of GO exposure and the development of exposure indices of GO and its photoproducts in human and ecologically relevant species will aid in accurately establishing risk.

2120 Liposomal Composition Can Affect Nanoparticle Transport into Epithelial and Endothelial Cells

W. Li[1], M. Ehrich[1], L. Costella[2], and Y. Hu[3]. *[1]Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA; [2]Luna, Charlottesville, VA; and [3]Luna, Danville, VA.*

Biologically compatible liposomes have value as vehicles for drug delivery. Potential capability of liposomes to cross membrane barriers of epithelial, endothelial, and astrocytic cells was examined using liposomes alone, liposomes with cholesterol, and liposomes with cholesterol and folate. The liposomes were composed of phosphatidylcholine derivatives and surfactants. FITC dye-labeled products were examined in transwell cultures of Caco-2 epithelial cells, HBEC-5i endothelial cells, and astrocyte cultures. With DMSO as a positive control, none of the liposomal products at 10 micromolar concentrations contributed to cell death in any of the cell cultures when examined 6 h after exposure. Cellular uptake measured at 4 h and 24 h demonstrated 34% and 88% of HBEC-5i had taken up the liposomes alone. Uptake of liposomes was 7.8% at 4 h and 34% at 24 h by astrocytes and 18% at 24 h by Caco-2 cells. Liposomes containing cholesterol with or without folate did not take up these FITC-labeled products in any of these cells. Liposomes with folate but without cholesterol resulted in 34% and 30% uptake, respectively, in Caco-2 and HBEC-5i cells after 24 hours. These results suggest that, for this particular liposomal nanomaterial, inclusion of cholesterol was detrimental to cellular uptake. *Supported at Virginia Tech by Luna Innovations, Inc.*

2121 Dermal Toxicity of Nickel- and Cobalt-Based Nanocatalysts

E. R. Kisin[1], S. Guppi[1], T. Khaliullin[1,2], N. Yanamala[1], and A. A. Shvedova[1,2]. *[1]NIOSH, Morgantown, WV; and [2]West Virginia University, Morgantown, WV.*

Nanocatalysis is a fast-growing field involving the use of nanomaterials as catalysts for a variety of applications, specifically, metal nanoparticles (NP) and their compounds, which have a large surface-to-volume ratio compared to bulk materials. Metal/metal oxide (Me/MeO) NP possess unique properties which can be useful in different applications including catalytic processes such as decomposition, reactions of dehydrogenation, oxidation, alkylation, C-C coupling, among others. Nonetheless, the same properties that make these metal nanocatalysts (NCT) very attractive can pose potential health risks. In addition to inhalation exposure route, workers may also be exposed through skin contact. In this study, we evaluated the ability of four different NCT ($NiFe_2O_4$, $CoFe_2O_4$, Ni and Co_3O_4) to initiate oxidative stress, induce redox-sensitive transcription factors and to trigger inflammation in primary human epidermal keratinocytes (HEK). Besides, due to the skin's vulnerability to UV radiation, it is important to assess whether metal NCT augment the adverse effects of UVB. HEKs exposure to the studied Me/MeO NCT (0-20 μg/cm^2) resulted in a dose- and time-dependent reduction in cell viability, cell damage, activation of NF-κB, elevated ROS generation, release of inflammatory mediators, and increase in oxidative stress markers. Co-exposure of HEK to UVB (4KJ/m^2) and Me/MeO caused marked amplification of the observed responses. UVB exposure alone induced significant cytotoxicity and secretion of cytokines/chemokines. Based on the hierarchical clustering analysis of the cytokine/chemokine responses, Co_3O_4 and Ni were segregated from the control and both ferrites-exposed samples. Pre-treatment with UVB resulted in separation of Ni, Co_3O_4 and $NiFe_2O_4$ responses from control and $CoFe_2O_4$ exposure groups. Overall the inflammatory responses in HEK cells induced by exposure to different Me/MeO NPs investigated, with or without UVB pre-treatment, were in order: Ni>Co_3O_4>$NiFe_2O_4$>$CoFe_2O_4$. Altogether, these data indicated that co-exposure of dermal cells *in vitro* to Me/MeO NP and UVB was associated with potentiation of the adverse effects as compared to the cells treated with NCT alone. *Disclaimer: The findings and conclusions of this report are those of the authors and do not necessarily reflect those of National Institute for Occupational Safety and Health.*

2122 Silver Nanoparticle-Mediated Mast Cell Degranulation Metabolic Pathway Shifts Are Distinct from IgE-Mediated Degranulation

R. Mendoza, C. Anderson, J. Roede, and J. Brown. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

Silver nanoparticles (AgNPs) are incorporated into a variety of consumer and medical products, primarily due to their antimicrobial properties, thereby leading to increased exposure in the general population. We have previously demonstrated that 20 nm AgNPs induce robust mast cell degranulation through a novel non-IgE mechanism. Mast cells are important effector cells in the immune system and are essential to an allergic response. To better understand this novel mechanism of mast cell degranulation, we characterized and compared cellular metabolic shifts across several mechanisms of degranulation (AgNP, IgE, compound 48/80 [non-IgE]) in murine bone marrow-derived mast cells (BMMCs). To explore these metabolic changes, we utilized functional assays to measure glycolysis and aerobic mitochondrial respiration in response to treatments. We observed an increase in ATP production which correlated to degranulation, however, differing levels of mitochondrial dysfunction and glucose uptake were observed between AgNP and other treatments. In addition, we utilized Seahorse XFp technology to measure: 1) preferential metabolic pathway phenotypes, 2) glycolytic metabolism, and 3) mitochondrial respiration metabolism. The cell phenotype test revealed that BMMCs shift away from glycolysis when degranulated via AgNP whereas IgE mediated degranulation preferentially utilized glycolysis. The Cell Mito stress test revealed a decrease in respiration for all mechanisms of degranulation, compared to control, with consistently lower levels for non-IgE degranulation. Compound 48/80, but not AgNP, also caused complete inhibition of glycolytic mitochondrial respiration reserve. We next observed a decrease in glycolysis that was most prominent in non-IgE degranulation. There was a complete depletion of glycolytic reserve, similar to mitochondrial respiration, with non-IgE degranulation (AgNPs and compound 48/80) that did not occur with IgE mediated degranulation. In conclusion, mast cell metabolism varies significantly between AgNP degranulation and IgE mediated degranulation suggesting novel cell regulatory mechanisms are potentially driving AgNP mediated mast cell degranulation.

2123 Potential Mitochondrial-Targeted Toxicity of Silver Nanoparticles in Mouse Hepatocytes

L. Wang[1], R. M. Zucker[2], D. F. Mello[1], W. K. Boyes[2], and J. N. Meyer[1]. *[1]Duke University, Durham, NC; and [2]US EPA/ORD, Research Triangle Park, NC.*

Silver nanoparticles (AgNPs) are a well-proven antimicrobial nanomaterial, which hold great promise for a wide range of biological applications. Despite the promising advantages, the significant human exposure to AgNPs has given rise to concerns over potential human health and environmental hazards. While multiple studies have investigated the toxic effects of various AgNPs at different levels, the underlying mechanism is still largely elusive. In this work, we explore the possible relationship between mitochondrial activity and the cytotoxicity of AgNPs with different coating and sizes, compared to silver ions, in cells cultured in glucose and galactose-based media. Since cells cultured in galactose rely mostly on oxidative phosphorylation (OXPHOS) to produce their ATP, they become more sensitive to mitochondrial toxicants than cells grown in glucose medium. Analysis of bioenergetic function with the XF Seahorse extracellular flux analyzer further confirmed that oxygen consumption rate (OCR) was significantly increased whereas extracellular acidification rate (ECAR), a measure of glycolysis, was decreased in cells grown in galactose. Cytotoxicity assays, mitochondrial stress analyses, and fluorescence and darkfield microscopy were used to investigate the effects of AgNPs on cell proliferation and metabolism. Our data suggest the sensitivity of mitochondria to AgNPs, which could in turn have an impact on cell viability and proliferation.

2124 *In Vitro* Pulmonary Toxicity of Copper Carbonate ($CuCO_3$) Particles Used as Outdoor Wood Preservatives

M. Hartman[1], M. Kubo[2], T. Luxton[3], C. Lau[3], and K. Dreher[3]. *[1]US EPA/ORAU, Oak Ridge, TN; [2]National Research Council, Washington, DC; and [3]US EPA, Research Triangle Park, NC.*

Micronized $CuCO_3$ containing nanoparticles (NPs) are employed as outdoor wood preservatives. This application raises a risk of human exposure to $CuCO_3$ NPs or their products with unknown health effects. Research examined the *in vitro* pulmonary toxicity of milled $CuCO_3$ particles and saw dust extracts (SDE) obtained from $CuCO_3$ treated and untreated wood. A thiobarbituric acid reactive substance (TBARS) assay measured the oxidative reactivity of all samples with and without the copper chelator triethylenetetraamine dihydrochloride (TETA). Analysis of milled $CuCO_3$ samples demonstrated samples containing the smallest size distribution displayed the greatest TBARS reactivity. SDE from only $CuCO_3$ treated wood displayed TBARS reactivity similar to milled $CuCO_3$ samples. TBARS reactivity of milled $CuCO_3$ and SDE from treated wood was eliminated after filtration through a 3kDa filter. TETA significantly attenuated TBARS reactivity of milled $CuCO_3$ samples but not SDE from treated wood indicating reactivity was not due to ionic Cu in the $CuCO_3$ treated wood. BEAS2B cells were exposed to either milled $CuCO_3$ samples (25 - 200 µg/ml) or SDEs (2.75 - 88 mg/ml) and cytotoxicity assessed using the WST1 assay at 22h post-exposure. Milled $CuCO_3$ samples with the smallest size distribution were most cytotoxic to BEAS2B cells. SDE from treated wood was more cytotoxic when compared to SDE from untreated wood. TETA attenuated BEAS2B cytotoxicity for both milled $CuCO_3$ particles and SDE from treated wood. On a molar dose metric, SDE from treated wood was more cytotoxic to BEAS2B cells compared to milled $CuCO_3$ samples. BEAS2B IL-6, IL-8, and HO-1 gene expression was examined by qRT-PCR after 3, 6, 12, 24, and 48h exposure to milled $CuCO_3$ samples or SDEs. Milled $CuCO_3$ and SDE samples induced proinflammatory and stress gene expression to varying extents in a time dependent manner and did not correlate with TBARS reactivity. Milled $CuCO_3$ particles elicited a completely different gene expression profile when compared to SDE from treated wood. These findings highlight the challenges in assessing the *in vitro* pulmonary toxicity of $CuCO_3$ treated outdoor wood samples using milled $CuCO_3$ with similar size distribution. The results indicate *in vitro* pulmonary toxicity should be assessed using the nano-enabled product. *This abstract does not represent US EPA policy.*

2125 Biological Effects of Long-Term Exposure of Human BEAS-2B and Met-5A Cells to Riebeckite/Tremolite Asbestos and Their Respective Cleavage Fragments

N. Yanamala[1], E. R. Kisin[1], S. Guppi[1], T. O. Khaliullin[1,2], M. Harper[3], and A. A. Shvedova[1,2]. *[1]NIOSH, Morgantown, WV; [2]West Virginia University, Morgantown, WV; and [3]Zefon International Inc., Ocala, FL.*

Asbestos is a commercial term that refers to 6 different fibrous minerals including riebeckite (RF) and tremolite (TF) amphibole asbestos. Inhalation of respirable forms of amphibole fibers, can cause asbestosis, lung cancer and both pleural and peritoneal mesothelioma. Amphiboles can also occur in a non-fibrous habit that can be mechanically broken into cleavage fragments (CF) which can meet the mineralogical/regulatory criteria for fibers. While the effects of RF and TF on health are well documented, there is uncertainty regarding the toxicity of riebeckite and tremolite CF. In this study, human epithelial (BEAS-2B) and mesothelial (MET-5A) cells were evaluated for the presence of several cancer hallmarks indicating the neoplastic-like transformation following continuous long-term (5 weeks) exposure to sub-toxic (2.5µg/cm^2) concentrations of RF, TF and their CF. TF- and RF-exposed cells, both BEAS-2B and MET-5A, revealed a neoplastic-like transformation phenotype characterized by significant increase in invasion/migration, anchorage-independent growth, proliferation, and morphological transformation, compared to controls. No anchorage-independent growth and invasion was observed in both cell types treated with riebeckite CF although an increase in DNA damage, migration, proliferation, and morphological changes were detected in BEAS-2B cells. In the case of tremolite CF, although a significant increase in proliferation, transformation and DNA damage was observed in both cell types, an increase in invasion/migration and anchorage-independent growth was detected only in BEAS-2B cells. Similarly, analysis of inflammatory responses suggested cell-type specific effects as well as treatment related differences. Overall, our data are compatible with the findings that amphibole asbestos fibers demonstrate higher neoplastic transformation potential compared to the respective CF (at the same mass dose) in both bronchial epithelial and mesothelial cells.

2126 Advanced *In Vitro* Models for the Assessment of Nanomaterial-Induced Lung Fibrosis

V. Sironval, D. Lison, and S. van den Brule. *Université Catholique de Louvain, Brussels, Belgium.*

Nanotechnology promises significant scientific, economic and societal benefits, but commercialization and growth are threatened by safety uncertainties. Existing *in vitro* hazard testing strategies to define the human health impact of nanomaterials (NM) commonly apply unrealistic acute, high-doses to cellular models that poorly reflect the *in vivo* environment. The H2020 project "*Physiologically Anchored Tools for Realistic nanOmateriaL hazard aSsessment*" (PATROLS) aims to establish innovative hazard assessment tools to predict adverse effects caused by long-term NM exposure, and support regulatory risk

decision making. In this project, we focus on the evaluation of the pro-fibrotic activities of NM and develop advanced *in vitro* models for the assessment of NM-induced lung fibrosis. Based on the central role of fibroblasts in lung fibrosis, we developed a strategy of fibroblast exposure mimicking the pulmonary environment of this cell type during inhalation exposure by assessing the responses to a direct contact of fibroblasts with NM, or indirect effects of NM on fibroblasts via their crosstalk with epithelial and inflammatory (mainly macrophages) cells. Pro-fibrotic responses to NM are examined in human lung fibroblast cell lines (MRC-5 and CRL1490) acutely (24 h) and chronically (8 weeks) exposed to low (realistic) doses of NM. Fibroblasts will also be treated with supernatants of epithelial and inflammatory cells (cultured alone or in co-culture) acutely or chronically exposed to NM to mimic the indirect activity of NM. Acute and chronic, as well as direct and indirect effects, will be compared to identify the modes of action of the tested NM. As we previously identified the activation of fibroblasts as a relevant key event with a high predictive value for lung fibrosis [1], we will focus on fibroblast proliferation, differentiation, collagen production, etc. The predictive value of the different models will be evaluated by comparing NM able to induce lung fibrosis *in vivo* (e.g. multi-wall carbon nanotubes, MWCNT) to non-fibrotic NM (e.g $BaSO_4$). High aspect ratio NM (MWCNT) will also be compared to low aspect ratio NM able to induce lung fibrosis (e.g. CeO_2). *In vitro* models and conditions are currently under development and preliminary results will be presented. 1. Vietti, G., D. Lison, and S. van den Brule, *Mechanisms of lung fibrosis induced by carbon nanotubes: towards an Adverse Outcome Pathway (AOP).* Part Fibre. Toxicol, 2016. 13(1): p. 11.

2127 Cytotoxicity of Engineered Nanomaterials on Primary Epithelial Cells in Air-Liquid Interface Culture

L. M. Tran, J. Bustamante, K. J. Mo, S. M. Thomasy, K. E. Pinkerton, and L. S. Van Winkle. *University of California Davis, Davis, CA.*

The unique physicochemical characteristics of engineered nanomaterials (ENMs) have led to their increased applications in pharmaceuticals, biomedical devices, and consumer products. ENMs range from 1-100 nm in at least one dimension and possess unique properties at an atomic level. They are often used to increase the quality of consumer products due to their stability, thermal conductivity, and mechanical properties and exhibit different properties depending on their size and surface area. Graphene is known for its optical transmittance and chemical inertness; graphene oxide and reduced graphene oxide nanoparticles have been incorporated in biomedicine for biosensing and drug delivery. Copper oxide nanoparticles exhibit high thermal conductivity, stability and potentially antimicrobial properties. The versatility and increasing use of ENMs raises concerns for human health since inhalation can be a major route of exposure with potential mechanisms of toxicity not well understood. Because ENMs vary in size, structure, and chemical properties, it is difficult to assess which characteristic is associated with biological toxicity. In order to shed light on the role of different physicochemical properties in respiratory toxicology *in vitro*, we exposed primary mouse tracheal epithelial cells on an air liquid interface (ALI) culture to well characterized ENMs of different chemical properties and sizes. These ENMs include: copper oxide, cadmium sulfide, molybdenum disulfide, hexagonal boron, graphene oxide in water, graphene oxide (250 nm), graphene (110 nm), and reduced graphene oxide. Cells were grown in culture until confluent and fully differentiated, then exposed to ENMs at concentrations of 125 or 250 µg/mL for 24 hours. Because assays for measuring cell number metabolically are prone to particle interference, cytotoxicity was determined by fluorescent microscopy on transwell membranes. Our results showed that copper oxide, hexagonal boron, graphene (110 nm), and reduced graphene oxide at a concentration of 250 µg/mL were cytotoxic as well as graphene oxide in water at 125 µg/mL. The remaining ENMs tested did not cause cytotoxicity. We conclude that this method can be used to study ENM toxicity and that copper oxide nanoparticles are cytotoxic to large airway epithelial cells. *Supported by U01 ES027288.*

2128 Exposure to Nanoparticles in a Food Matrix Alters Intestinal Function in an *In Vitro* Model

M. Malik, C. N. Marques, and G. Mahler. *Binghamton University, Binghamton, NY.*

Overall well-being is related to gut health and function. The gastrointestinal (GI) tract forms a selective barrier that protects the host from harmful luminal content and allows essential nutrients and water to pass into circulation. Food additives and microbial dysbiosis may influence intestinal health and activity of intestinal alkaline phosphatase (IAP), a gut mucosal defence factor, while playing a role in the development of GI disorders. An average of 10^{12}-10^{14} edible metal oxide nanoparticles (NP) are consumed per day. In this study, a Caco-2 and HT29-MTX E12 intestinal model of the GI tract was used to study the effects of food-grade titanium dioxide NP in a food matrix (FM) on intestinal permeability, IAP activity, and nutrient transport. The NP-microbiota-gut interaction was tested by including Gram-positive, commensal (*LactoBacillus rhamnosus*, *Bifidobacterium bifidum*) or Gram-negative, opportunistic (*Escherichia coli*) bacteria into the model. The model was subjected to 10^3 CFU/mL of bacteria and physiological doses of digested TiO_2 NP in FM. The FM was a semi-synthetic meal prepared with all the essential components of a regular diet. Cell membrane permeability was assessed by a Lucifer Yellow (LY) permeability assay. Glucose, protein and fatty acid transport were assessed using colorimetric assays. Post-exposure, bacterial cell viability was assessed with a drop plate method. While FM did not affect the barrier integrity, *E. coli*+TiO_2 NP in FM showed a decrease in permeability ($p<0.0001$) and IAP activity ($p<0.001$) compared to no bacteria condition. TiO_2 in FM led to a decrease in protein and triglyceride transport across the barrier. *E. coli* remediated this effect of NP. Glucose transport was unaffected by the NP. A permeable intestinal barrier can lead to systemic inflammation and potential tissue damage. The results of this study suggest that while TiO_2 affects protein transport, *E. coli* can ameliorate the changes. Dietary conditions influence the attachment of bacterial cells to the cell monolayer, further affecting the intestinal function. These results highlight the complex interaction of the microbiome, diet, and gut function. With the use of multiple human intestinal cell types, human-derived bacteria and digestion, our *in vitro* model provides a physiologically relevant method to investigate these interactions.

2129 Mechanisms of Rare Earth Metal Oxide Nanoparticle Toxicity in Macrophages

K. L. Rogers, K. N. Nguyen, and J. M. Brown. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

Rare earth metal oxide nanoparticles (REMO NPs) are synthesized from lanthanide series metals complexed with oxygen. REMO NPs are desired due to their unique chemical, catalytic, electrical, magnetic, and luminescent properties for applications in both material science and medicine. Occupational exposure to REMO NPs may occur through inhalation during their manufacturing. Additionally, biomedical use of these nanoparticles is increasing therefore it is important to understand their toxicity. Further, due to their novelty, the toxicity of these particles is not well characterized. Recently, several studies have shown adverse effects associated with exposure to REMO NPs including pulmonary inflammation *in vivo* and cytotoxicity *in vitro*. We hypothesized that toxicity of REMO NPs is due to their unique physicochemical properties and would elicit adverse immune responses in macrophages. Ten different REMO NPs were screened for cytotoxic effects by dosing the RAW 264.7 macrophage cell line with 1-50 µg/mL for 24 hours. Four nanoparticle types were selected for further testing and characterization based on differences in cytotoxicity profiles. These four were lanthanum oxide (La_2O_3) (high toxicity), gadolinium oxide (Gd_2O_3) (medium toxicity), neodymium oxide (Nd_2O_3) (medium toxicity), and europium oxide (Eu_2O_3) (low toxicity). Using these four REMO NPs, we further investigated the correlation of physicochemical properties to cytotoxicity and activation of macrophages including reactive oxygen species generation and cytokine production. It was found that hydrodynamic size and the amount of REMO NP uptake by macrophages directly correlated to cytotoxicity, mitochondrial disfunction, and inflammatory responses, thus, linking the physicochemical properties of REMO NPs to their effect on macrophages. In conclusion, the safety profile of REMO NPs should be further evaluated prior to incorporation in biomedical applications.

2130 Disruption of Bronchial Cell Monolayer Integrity by Organomodified Nanoclays and Their Incinerated Byproducts

T. Stueckle[1], A. White[2], A. Wagner[2], R. Gupta[2], Y. Rojanasakul[2], and C. Dinu[2]. *[1]NIOSH, Morgantown, WV; and [2]West Virginia University, Morgantown, WV.*

Organomodified nanoclays (ONCs) represent one of the most used engineered nanomaterials (ENMs) as nanofiller in emerging advanced manufacturing strategies to produce a diverse number of polymer nanocomposites. Different organic quaternary ammonium coatings on these 2-dimensional montmorillonite nanoclays allow for their incorporation in novel or replacement technologies in thin-film, aerospace, automobile, consumer, and health care polymer nanocomposite applications. Compared with other ENMs, little information exists on risks to occupational pulmonary health along the ONC life cycle that encompass synthesis, handling, manipulation, and disposal. This study hypothesized that coating type, incineration status, and time-dependent effects of ONC exposure would impact bronchial epithelial cell monolayer integrity, a key target following inhalation exposure. High-throughput *in vitro* screening strategies including high content imaging, electric cell impedance sensing, and flow cytometry were employed to evaluate a

set of pre- and post-incinerated ONCs for acute effects and fate of the monolayer post-exposure. Using each particle's IC_{50} cell viability in a BEAS-2B cell model, pristine nanoclay exposure caused acute loss of monolayer integrity, decreased metabolism, and increased apoptosis. Three different ONCs, however, displayed minimal loss to monolayer integrity despite coating type-dependent differences in apoptosis induction and decreased cell metabolism. Conversely, incinerated nanoclay byproducts caused decreased monolayer integrity, increased cell necrosis, and little evidence for reestablishment of the epithelial monolayer. These results suggest the type of quaternary ammonium coating and incineration status largely impacts mechanism of cytotoxicity, cell metabolism, and the recovery ability of the exposed bronchial epithelial cell monolayer. An integrated high-throughput *in vitro* screening strategy, using high content imaging and traditional *in vitro* methods, represents a rapid pulmonary epithelial toxicity assessment approach to prioritize ENMs for further evaluation and serves to inform 'prevention-by-design' material development strategies.

PS 2131 Selective Uptake of Carboxylated Multiwalled Carbon Nanotubes via Class A Type 1 Scavenger Receptors Impairs Viability and Phagocytic Activity in Macrophages

R. Wang, E. Chow, R. Lohray, P. Gangupantula, L. L. Smith, and R. Draper. *University of Texas at Dallas, Richardson, TX.*

Class A type 1 scavenger receptors (SR-A1) are involved in a variety of immunological and pathological responses. Our published work suggested that SR-A1 may be involved in the marked accumulation by cells of carboxylated multi-walled carbon nanotubes (C-MWNTs) compared to pristine MWNTs (P-MWNTs) (Wang et. al., *Nanotoxicology*, 2018). The studies in this poster confirm and extend the role of SR-A1 in mediating C-MWNT uptake. 1. Selective C-MWNTs accumulation correlates with surface SR-A1 receptor expression. RAW 264.7 and wild type B6 macrophages, which express high SR-A1 levels, accumulated high amounts of C-MWNTs, but not P-MWNTs or amino-functionalized MWNTs (N-MWNTs) at 37 °C. However, ZK macrophages, which are genetically deficient in SR-A1 receptors, did not accumulate significant amounts of C-MWNTs above background level. Further, stably transfected CHO cells that express mouse SR-A1 receptors had increased uptake of C-MWNTs compared to untransfected controls. 2. C-MWNT accumulation impairs phagocytic function via SR-A1 receptors. The physiological impact of C-MWNTs on subsequent phagocytosis of ligands that are known to interact with SR-A1 receptors was determined using confocal fluorescence microscopy and flow cytometry. There were significant reductions in the uptake of polystyrene beads and *E. coli* by RAW 264.7 cells pre-treated with C-MWNTs, but not with P- or N-MWNTs. The study on oxLDL uptake is underway. Further, the 24h continuous exposure of RAW 264.7 cells to C-MWNTs reduced surface SR-A1 receptors by almost 50%. 3. C-MWNT accumulation impairs macrophage viability. The impact of C-MWNTs on the proliferation of RAW 264.7 cells was assessed using a crystal violet assay and an 8d colony formation efficiency (CFE) assay. The accumulation of C-MWNTs impaired cell proliferation with IC50 values of 120 and 80 µg/mL for 48 and 72h exposure, respectively. P- and N-MWNTs have minimal effect on cell proliferation. In CFE assays, C-MWNTs reduced colony formation during an 8 day exposure with and IC50 of 29 µg/mL. These results confirmed that SR-A1 significantly contributes to the selective uptake of C-MWNTs and that SR-A1-mediated uptake of C-MWNTs impaired SR-A1-dependent phagocytic activities in macrophages and reduced cell viability.

PS 2132 Effect of Titanium Dioxide Nanoparticles on DNA Methylation in Human Cells

M. Pogribna, N. Koonce, A. Mathew, B. Word, A. K. Patri, B. D. Lyn-Cook, and G. J. Hammons. *US FDA/NCTR, Jefferson, AR.* Sponsor: I. Pogribny

The dramatically increased use of nanomaterials, including nanoscale titanium dioxide (TiO_2), raised the concern of their potential risk to human health. The present study aimed to further the understanding of the underlying mechanism of TiO_2 nanoparticles toxicity by examining the time-dependent alterations in cytosine DNA methylation induced by TiO_2 nanoparticles exposure *in vitro*. Human skin (A-431), lung (NL20), liver (HepG2), and colon (Caco-2) cells were treated with TiO_2 nanoparticles at the sub-cytotoxic doses for 24 and 72 hours. Treatment with TiO_2 nanoparticles resulted in global and gene-specific cytosine DNA methylation alterations. In particular, global DNA methylation decreased in three cell lines (Caco-2, HepG2, and A-431), while across the four examined cell lines, eight genes indicative of cellular stress response and toxicity (CDKN1A, DNAJC15, GADD45A, GDF15, INSIG1, SCARA3, TP53, and BNIP3) exhibited increased DNA methylation. Additionally, treatment with TiO_2 nanoparticles altered the expression of genes involved in establishing and maintaining DNA methylation patterns (DNMT1, DNMT3A, DNMT3B, MBD2, and UHRF) in cell-type- and time-dependent manner, with the greatest effects being found in NL20 and A-431 cells. The results of this study demonstrate that the sub-cytotoxic concentrations of TiO_2 nanoparticles induced treatment-related cytosine DNA methylation changes, indicating the potential value of epigenetic evaluation in the toxicity assessment of nanoparticles.

PS 2133 Survival Mechanisms in Keratinocytes Exposed to Subtoxic Concentrations of Metal-Derived Nanoparticles and Their Susceptibility to Xenobiotic Exposure

V. Montesinos[1], J. Rose[2], A. De Vizcaya[1], and R. Franco[2]. *[1]CINVESTAV, Mexico, Mexico; and [2]University of Nebraska, Lincoln, Nebraska, NE.*

Metal-derived nanoparticles (Mt-NPs) are increasingly used in cosmetology due to their ultraviolet shielding (titanium dioxide [TiO_2]), antioxidant (cerium dioxide [CeO_2]), and/or biocidal (silver [Ag]) properties. In the absence of overt toxicity (i.e. cell death), Mt-NPs are considered safe for their use in cosmetology. However, there is little understanding about the mechanisms involved in the survival of keratinocytes exposed to subtoxic levels of Mt-NPs, an issue that we aimed to address in this study. Human keratinocytes (HACAT) were exposed subacutely (48-72 h) to subtoxic concentrations (≤30 µg/ml), of rutile (r) TiO_2 (cylindrical), CeO_2 (cubic) and Ag (spherical) with a core / hydrodynamic size of <40 / <100 nm and >98% purity. Mt-NP uptake was quantified by changes in the light side scatter (SSC), where the kinetics (time-dose-response) suggested that they were internalized to a similarly extent by keratinocytes. rTiO_2 and CeO_2, but not Ag NPs, increased autophagy, and inhibition of autophagy flux (chloroquine) and autophagosome elongation (3-methyladenine) prompted cell death. In contrast, no increase in the steady-state levels of reactive oxygen species (ROS) was induced by exposure to any of the Mt-NPs tested. Interestingly, intracellular Ag aggregates observed a far-red autofluorescence (≥740 nm em), which has been ascribed to their binding to thiol molecules such as glutathione (GSH). Accordingly, inhibition of GSH synthesis with buthionine sulfoximine sensitized keratinocytes to Ag, but 6-aminonicotinamide, which impairs the recycling of oxidized GSH, had no effect on cell viability. rTiO_2 and Ag, compromised metabolic flux (glycolysis and mitochondrial respiration), but ATP levels were unaltered. Finally, we observed that Mt-NPs sensitized keratinocytes to non-UV xenobiotics (arsenite and paraquat). Our results demonstrate the differential contribution of autophagy and GSH metabolism to the survival of keratinocytes exposed to subtoxic concentrations of Mt-NPs, and highlight the increased susceptibility of keratinocytes exposed to Mt-NPs to xenobiotic exposure.

PS 2134 The ToxTracker Reporter Assay as a Tool for Mechanism-Based (Geno)toxicity Screening of Nanoparticles: Metals, Oxides, and Quantum Dots

S. McCarrick[1], F. Cappellini[1], N. Moelijker[2], R. Derr[2], G. Hendriks[2], and H. L. Karlsson[1]. *[1]Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; and [2]Toxys B.V., Leiden, Netherlands.*

The increased manufacturing and use of nanoparticles (NPs) require faster and more efficient testing of their potential toxic effects. Traditional *in vitro* genotoxicity assays are often time-consuming and have the limitation that they generally lack the ability to provide insight into the mechanisms. One alternative approach is the use of reporter cell lines to quickly assess the cellular stress response pathways that are activated after exposure to NPs. In this study the applicability of the ToxTracker reporter cell lines to identify the (geno)toxicity of various metallic- or metal oxide NPs (n=18) including quantum dots (QDs) of various sizes was explored. The ToxTracker results were compared with historical genotoxicity results and physico-chemical characterization of the various nanomaterials. The results show a large variation in cytotoxicity of the tested NPs. Furthermore, the primarily effect observed in ToxTracker was activation of the oxidative stress reporters although some NPs also induced the reporters for DNA damage. Some NPs were non-cytotoxic and did not cause a clear activation of any of the reporter cell lines (Au, Cr, Cr_2O_3, Pt, SnO_2 and V). Other NPs were highly toxic e.g. antimony (Sb) NPs causing cytotoxicity and activation of reporters at relatively low doses (<2µg/ml). These effects were also observed for Sb_2O_3 but at much higher doses. NPs of manganese (Mn and Mn_3O_4) induced the most remarkable response in the ToxTracker assay with induction of reporters for oxidative stress, DNA damage, protein unfolding and p53-related stress. The CdTe QDs were also highly toxic showing clearly size-dependent effects and calculations suggest that surface area is the most relevant dose metric. Of all metal- and metal oxide NPs investigated (n=33), CuO, Co, CoO, CdTe QDs, Mn, Mn_3O_4, V_2O_5, and welding NPs clearly induced the Rtkn DNA damage reporter (> 2-fold). Also, NPs of Ni, NiO and Cr_2O_3 induced a weak response of this reporter (>1.5

fold, <2-fold). Thus, these NPs may be of particular concern when considering genotoxicity of metal- and metal oxide NPs. Furthermore, these results indicate that ToxTracker can be used for rapid screening, ranking and first indication regarding which nanoparticles may be grouped together during risk assessment.

PS 2135 Assessing the Biological Impact of PEGylated Graphene Quantum Dots in THP1 Human Macrophages

D. Diaz-Diestra[1], M. Shehzad[2], T. Palacios[1], J. Noble[1], S. Skoog[1], B. Thapa[2], J. Zheng[1], J. Beltran-Huarac[3], J. Centeno[1], P. Goering[1], G. Morell[4], and B. Weiner[2]. *[1]US FDA, Silver Spring, MD; [2]Universidad de Puerto Rico, Rio Piedras, PR; [3]East Carolina University, Greenville, NC; and [4]Universidad de Puerto Rico, San Juan, PR.*

Novel uses of engineered nanomaterials in medical applications have increased patient exposures raising safety concerns that require further studies to elucidate cellular interactions at the nano-bio interface. Past evidence suggests that polyethylene glycol-functionalized (PEGylated) nanomaterials are largely biocompatible and elicit minimal immune/inflammatory responses compared to their uncoated counterparts. This finding was recently found to be contradictory in the case of graphene-related nanomaterials. Graphene quantum dots (GQDs) are a graphene derivative that are being investigated for different biomedical applications given their unique optical properties and high biocompatibility. The goal of this study was to assess the potential *in vitro* immunomodulatory effects of PEGylated GQDs on the expression of pro-inflammatory cytokines and NLRP3 inflammasome components in human macrophages. The influence of the polymer molecular weight (2K, 5K Da) and surface functional groups (carboxyl, amino, bare) on THP1 human macrophages was assessed by evaluating cell viability, cell uptake of nanoparticles, cytokine secretion, and lysosomal stability. Cells were exposed to 15, 100, or 200 µg/mL GQDs for 24 and 48 hr. No significant cytotoxicity was observed for bare and carboxyl-PEG-coated GQDs at all concentrations and different PEG molecular weights. For amino-PEG-coated particles, a decrease of 40% in cell viability was observed at concentrations >100 µg/mL after 48 hr at the 2KDa molecular weight. Likewise, amino-PEG-coated GQDs induced the higher production of pro-inflammatory cytokines in a concentration-dependent manner. Further, confocal imaging of cellular structure indicated a higher uptake of amino-PEG-coated nanoparticles, as well as lysosome dysfunction. Induced caspase 1 and IL-1β production after exposure to this group suggests the involvement of NLRP3 inflammasome components in this process. More importantly, our results indicate that by controlling PEG coating features in GQDs, such as surface functionalities (i.e., carboxyl and amino) and molecular weight, immunological reactions can be mitigated or stimulated and thereby provide useful tools for a safe-by-design approach.

PS 2136 Risk Assessment of *Fusarium* Synthesized Silver Nanoparticles on a Dermal Cell Line A431

I. R. Gupta[1], and M. K. Rai[2]. *[1]Govt. Institute of Science, Aurangabad, India; and [2]Sant Gadge Baba Amravati University, Amravati, India.* Sponsor: I. Gupta, American College of Toxicology

Regardless of development of nanotechnology and nanomaterials, their potential risks are also increasing. Although there is huge development in the synthesis of silver nanoparticles (AgNPs) by various routes and their applications, a little information is available on the risk associated with their use. Hence, the present study was focused on *Fusarium* mediated synthesis of AgNPs, followed by their in depth characterization and *in vitro* toxicity. We screened six *Fusarium* species viz., *F. graminearum*, *F. oxysporum*, *F. culmorum*, *F. tricinctum*, *F. equiseti* and *F. moniliforme* for the synthesis of AgNPs. The fungal filtrate of all these species shown the ability to reduce the aqueous silver ions into AgNPs. Analysis of all samples via UV-Visible spectrophotometry shown the absorption peaks at about 420 nm, which is specific for plasmon band of AgNPs. The Fourier Transform Infrared spectroscopic analyses indicated that proteins or peptides might have coated over the AgNPs, thereby avoiding their aggregation and therefore increasing their stability. This protein capping of nanoparticles provided AgNP a higher zeta potential value which was confirmed by Zeta Potential measurement. Nanoparticle Tracking Analysis (NTA) shown their mean diameter ranging from 25- 70 nm in aqueous media, whereas Transmission Electron Microscopic observation shown their size from 5-25 nm. *F. oxysporum* synthesised AgNPs were highly stable and uniform in size, hence, used for toxicity assessment. *In vitro* toxicity study was performed on A431 cell line derived from squamous cell carcinoma. The MTT assay concluded the IC50 value for AgNPs to be 32 µg/ml. The Lactate Dehydrogenase (LDH) leakage assay results demonstrated that exposure to AgNPs for 24 hours resulted in significant increase in LDH leakage in dose-dependent manner. Generation of Reactive Oxygen Species in cell exposed to AgNPs were confirmed by flow cytometry analysis. DNA fragmentation assay results showed AgNPs induced DNA damage to cells. The cell cycle analysis confirmed the higher percentage of cell arrest in G0/G1 phase due to cells treated with AgNPs exposure which supports the DNA fragmentation data. The study thus concludes that AgNPs cause damage to A431 cells, resulting into accumulation of ROS, DNA damage and injury to cell membrane. This mechanism of causing injury leads to death of cells exposed to fungal synthesized AgNPs. The data of the present study can be useful for safer application AgNPs.

PS 2137 Cytotoxicity of Zinc Oxide (Nano) Particles in a Rat Intestinal Cell Model: Effect on Cellular Glutathione and Mitochondria

T. E. Henson[1], J. Navratilova[2], A. H. Tennant[3], K. D. Bradham[3], K. R. Rogers[3], and M. F. Hughes[3]. *[1]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; [2]US EPA/NRC, Research Triangle Park, NC; and [3]US EPA/ORD, Research Triangle Park, NC.*

Zinc oxide nanoparticles (NPs) have a variety of commercial and biomedical applications ranging from UV filtration in sunscreen to anti-cancer, fungal and anti-microbial agents. Human oral exposure to zinc oxide NPs may occur following accidental or intentional ingestion, hand-to-mouth activity, or mucociliary transport following inhalation. This study assessed the cytotoxicity of two different sized ZnO particles (10 and 150 nm) in rat intestinal cells (IEC-6). The 10 nm particle is classified as a nanoparticle. Previously we have reported that the cytotoxicity of these two particles and Zn ions are time- and dose-dependent in these cells. Dissolution of the particles and $ZnSO_4$ in media with 10% serum protein was assessed over 24 h. Zn concentration in incubation filtrate was determined by ICP-OES and was assumed to be free Zn ion. Intracellular glutathione (GSH) concentrations and mitochondrial area were assessed in the IEC-6 cells using spectroscopic methods after a 4-h exposure to the particles (0.1 - 100 ug/mL) or $ZnSO_4$ (100 ug/mL). Dissolution studies in media showed that both particles formed soluble Zn ions, and that media components bind these ions. At 24 h, approximately 40% of $ZnSO_4$, 40% of 10 nm ZnO and 30% of 150 nm ZnO was detected as free Zn ion in the filtrate. In H_2O, 100% $ZnSO_4$ was detected in filtrate at 24 h, showing complete dissolution. A significant dose-dependent decrease in cellular GSH and mitochondrial area was detected in the IEC-6 cells after a 4-h exposure to both particles and $ZnSO_4$. Both cellular GSH and mitochondrial area in treated cells decreased up to 40% relative to non-treated cells. The results suggest that ZnO particles, of both the measured sizes, form Zn ions in media. Decreased cellular GSH may result from the reaction of this thiol with reactive oxygen species, which may be formed by Zn ions. The increased oxidative stress in the treated cells may also be damaging to the mitochondria. An imbalance of a cellular antioxidant such as GSH caused indirectly by Zn ions formed from ZnO particles may result in impairment of organelles such as the mitochondria resulting in cell death. *This abstract does not represent US EPA policy.*

PS 2138 Characterization of the Trajectory of Human Neural Progenitor Cells *In Vitro*: System Comparisons for Sex-Specific Developmental Neurotoxicity Testing

Y. J. Suh[1], D. M. Leme[2], S. Hong[1], S. H. Wegner[1], J. J. Park[1], T. Workman[1], M. N. Smith[1], W. C. Griffith[1], and E. M. Faustman[1]. *[1]University of Washington, Seattle, WA; and [2]Universidade Federal do Paraná, Curitiba, Brazil.*

Growing efforts have been designated to develop *in vitro* models capable of evaluating chemical effects on developing brains due to the relevance of this organ on the quality of human life. Several methods based on brain-derived cells in culture have been proposed; however, they were not designed to evaluate effects including biological variables such as sex. Sex influences cellular function and metabolism that may lead cells to respond to environmental toxicants in sex-specific manner, which, in turn, may result in difference of disease incidences between men and women. Our previous study has characterized the normal temporal pathway dynamics of differentiation of a promising *in vitro* model for toxicity screening by culturing human neural progenitor cells (hNPCs) of female origin (H9, hNP1™). In the present study, we have described the behavior of hNPCs originated from male donor (H14, NSC-H14) to verify the applicability of this hNPC line together with H9 in *in vitro* sex-specific developmental neurotoxicity testing. To compare, both cell lines were maintained under the same culture conditions (*i.e.*, coated plates, culture media, passage number) and their *in vitro* behavior were evaluated regarding doubling time, morphology, and dynamics of neuronal differen-

tiation (hematoxylin and immunohistochemical staining, and western blot) up to 21 days *in vitro* (DIV). Both hNPCs presented population doubling time of 72 hours and they were able to differentiate *in vitro* and to form neurons, increasing extension of neurite outgrowth and neuronal foci formation across *in vitro* culture. Hematoxylin staining allowed for a comparison of foci development. Western blot analysis with specific neuronal markers was used to track the similarities between the differentiation profile. Our characterization of normal development of hNPCs from male and female origins *in vitro* and observation of differences and similarities would be an essential tool when interpreting toxicological effects and examining role of sex in neurodevelopmental toxicity.

PS 2139 Biotransformed Nanomaterial Surface Charge Influence on Human Liver Cell Line Toxicity

M. R. Mulenos, H. Lujan, L. R. Pitts, and C. M. Sayes. *Baylor University, Waco, TX.*

Interest in silver nanoparticle transformation has grown due to the roles they play in maintaining the sterility of biomedical products, food storage bags, and personal care products. Silver nanoparticles are intentionally ingested in fruit juices where they act as clarifying agents and unintentionally ingested when they leech from food packaging. While the literature has extensively studied the adverse health outcomes of silver nanoparticles, these studies have been limited to engineered nanoparticles. There is an increasing need to investigate the toxicity of biologically transformed nanomaterials. Ionic silver nanoparticles elicit toxicological effects at high and low concentrations, however it is unclear if biotransformed nanoparticles will illicit the same responses. Here, we studied biotransformed silver nanoparticles of either positive, negative, or neutral charge. Each nanoparticle system was incubated in different physiologically-relevant environments: acidic stomach fluid, neutral blood serum, and basic surfactant fluid. Their associated effects were studied on human hepatoma cells, HepG2. Endpoints of viability, oxidative stress, and DNA and mitochondrial damage were measured. Our results indicate that the positive and negative nanoparticles biotransformed with acidic stomach fluid increased oxidative stress in the cells compared to other nanoparticles due to their increased ion production. Nanoparticles incubated in neutral blood serum produced a net negative surface charge due to protein corona formation on the surface. The nanoparticle protein corona complexes were seen to have a decrease in adverse effects due to the protective protein corona masking potentially disruptive mechanisms from occurring. The nanoparticles incubated in basic surfactant fluid had negligible effects compared to the other biotransformed nanoparticles. Additionally, surface charge influenced the uptake mechanism in which the biotransformed particles entered the cell, which was confirmed by hyperspectral imaging. Monitoring the toxicological effects of biotransformed nanoparticles along their product life cycle is necessary to accurately describe real life exposure scenarios.

PS 2140 Changes in Cellular and Secreted Lipids after Exposure to Single-Walled Carbon Nanotubes Have Impacts on Susceptibility to Influenza A Virus

T. Sabo-Attwood[1], S. Humes[1], L. Ingram[2], M. Finnerty[2], J. Lednicky[1], and B. Cummings[2]. *[1]University of Florida, Gainesville, FL; and [2]University of Georgia, Athens, GA.*

Nanoparticles (NP) are used in industry and consumer products; however, we are just beginning to mechanistically understand how exposure to NP impacts human health. Research has focused on pulmonary endpoints such as fibrosis, allergic-type reactions, and cancer, while the area of viral susceptibility remains less well explored. Work by our group has determined that exposure of human small airway epithelial cells (SAECs) to single-walled carbon nanotubes (SWNTs) increases host susceptibility to Influenza A virus (IAV) infection, as evidenced by increased viral titers and repressed anti-viral gene expression. We also demonstrated that this effect is only observed if SWNT exposure precedes IAV infection by 24 hours, suggesting that the cells are "primed" in a way which makes them more susceptible to infection. To elucidate perturbations that might act as priming mechanisms, we investigated how SWNTs modulate cellular and secreted lipids using untargeted lipidomics. We hypothesized that SWNTs change intracellular membrane and secreted lipids, resulting in an environment that is more conducive to supporting a productive IAV life cycle. For our approach, we exposed SAECs to 20 µg/mL SWNTs for 24 hrs and collected the cells and media for separate lipidomics analyses. Lipids were extracted per the Bligh-Dyer method, followed by LC-ESI-MS/MS analysis. We observed enrichment of several classes and species in both the cellular and secreted lipid landscapes. In cells, SWNT exposure resulted in significant enrichment of phosphatidylcholines (PC), phosphatidyethanolamines (PE), plasmenyl species, sphingomyelins (SM), and oxidized triglycerides (OxTG). In the secreted lipidome, SWNT exposure resulted in significant increases in PE, oxidized lysophosphatidylethanolamines (OxLPE), plasmenyl species, SM, ceramides (Cer), and OxTG. We speculate that these changes could "prime" the cells to be more susceptible to virus infections, perhaps by altering the host cell membrane to aid IAV in entry and egress. These observations demonstrate a novel role for SWNTs in perturbing both cellular and secreted lipid landscapes, with downstream impacts on susceptibility to infection. Future work will focus on impacts of increasing or decreasing lipid levels in cells, in the absence of SWNTs, and the subsequent effects on IAV infection in SAECs. These studies highlight the important role that lipid metabolism plays in host-pathogen interactions and targets these pathways in SWNT toxicity.

PS 2141 Using a Model Lysosome Membrane to Study Nanomaterial-Membrane Interactions That Cause Cytotoxicity

D. S. Anderson, M. J. Sydor, H. B. Steele, B. L. Kendall, S. J. Ross, and A. Holian. *University of Montana, Missoula, MT.*

The increased production of engineered nanomaterials (ENM) have enhanced the risk of human exposure. Many types of ENM are taken-up by phagocytic cells, such as alveolar macrophages, where the ENM accumulate in phagolysosomes. Accumulated ENM have been shown to cause a leakage of phagolysosomes membranes, resulting in phagolysosomal membrane permeability and the release of hydrolytic enzymes into the cytosol, causing inflammation and cytotoxicity. This suggests that ENM may interact directly with lipid membranes. We designed model lipid systems to study interactions between ENM and lipid membranes to assess ENM-lipid interaction. Liposomes (100 nm) were generated from lipids found in lysosomes: bis(monooleoylglycero) phosphate (BMP), 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC), and 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine (DOPE) or 1,2-dioleoyl-sn-glycero-3-phospho-L-serine (DOPS), in a molar ratio of 2:3:3. Tris-buffered saline (TBS, pH 7.4) and acetate-buffered saline (ABS, pH 4.5) were used to mimic the pH of early and late lysosomes. Liposome structure was evaluated using transmission electron microscopy; all preparations were 100 nm in diameter and unilamellar. Liposomes were exposed to either two types of titanium dioxide (TiO_2) ENM, nanospheres (TNS) or nanobelts (TNB), or zinc oxide (ZnO) nanospheres for 2 hours at 25, 100 or 200 µg/ml. Time-resolved fluorescence anisotropy, a measure of depolarized light, was performed using the fluorescence membrane probe di-4-ANEPPDHQ and a custom-built time-resolved fluorometer to measure changes in membrane fluidity (reported in cone angle, a measure of probe wobble). Liposomes (BMP:DOPC:DOPE) exposed to TNS (100 µg/ml) showed no difference in cone angle versus control in either buffer. However, TNB exposure produced significant decreases in cone angle in TBS at 200 µg/ml (36.42±0.31° to 32.84±0.33°) and in ABS at both 100 and 200 µg/ml (34.92±0.52° to 34.30±0.83° and 30.88±0.12°). Even though the surface area of TNS was greater than TNB the lack of effect supported that shape was important. ZnO ENM exposed liposomes composed of BMP:DOPC:DOPE showed no significant change in cone angle (100 µg/ml). However, BMP:DOPC:DOPS liposome had a significant decrease in cone angle (37.60±0.35° to 34.12±0.30°), indicating lipid headgroup can influence interactions. *Funding: NIH R01ES023209, 1F32ES027324, P20GM103546, P30GM103338 and J Murdock Charitable Trust.*

PS 2142 Novel Approach for Characterizing Exposure and Response to Engineered Nanomaterials in the Gut

J. Oldach, P. Llanos, M. Klausner, A. Armento, Y. Kaluzhny, and S. Ayehunie. *MatTek, Ashland, MA.*

Despite the expanding number of applications for engineered nanoparticles (ENPs), human health concerns associated with ingested nanoparticles are poorly understood. In this study we utilized 3D human small intestinal tissue model to develop a physiologically relevant test system to assess toxicological profiles of ingestible nanomaterials. We examined barrier integrity and cytotoxicity of the human 3D intestinal tissue model following exposure (4 doses of each nanoparticle to Cupric (II) oxide (CuO) (50 nm in size), zinc oxide (ZnO, 35-45 nm in size)), and titanium oxide (TiO_2, 40 nm in size). To monitor reproducibility of the test method the nanoparticles were tested using 3-4 intestinal tissue lots. To determine the effect of the nanoparticles on the small intestinal tissues, we examined 1) barrier integrity (TEER), 2) tissue viability (MTT), and inflammatory response (ELISA assay). In the various experiments performed, the tissues were exposed to 40 ul of different doses of sonicated nanoparticles under rocking condition for 4 hr. After 4 hrs, dosed tissues were further cultured for overnight under static condition. Using IC_{15} (concentration that reduces barrier function or tissue viability by 15%) as a cut off, we

observed a dose response reduction of barrier integrity and tissue viability for CuO and ZnO. However, Titanium oxide did not induce toxicity for the concentrations tested. Furthermore, culture supernatants collected from at 24 hr of the culture period were also analyzed for inflammatory response and the result showed a dose dependent release of IL-8 for CuO and ZnO. Overall, the TEER measurement was a sensitive endpoint compared to the MTT tissue viability assay. In summary, the use SMI tissue model to examine the toxicity profile of ingested nanotoxicity will also enhance our understanding of nanoparticle-host cell interaction, improve dose/design, generate a physiologically relevant data set, and provide greater insight into *in vivo* responses.

PS 2143 Silver Nanoparticles (AgNP) Exposures on *In Vitro* Proliferating and Differentiating Human Neural Progenitor Cells (hNPCs): Importance of Windows of Susceptibility

J. J. Park, S. Hong, T. Workman, R. Dills, J. Lee, W. C. Griffith, and E. M. Faustman. *University of Washington, Seattle, WA.*

Silver nanoparticles (AgNPs) have been used increasingly in various consumer, medical, and commercial products for their unique antibacterial properties. Increasing number of studies, however, have raised concerns regarding exposures to AgNPs regarding their potential adverse impacts on humans, specifically for effects on brain development and function. This study was designed to examine the effects of gold-cored AgNPs on *in vitro* human neural progenitor cell (hNPC) cultures and evaluate dose-response related impacts to using commercially available hNPC H9 (hNP1™). Three types of AgNPs—20 nm AgCitrate, 110 nm AgCitrate, and 110 nm AgPVP—were used, and the effects of these particles by size and coating were evaluated on proliferating at day 1 or differentiating hNPCs at day 1 or 7. Exposures to AgNPs (0 – 50 µg/mL) demonstrated significant dose-dependent decreases in cell viability. We discovered that the differentiating hNPCs at day 7 received the least impact compared to proliferating and differentiating hNPCs at day 1. For 20 nm AgCitrate, differentiating hNPCs at day 1 were the most susceptible to AgNPs; however, proliferating hNPCs at day 1 were most vulnerable to larger AgNPs (110 nm AgCitrate and 110 nm AgPVP). Significant effects of particle coatings, sizes, and neurodevelopmental stages were observed for all particles. Our results suggested that the "window of susceptibility" for AgNPs is dependent on particle sizes; however, the impacts may be greater during the early developmental period than late. Together with other *in vitro* neurodevelopmental models, these offer approaches to assess both environmental and time-specific factors influencing neurodevelopmental susceptibility.

PS 2144 Titanate Nanosheets Cause Vacuolar ATPase-Dependent Apoptosis of Human Monocytes through Lysosomal Toxicity Not Related with Augmented Autophagy

Y. Nishimura, D. Yoishioka, N. Kumagai-Takei, S. Lee, K. Yoshitome, and T. Otsuki. *Kawasaki Medical School, Kurashiki, Japan.*

Titanate nanosheet (TiNS) is a promising 2D material with very thin structure. In our previous study, it had been found that TiNS exposure caused caspase-dependent apoptosis of human monocytes with formation of giant vacuoles, in which there were engulfed TiNSs. Therefore, the present study examined functions of lysosome and autophagy in human monocytes exposed to TiNS. $CD14^+$ monocytes were magnetically purified from PBMCs and cultured with TiNS or TiO_2-P25 nanoparticles at 10 µg/ml. TiNSs, having thin and diamond-like shape with about 20 and 30 nm diagonals, were synthesized from $Ti(O\text{-}i\text{-}Pr)_4$ and NEt_4OH by a method of liquid-phase synthesis. Both of TiNS and TiO_2 caused increase in lysosome at the early stage of culture assayed by flow cytometry, but TiNS-exposure monocytes finally showed five times greater lysosome level than TiO_2-exposed those. On the other hand, when mRNA expressions of autophagy-related genes functioning in the stages of nucleation, omegasome formation and elongation were examined by realtime RT-PCR, TiNS-exposed monocytes showed increases in expression of many kinds of genes including ATG101, Beclin-1, ATG9A, ATG3, ATG7, ATG12 in contrast to TiO_2 exposed those, indicating augmented autophagic machinery. As autophagy finish through fusion of autophagosome and lysosome, we examined which excessive generation of lysosomes or augmentation of autophagic machinery is attributed to apoptosis of monocytes exposed to TiNS. Bafilomycin A1, which suppresses vesicular acidification by inhibiting vacuolar ATPase (v-ATPase) in lysosomes, reduced formation of giant vacuoles and apoptosis of monocytes upon exposure to TiNS. In contrast, wortmannin, an inhibitor for PI3K which functions in autophagy, did not increase or decrease apoptosis of monocytes upon exposure to TiNS. In addition, bafilomycin A1 partially restored suppression in cell growth of human monocyte-like cell line THP1, whereas wortmannin caused more suppression in it. Those results indicate that TiNS has a harmful potential to cause v-ATPase-dependent apoptosis of monocytes through lysosomal toxicity, not related with augmented autophagy. Our findings suggest characteristic toxicity of TiNS which is not observed in TiO_2 nanoparticles.

PS 2145 Linking Aluminum Nanomaterial Induced Changes in Mitochondrial Ultrastructure to Alterations of Extracellular Flux: Structure/Function Validation of Mitochondrial Dysregulation

H. Lujan, M. R. Mulenos, M. Gibb, L. R. Steele, D. Carrasco, and C. M. Sayes. *Baylor University, Waco, TX.*

The use of engineered aluminum nanomaterials as an additive in consumer and industrial products is increasing due to their special properties. Specifically, aluminum is highly utilized as a fuel additive, in automotive construction, and in a multitude of consumer products. There is a high risk of occupational, consumer, and environmental exposure, however the mitochondrial toxicity of aluminum and aluminum oxide nanomaterials is relativity unknown. Aluminum nanomaterials are known to accumulate within mitochondria and perturb mitochondrial processes, but the specific mechanisms of toxic action remain unknown. There is a need to develop high throughput toxicological testing methods focused on elucidating aluminum nanoparticle (AlNP) toxicities. The purpose of this study was to determine the extent of AlNP induced changes in mitochondrial structure and perturbation of mitochondrial health in an effort to link together these two endpoints. To determine changes in mitochondrial health, three different epithelial cell-types from the upper airway with varying phenotypes were selected as a test system. The three phenotypes include primary cells (PTBE), cancer cells (A549), and asthma cells (DHBE). These cells were selected because (1) they represent a wide range of cell lines that are commonly used in pulmonary toxicology and (2) it is possible to determine the extent the phenotype will modulate resultant toxicities. Mitochondrial ultrastructure was assessed via transmission electron microscopy while cellular mitochondrial biogenesis (i.e. ATP production) was measured using multiple assays on an extracellular flux analyzer. Differential dose-response patterns were seen in both the morphological and bioenergetic assessments. The alterations of mitochondrial shape and cristae structure integrity measured via transmission electron microscopy analysis was correlated to the resulting changes in mitochondrial coupling efficiencies as well as real-time ATP production. These results exemplify the necessity to conduct multitargeted analyses to better evaluate mitochondrial health. Furthermore, the techniques used to probe overall mitochondrial health and mitochondrial specific ATP production after exposure to environmental contaminants will become increasing important as the production of nanomaterials continues to increase.

PS 2146 Effects of Nanoparticle and Microbiota Exposure on Mucus Composition in an *In Vitro* Gastrointestinal (GI) Tract Model

R. Limage[1], E. Tako[2], C. N. Marques[1], and G. J. Mahler[1]. *[1]Binghamton University, Binghamton, NY; and [2]USDA-ARS, Robert W. Holley Center for Agriculture and Health, Ithaca, NY.*

In vitro models of the gastrointestinal (GI) tract incorporating co-cultures of Caco-2/HT29-MTX-E12 have been shown to be a reliable and cost-effective experimental method to understand the effects of commonly used metal oxide nanoparticles (NP) as food additive. The relatively small size of NP enables them to easily cross cellular barriers and create free radical in tissues that can damage the cells and mucus layer that line the GI tract. The human GI tract is composed of a single layer of epithelial cells protected by a mucus layer, and the microbiota. The GI mucus forms a single, easily removable layer in the small intestine and a double layer firmly attached to the epithelium in the colon. The mucus traps and transports debris and bacteria, lubricates, and lowers mechanical stress on the epithelium. However, few studies have been performed on the intestinal mucus lining to better understand the role it plays as a protective barrier. The goal of this study is to determine if and how the mucus layer is affected by the presence of commensal, Gram positive (*LactoBacillus rhamnosus GG*) or opportunistic Gram negative (*Escherichia coli* ATCC 11775) bacteria and exposure to physiologically relevant doses of pristine or digested metal oxide NP using an *in vitro* model of GI tract. To observe and measure the role of bacteria on mucus function and how food additives might alter this relationship, cells monolayer was exposed to bacteria and physiologically relevant doses of TiO_2, ZnO, Fe_2O_3 or SiO_2 nanoparticles for up to four hours. Mucus was then stained with Alcian Blue (AB), Periodic Acid Schiff (PAS), or an Alexa Fluor® 488 conjugate of Wheat germ agglutinin (WGA) to determine mucus thickness and composition. The composition of mucosubstances in the cell culture model was then analyzed and the results indicate that mucus secretion increased in the presence of bacteria and sig-

nificantly decreased following exposure to pristine or digested NP and bacteria. Exposure to both commensal bacteria, opportunistic bacteria, and NP has impacts on the mucus layer. Changes in the distribution or pattern of acidic and neutral mucins are indicative of certain pathological conditions, and our model provides a platform for understanding changes in the mucus layer.

2147 High Content Single Cell Image Analysis of Sub-Cytotoxic Phenotypic Changes Driven by Carbon Nanomaterial Exposure

A. E. Simmons, I. Wong, and A. Kane. *Brown University, Providence, RI.*

Toxicologists experience challenges evaluating sub-cytotoxic toxicant exposures. We have developed a single-cell screening platform capable of evaluating high-content confocal images to quantify single-cell, sublethal phenotypic changes driven by carbon nanomaterial exposure. We hypothesized that dysregulation of fibroblasts, wound-healing cells responsible for excessive ECM deposition in fibrosis, could be driven in part by the mechanical stimuli associated with stiff, pristine carbon nanomaterials and that this response is masked by traditional stiff cell culture techniques. Through image segmentation pipelines and multivariable regression analyses, we identified single-cell features predictive of phenotypic change driven by carbon nanotubes and 5 µm graphene exposures, but not non-toxic carbon black or nano-graphenes. Soft substrate culture marginally decreases overall fibroblast differentiation but promotes significant changes to nuclear morphometry, cytoskeletal and nuclear texture, and differentiation mechanism endpoints. Cells exposed to any nanomaterial on stiff substrates have similar phenotypic signatures, while soft substrates sensitize cells to carbon nanotubes and group graphene exposures together, suggesting geometry-specific responses masked by stiff substrate culture. Multi-variable PCA plotting identifies a greater spread of soft substrate cell phenotypes associated with carbon nanotube and 5 µm graphene exposures, quantifying single-cell sensitivity to nanomaterial exposure typically unquantifiable without single-cell omics. Finally, we identified predictive phenotypic features through correlation and feature reduction analyses, highlighting 16 significant soft substrate feature relationships. These image analysis and quantification platforms can be used by toxicologists to identify predictive features of sub-cytotoxic and toxic effects in any cell type. Additionally, this universally relevant platform can also be used to evaluate the phenotypes of collected primary cells, stem cells, cancer-associated fibroblasts, etc. This work is currently being adapted to analyze monoculture and coculture 3D *in vitro* microtissue models of disease for nanomaterial toxicity screening. *This research is supported by the NIEHS Training Grant T32 ES07272, NIEHS Superfund Research Program P42 ES013660, NIEHS U01ES028184-02, and Unilever.*

2148 Understanding the Protective Role of Gut Microbiota following Metal Oxide Nanoparticles Exposure Used as Food Additives

A. Garcia Rodriguez, F. Moreno-Olivas, C. N. H. Marques, and G. Mahler. *Binghamton University, Binghamton, NY.*

Nano-sized metal oxides are commonly added to processed foods and food packaging as have been demonstrated to improve food quality. The present study mainly focused on evaluating the potential effects of four different types of metal oxide nanoparticles (NP) that are commonly used in food packaging, like zinc oxide, or as food additives like iron oxide, silicon dioxide, and titanium dioxide. Since this NPs will be orally ingested, digested and finally reaching the duodenum (the first part of the small intestine), our laboratory has aimed to mimic this environment using an *in vitro* model of the gastrointestinal tract (GIT) called Caco-2/HT29-MTX. This model has gained attention in nanotoxicology as a useful method for evaluating the digestion of NP. The GIT environment, however, is composed of both human cells and gut microbiota. It is well-known that the intestinal microbiota, which is primarily composed of bacteria, forms a complex ecosystem and plays an important role in the health of the host. The gut microbiota has been shown to be involved in basic human biological processes, like regulating epithelial development and influencing innate immunity. Thus, to observe the role of bacteria in the gut function and to determine how NP can alter this relationship, we co-exposed the model with bacteria to all four NP and analyzed intestinal alkaline phosphatase (IAP), aminopeptidase-N (APN), sucrase-isomaltase (SI) and Na^+/K^+ ATPase activity. For that purpose, we used two common strains of commensal and opportunistic intestinal bacteria, *LactoBacillus rhamnosus GG and* a non-pathogenic *Escherichia coli* strain, respectively. Our results showed that following exposure to digested NP, the IAP, APN and SI activity was altered. Brush border enzymes are known to control many physiological gut processes and activities, such as the digestion of peptides and nutrient transport. Changes in their activity may be related to chronic diseases such as obesity, inflammatory processes, and malnutrition. However, the presence of bacteria attenuated the NP effects playing then a protective role toward the small intestine. We finally demonstrate by confocal imaging that these bacteria can attach, and in some cases surround, to big NP aggregates impeding them to get in contact with the cell membrane and cell microvilli.

2149 Elucidation of Carbon Nanodot Uptake Routes in Macrophages

A. Dunphy[1], A. Penningon[1], K. Patel[1], S. Belperain[1], N. Chiu[1], H. Zhu[2], R. Y. Li[2], and Z. Jia[1]. *[1]University of North Carolina at Greensboro, Greensboro, NC; and [2]Campbell University School of Osteopathic Medicine, Buies Creek, NC.*

Carbon nanodots (CNDs) are among the most recent nanoparticles to generate interest in the research. CNDs are less than 10 nm in size and exhibit ideal and unique properties such as photoluminescence and biocompatibility. These properties make CNDs useful in bio-sensing, bio-imaging, and drug delivery. However, there is no report denoting potential uptake routes of CNDs into any cell type. In this study, THP-1 human monocytes were used to be differentiated into macrophages by 12-o-tetradecanoylphorbol acetate (TPA). We examined CNDs cellular uptake by quantification of the fluorescence of this nanoparticle in THP-1 monocyte-derived macrophages, and potential uptake routes by treatment with a selection of transport inhibitors. Cytochalasin A was used to inhibit the polymerization of actin and nocodazole was used to inhibit microtubule cytoskeleton. The result showed that CNDs were found to be uptaken into macrophages. However, cells treated with either cytochalasin A or nocodazole showed significant inhibition of CNDs uptake. These results suggest that both actin and microtubule cytoskeleton might be implied in the CNDs uptake mechanisms.

2150 Critical Evaluation of Potential Nickel-Containing Nanoparticles Toxicity

S. L. More[1], M. Kovochich[2], T. Lyons-Darden[3], M. Taylor[3], A. M. Schulte[4], and A. K. Madl[4]. *[1]Cardno ChemRisk, Portland, OR; [2]Cardno ChemRisk, Chicago, IL; [3]NiPERA, Durham, NC; and [4]Cardno ChemRisk, Aliso Viejo, CA.*

The exceptional physical and chemical properties of nickel nanomaterials have been exploited in a range of applications including catalytic reactions, electrical conductors, magnetic materials, fuel cells, pigmentation, alloys, batteries, and biomedical materials. However, it has been suggested that these unique properties of nickel nanomaterials may allow for increased bioavailability, bio-reactivity, and potential adverse health effects. Therefore, the purpose of this study was to critically evaluate data regarding the toxicity of nickel nanoparticles with respect to: 1) physicochemistry - metal specification, surface chemistry, dissolution, size distribution, morphological characteristics, 2) quality of nanomaterial characterization in the defined delivery media, 3) routes of exposure and target organ effects, 4) appropriateness of model system and translation to potential human effects, and 5) current research data gaps and likely directions of future research. A literature search was conducted through October 2017 and a total of 112 relevant articles were identified. The reliability of the studies was evaluated using modified Klimisch scoring. Nickel oxide and metallic nickel were the most common forms of nickel nanoparticles and particle size ranged from 4 to 100 nm. Inhalation data in rodents indicated that the inflammatory response induced by doses of nickel nanoparticles up to 1222 µg/m^3 was characterized as acute in nature and only displayed chronic effects after relatively large exposures. Furthermore, there is no evidence, thus far, to suggest that the effects induced by nickel nanoparticles, including inflammation, oxidative stress, and cytotoxicity, are related to preneoplastic events. There is some data to suggest that nano- and micron-sized nickel particles follow a similar dose response when normalized to surface area. However, future experiments need to be conducted to better characterize the dose-response relationship according to surface area, which drives particle dissolution and potential biological responses. Taken together, this analysis critically evaluated the biological responses and associated health endpoints for nickel nanoparticles along with considerations that should be taken into account when interpreting the data.

2151 Activities of Renal and Testicular Electron Transport Chain Enzymes in Wistar Rats Exposed to Titanium Dioxide Nanoparticles

S. A. Kehinde. *Federal University of Agriculture, Abeokuta, Nigeria.*

Safety of Titanium dioxide nanoparticles (TiO_2 NPs) remains unclear because data on absorption, distribution, elimination or any adverse effects after oral exposure are extremely limited. Since disorders of energy metabolism are being recognized as incipient biochemical events in the toxicity associated with toxicants, this study determined the activities of electron transport chain (ETC) enzymes-Combined complex I+III, CPI+III; Combined Complex II+III, CPII+III; Complex IV, CPIV in male wistar rats exposed orally to TiO_2 NPs (8-12nm) (50, 150 and 250 mg/kg body weight [BW]) for 4, 8 and 12 weeks. Control rats received distilled water for the same period. At the end of TiO_2 NPs exposure, mitochondria were isolated from kidney and testes and activities of the ETC enzymes determined. While renal CPI+III was down-regulated at 8 and 12 weeks, renal CP II+III activity was increased at 4 weeks, with the highest increase occasioned by exposure to 150mg/kg BW dose of TiO_2NPs. At 12 weeks however, the three doses of TiO_2 NPs decreased the activity of the renal enzyme especially with the 250 mg/kg BW of TiO_2 NPs. Renal CPIV followed the same pattern as that of CPII+III. The three doses of TiO_2 NPs increased testicular CPI+III at 4 weeks, with the highest increase (5-fold increase) observed with the 150mg/kg BW of TiO2 NPs. While a duration-dependent increase in activity of testicular CPII+III was observed with exposure to 50mg/kg BW of TiO_2 NPs, a duration-dependent decrease was observed with the 250 mg/kg BW of TiO_2 NPs. The 150mg/kg body weight of TiO_2 NPs however increased the activity of the testicular enzyme by 60% at 4 weeks but decreased the same at 12 weeks by 26%. In contrast to CPII+III, testicular CPIV was characterized by a duration-dependent increase on exposure to the 250mg/kg BW and a duration-dependent decrease with the 150mg/kg BW dose of TiO_2 NPs. Our findings indicate that exposure to TiO_2 NPs modulates renal and testicular ETC and this might be important in renal and reproductive pathologies.

2152 Evaluation of *Hyalella azteca* Sensitivity to Acute and Chronic Silver Nanoparticle Exposures

J. Kusi. *East Tennessee State University, Johnson City, TN.*

There is limited information on *Hyalella azteca* responses to silver nanoparticles despite the widespread incorporation of nanoparticles in medical and consumer products as a result of their antimicrobial properties. About 220 to 312 tons of AgNPs are produced globally per year and 0.1 ng/L AgNPs with 14 nm has been detected in surface waters indicating the presence of the nanoparticles in aquatic systems. *Hyalella azteca* are likely to be affected by AgNP exposure because they are highly sensitive to ionic silver. The current study evaluated AgNP toxicity to *H. azteca* in reformulated moderately hard reconstituted water to determine whether the amphipods are sensitive to nanoparticle exposure. Test organisms (7-8 days old) were exposed to different concentrations of 10 nm citrate-coated AgNP with five replicate beakers for 10 and 28 days in a static-water-renewal system. Ten *H. azteca* were added to each replicate beaker containing 100 mL sand as a substrate. Aliquots of test solutions were centrifuged, digested, and analyzed using furnace atomic absorption spectrometer to measure dissolved Ag, which was used for all statistical analyses. One-way ANOVA and Dunnett's test were used to determine the effects of citrate-coated AgNP on the survival and growth of *H. azteca*. Median lethal concentration (LC50) for survival and median effective concentration (EC50) for growth were calculated using probit analysis and Toxicity Relationship Analysis Trap respectively. Citrate-coated AgNP significantly reduced growth (dry weight) from 0.15 to 0.07 mg at 10.8 µg/L ($p < 0.05$) for the 10-day acute exposure. For the 28-day chronic exposure, citrate-coated AgNP significantly reduced growth from 0.63 to 0.40 mg at 7.2 µg/L ($p = 0.01$). The LC50 (95% confidence interval) for survival in the acute exposure was 7.8 (7.2-8.4) µg/L and the EC50 (95% confidence interval) for growth was 3.4 (1.2-9.4) µg/L. The LC50 for survival in the chronic exposure was 4.1 (1.4-5.5) µg/L and the EC50 for growth was 1.0 (0.1-8.3) µg/L. Growth was more sensitive to citrate-coated AgNP compared to survival in both acute and chronic exposures. We conclude for the first time that citrate-coated AgNP poses a potential risk to survival and growth of freshwater *H. azteca* populations, thus there may be the need to monitor the release of AgNPs into aquatic systems.

2153 Public Health Application of Sustainable Nano-Drugs and Nanocarriers

B. Sharp[1], T. Varzeas[1], T. Ameh[1], C. Sayes[1], and E. Braswell[2]. [1]*Baylor University, Waco, TX; and* [2]*USDA Animal and Plant Health Inspection Service, Edinburg, TX.*

Metal nanoparticles have found a vast range of applications in many commercial products, environmental remediation, and biological therapy. Some metal nanoparticles, particularly silver and copper, display antimicrobial properties at the nano scale. This concept further illuminates their potential to be synthesized and used in the control of disease pathogens of public health significance. In the present work, silver and copper nanoparticles were synthesized using three different capping agents and were characterized through dynamic light scattering (DLS), ultraviolet-visible spectroscopy (UV-Vis) and Fourier-transform infrared spectroscopy (FTIR). Silver and copper nanoparticles were synthesized and functionalized with surface capping agents to give them unique surface properties; polyvinylpyrrolidone (PVP), cetyltrimethylammonium bromide (CTAB), and citrate (Cit) coated silver nanoparticles as well as PVP, CTAB and ascorbic acid (AA) copper nanoparticles were synthesized. The synthesized nanoparticles were exposed to Gram-negative *Escherichia coli* and gram-positive *Staphylococcus aureus* bacteria to assess antimicrobial sensitivity of the nanoparticles using the disk diffusion method. The results show that AA coated copper nanoparticles and PVP coated silver nanoparticles had the highest mean zones of inhibition against the growth of *E. coli* (11.56 mm, 10.44 mm respectively) and *S. aureus* (17.33 mm, 14.67 mm respectively) in comparison to other nanoparticles after 24 h of incubation. The Cit coated silver nanoparticles showed no effects on inhibition of both gram-negative and gram-positive bacteria growth. These results illustrate the efficacy of zerovalent nanoparticles as nanocarriers and nanodrug agents in the control of disease causing bacterial pathogens of public health significance due to their antibacterial properties at the nanoscale.

2154 A Novel Strategy to Evaluate the Degradation of Quantum Dots: Identification and Quantification of CdTe Quantum Dots and Corresponding Ionic Species by CZE-ICP-MS

P. Huang, and P. Meng. *Capital Medical University School of Public Health, Beijing, China.*

Understanding of the potential risks of quantum dots (QDs) to human health is becoming hotspot in the study of clinical applications of QDs. The gradation of QDs has been suggested to be the causes of their overall toxicity. However, further exploring the toxic mechanism of QDs still has a great technical challenge, especially how to identify and quantify QDs and its degradation products (corresponding ionic species) *in vivo* and *in vitro*. A method for the separation and simultaneous determination of CdTe QDs and its corresponding ionic species (Cd^{2+} and TeO_3^{2-}) in complex matrices was developed using capillary zone electrophoresis (CZE) coupled to inductively coupled plasma-mass spectrometry (ICP-MS) for the first time. Under optimal experiment conditions, the Cd^{2+} in different matrices was proportionally transformed into Cd^{2+}[1]and Cd^{2+}[2] species. The Cd^{2+}[1] was considered to be a kind of complex of $Cd^{2+}$and serum albumin. The Cd^{2+}[2] was probably a Cd^{2+}-$B_4O_7^{2-}$-H_3BO_3 complex. The values of the Cd^{2+} and Cd of CdTe QDs were quantified by the external calibrationcurve of Cd^{2+}[2] and Cd^{2+} (Cd^{2+}[1]+Cd^{2+}[2]), respectively, with a limit of detection(LOD) of sub-microgram per liter. The TeO_3^{2-} and Te of CdTe QDs were quantified by the external calibration curve of TeO_3^{2-} with a LOD of microgram per liter. Moreover, the quality assessment of commercial CdTe QDs and serum pharmacokinetics of synthesized CdTe QDs in rats were successfully undertaken by the developed CZEICP-MS. The identification and quantification of CdTe QDs and its degradation products can be determined simultaneously in a single run by the proposed CZE-ICPMS. This developed method provides a strategy not only for the systematic investigation of absorption, distribution, metabolism, excretion, and transformation (ADME/T) of QDs in animal tissue and cells but also for comprehensively understanding the degradation rules of QDs and their toxicity mechanism.

2155 Effects of Transport Inhibitors on the Cellular Uptake of Carbon Nanodots in Human Microvascular Endothelial Cells

S. Belperain, Z. Kang, R. Mahmoud, N. Chiu, H. Zhu, R. Y. Li, and Z. Jia. *University of North Carolina at Greensboro, Greensboro, NC.*

Carbon nanodots (CNDs) are a new form of nanoparticles that have been utilized in many areas in medical research. With these particles being less than 10nm in size and possessing unique photoluminescent characteristics, they

receive much attention for their potential usages in biosensing, bioimaging, and drug delivery. With the potential biomedical applications of CNDs, knowing and understanding their route of uptake into a cell is a critical piece of information that is still unanswered. In this study, we examined the possible route of uptake of CNDs within human microvascular endothelial cells (HMECs) by using several known transport inhibitors. The result showed that CNDs can uptake into HMECs, which utilize the intrinsic fluorescence of CNDs that has an emission signal at 460 nm upon excitation with a 360 nm laser. CNDs uptake was significantly affected by ebselen, which is a known inhibitor of mammalian H+, K+-ATPase, n-phenylanthranilic acid, a known chloride channel inhibitor, and chlorpromazine, a known suppressor of clathrin disassembly. Our data has suggested that CNDs might use different pathways to enter endothelial cells.

2156 ICONS: Integrated Testing Strategy for Mechanistically Assessing the Respiratory Toxicity of Functionalized MWCNT

O. H. Creutzenberg[1], D. Lison[2], S. Van Den Brule[2], F. Turcu[3], J. C. Bonner[4], and C. Ziemann[1]. *[1]Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany; [2]Louvain Centre for Toxicology and Applied Pharmacology, Louvain, Belgium; [3]Universitatea Babeş-Bolyai, Cluj, Romania; and [4]North Carolina State University, Raleigh, NC.*

Toxicological concerns are opposed to the promising technical properties of multiwalled carbon nanotubes (MWCNT). Meeting WHO fiber criteria MWCNT can be carcinogenic (rigid type) or non-carcinogenic (tangled type) depending on fiber length and diameter. The project ICONS focused on the comparison of core MWCNT vs. surface-modified MWCNT (both tangled type) regarding their fibrotic and genotoxic potential. Purification of core MWCNT (chemically or thermally) and surface functionalization (-COOH or -NH2) of the industrially relevant Nanocyl NC7000 were varied. At Fraunhofer ITEM, the eight resulting MWCNT (pristine, milled, purified, and functionalized) were tested for sterility and endotoxin contamination. For *in vitro* use, they were dispersed using an ultrasound-based protocol, and characterized by light and scanning electron microscopy. Subsequent *in vitro* (geno)toxicity testing with MRC-5 primary human lung fibroblasts revealed differential inhibition of proliferation (RICC, mitotic index) and induction of membrane damage, DNA-strand breaks and micronuclei. Using primary human mesothelial LP9 cells, a variable number of differentially expressed genes was noted. Based on these *in vitro* data and the *in vivo* data, generated by LTAP and NCSU, the COOH-functionalized chemically purified (NC3151) and thermally purified (NC-PlacylCOOH) samples were selected for a 4-wk inhalation study in rats (design based on OECD TG 412; 0.2, 1 and 5 mg/m^3), including a 4-wk recovery (validation test). As a reference group, the thermally purified NX7100 sample (non-functionalised core) was included with 5 mg/m^3 only. Pre-trials demonstrated feasibility of generating respirable MWCNT aerosols by dry dispersion with pressurized air, supported by a jet mill. The differential cell count analysis, the levels of lactic dehydrogenase, beta-glucuronidase and total protein in bronchoalveolar lavage fluid and the histopathological examination resulted in the following ranking: NC3151 < NX-7100 (core) = NC-PlacylCOOH, indicating that the purification method seems to be important. *This ERA-NET SIINN project was funded by the German BMBF (FKZ: 03XP0063).*

2157 Investigating Barrier Capacity of Human Placenta to Foodborne TiO_2 Nanoparticles (E171) Using an *Ex Vivo* Perfusion Model and Ti Quantification in the Placenta and Meconium

A. Guillard[1], E. Gaultier[1], C. Cartier[1], L. Devoille[2], J. Noireaux[2], L. Chevalier[3], F. Grandin[1], C. Coméra[1], M. Morin[4], C. Vayssière[4], N. Feltin[2], N. Bekhti[5], K. Adel-Patient[5], K. Chardon[6], V. Bach[6], P. Fisicaro[2], N. Picard-Hagen[1], and E. Houdeau[1]. *[1]Toxalim INRA, Toulouse, France; [2]LNE, Paris, France; [3]GPM CNRS, Rouen, France; [4]Centre Hospitalier Universitaire de Toulouse, Toulouse, France; [5]SPI CEA-INRA, Saclay, France; and [6]PERITOX, Université de Picardie Jules Verne, Amiens, France.* Sponsor: R. Barouki

Food-grade titanium dioxide (TiO_2, white pigment E171 in EU) contains up to 55% (number-based) of nanoparticles (NPs). Despite low intestinal absorption, human dietary exposure is chronic (0.2-10 mg/kg/day) and TiO_2-NPs pass to the bloodstream and accumulate in systemic organs. In rodents, perinatal exposure to TiO_2-NP models showed transplacental transfer with health effects in offspring. The current study aims at evaluating whether the NP fraction of E171 may cross the human placenta. Term placentae and meconium were collected after delivery with mother consents. Basal titanium (Ti) levels were assessed by inductively coupled plasma-mass spectrometry (ICP-MS). Crystal TiO_2 forms were assessed on placenta tissue sections and fetal exudate by energy dispersive X-ray analysis (EDX) coupled with transmission and scanning electron microscopy (TEM/SEM-EDX), respectively. Placentae were perfused in a double open circuit for 30min of equilibrium with Earle's medium (EM), followed by 1h of EM alone (controls, n=2) or supplemented with E171 (15µg/ml, n=7). Passive antipyrine transfer rate served as viability marker. Passage of laser-reflective particles was evaluated by confocal microscopy on fetal exudate every 5min, and particle nature and size analyzed by SEM-EDX and ImageJ software. Basal Ti levels were 0.10±0.13 mg/kg in 92% of placentae (n=23/25), and 0.19±0.13 mg/kg in 36% of meconium (n=4/11). Anatase and rutile TiO_2 particles were commonly found in placentae. Laser-reflecting particles were detected in fetal exudate 10min after E171 addition in the maternal side. SEM-EDX imaging showed TiO_2 particles of diameters <200nm in the fetal side, 83% of them were NPs. In conclusion, circulating TiO_2 accumulates in the human placenta with Ti recovered in the meconium, demonstrating materno-fetal passage. *Ex vivo*, a placental transfer of E171 (TiO_2) particles mostly concerned NP fraction. These data emphasize the need of risk assessment in pregnant women of chronic exposure to TiO_2-NPs of dietary origin.

2158 DNA Damage Caused by Nickel Nanoparticle Exposure in Lung Epithelial Cells

Y. Mo, Y. Zhang, and Q. Zhang. *University of Louisville, Louisville, KY.*

Nickel and nickel compounds are highly carcinogenic and nickel nanoparticles (Nano-Ni) are becoming increasingly used in industry (e.g. magnetic tape, pastes, catalytic materials, microfilters, etc). More interestingly, due to unique chemical and physical properties of nanostructure, nickel alloy nanomaterials have received special interest in biomedical applications. Our previous studies showed that exposure to Nano-Ni caused severe and persistent lung inflammation, which were strongly associated with pulmonary toxicity. In addition, exposure to Nano-Ni caused HIF-1α nuclear accumulation. The overall hypothesis of this study is that Nano-Ni may exert genotoxic effects via alternation of cell homeostasis through a mechanism mediated by activation of ataxia-telangiectasia mutated (ATM) and HIF-1α accumulation. We compared the ability of non-toxic doses of Nano-Ni and Nano-TiO_2 to cause DNA damage and explored the possible mechanisms. Our results showed that exposure of normal human bronchial epithelial cells BEAS-2B to Nano-Ni caused a dose- and time-response increase in the expression of phosphorylated histone H2AX (γ-H2AX), Rad51 and phosphorylated p53, indicating DNA damage. However, exposure to Nano-TiO_2 did not cause those effects. To investigate the potential pathways involved in the Nano-Ni-induced DNA damage, we determined the phosphorylation of ATM and found that phosphorylation of ATM was increased when BEAS-2B cells were exposed to Nano-Ni. Furthermore, pre-treatment with KU55933, a specific inhibitor of ATM, suppressed Nano-Ni-induced p53 phosphorylation and Rad51 expression. Our results also showed that exposure of BEAS-2B cells to Nano-Ni caused HIF-1α accumulation, up-regulation of miR-210, and down-regulation of Rad52. Rad52 is a key factor in homologous recombination repair. Our *in vivo* studies also showed that exposure of mice to Nano-Ni caused increased expression of phosphorylated γ-H2AX and Rad51, and enhanced phosphorylation of p53 in the lungs. Thus, Nano-Ni-induced DNA damage may be induced by Nano-Ni-induced ATM activation and HIF-1α accumulation. These findings have important implications for understanding the potential health effects of nanoparticle exposure. *This work was partly supported by ES023693, ES028911, and HL147856 from NIH, and Kentucky Lung Cancer Research Program to Dr. Qunwei Zhang.*

2159 Modeling the Influence of Carbon Nanotube and Nanofiber Physicochemical Properties on Key Molecular Initiating Events and Functional Endpoints Using Epithelial, Macrophage, and Fibroblast Cell Models

V. K. Kodali[1], F. Kelly[1], J. Hubczak[1], K. Siegrist[2], A. K. Bauer[2], L. M. Sargent[1], M. Shoeb[1], T. A. Stueckle[1], T. Eye[1], A. Stefaniak[1], M. M. Dahm[1], M. Schubauer-Berigan[1], T. Boots[1], N. Yanamala[1], and A. D. Erdely[1]. *[1]NIOSH, Morgantown, WV; and [2]University of Colorado Anschutz Medical Campus, Aurora, CO.*

There is a significant interest in using *in vitro* systems to evaluate toxicity of ever-increasing nanomaterial variants and other toxicants. We used 7 multiwalled carbon nanotubes and 2 carbon nanofibers (CNT/F) from U.S facilities to evaluate predictability, sensitivity, and the relationship of physicochemical characteristics to key molecular initiating events and functional responses following exposure. Additionally, the predictability of *in vitro* model systems to *in vivo* outcomes from a complementary study was determined. The CNT/F represent a good model as they are known to induce cytotoxicity, inflammation, pathology, and genotoxicity. The particulates had a wide distribution in

length (0.1-50 µm), diameter (6-397 nm), dustiness (0.2-4.9 %), metal contaminants (0.3-6.2 %), surface area (18–238 m2/g), and density (0.007–0.22 g/cm3). Endotoxin and PAH levels were below detection limit and zeta potential were similar for all materials. Genotoxicity was evaluated in human lung epithelial cell line, BEAS-2B, at 0-24 µg/ml. Acute toxicity, inflammation, inflammasome signaling, and phagocytic activity were evaluated in the differentiated human monocyte cell line, THP-1, at 0-60 µg/ml. Collagen production, TGFβ levels, and αSMA signaling were evaluated in primary human lung fibroblast cells at 0-9.6 µg/ml. Unsupervised approaches were initially used to identify classes of materials with similar outcomes followed by supervised learning approaches to identify specific physicochemical characteristics driving toxicity responses. It was clear certain physicochemical characteristics were the primary drivers of specific outcomes. Often, a multifactorial approach, meaning a combination of physicochemical characteristics, best described a particular outcome. Analysis of complementary endpoints in a concurrent *in vivo* study indicated some *in vitro* tests shared similar predictability suggesting some utility for predictive *in vitro* toxicity evaluation. These included specific measures of inflammation and pathological outcomes. The general conclusions of the analysis suggest that the class of materials, carbon nanotubes and nanofibers, can be subdivided based on specific endpoints, some aspects of *in vitro* outcomes predict *in vivo* toxicity, and the methodological approach can possibly be adapted beyond the finite scope of this study.

PS 2160 The Role of Macrophage Surface Receptors on the Uptake and Binding of Protein-Coated MWNTs

M. Huynh, C. Mikoryak, P. Pantano, and R. Draper. *University of Texas at Dallas, Richardson, TX.*

Multi-walled carbon nanotubes (MWNTs) pose a human respiratory hazard because they can cause pulmonary fibrosis, which may lead to mesothelioma. A key event in the fibrotic pathway is the interaction of MWNTs with macrophages that may result in chronic inflammatory responses, but the mechanisms are not clear. An important question is whether macrophages have MWNT receptors that might initiate or modulate signals involved in inflammation. A complicating factor is that *in vivo* a protein corona, derived from serum proteins such as bovine serum albumin (BSA), may influence the interaction of MWNTs with cells. The interaction of BSA-coated carboxylated MWNTs (cMWNTs) and pristine (pMWNTs) with mouse RAW 264.7 macrophage cells was studied using a gel electrophoresis assay to quantify cell-associated MWNTs (Wang et al., *Anal. Chem.* 2009, 81, 8, 2944-2952). Both MWNT types accumulated as a function of time and concentration. To assess the potential role of cell surface receptors on macrophages, the binding of BSA-coated cMWNTs and pMWNTs to RAW 264.7 cells at 4°C in medium without serum was measured. At low temperature phagocytosis is inhibited, so that only binding of MWNTs on the cell surface is measured. Further, the absence of serum eliminates complications in interpreting the data that could arise due to the interaction of other serum proteins with the MWNTs to form an undefined protein corona. These studies directly demonstrated binding of both MWNT types to the cell surface that was a saturable function of MWNT concentration, supporting the idea that receptors bind BSA-coated MWNTs. The effect of BSA on the binding of BSA-coated MWNTs to the cells at 4°C showed that BSA reduced binding by 50%. Previous work suggests that scavenger receptors on macrophages bind cMWNTs (Wang et. al., Nanotoxicology, 2018, 12, 7, 677-698, DOI: 10.1080/17435390.2018.1472309). We found here that dextran sulfate, a known antagonist of Class A scavenger receptors, inhibited the binding of BSA-coated MWNTs to RAW 264.7 cells by a maximum of 50%. This suggests that on these macrophages there might be dextran sulfate sensitive and insensitive receptors.

PS 2161 Toxic Effects of Molybdenum Trioxide Nanoparticles (MoO_3 NPs) on Rat Pleural Mesothelial Cells (RPMCs) and Lavaged Cells from the Lungs of Golden Syrian Hamsters

E. A. Huber, and J. M. Cerreta. *St. John's University, Queens, NY.*

MoO_3 NPs are used in industrial, agricultural and biomedical applications due to their physical characteristics. The risk of exposure and possible adverse health effects to humans increases during the manufacturing and handling of such materials. The purpose of this study was to investigate the toxicity of MoO_3 NPs in cultured cells and in the cells isolated from bronchoalveolar lavage fluid (BALF) from Golden Syrian hamsters. Cultures of RPMCs (CCL-216) were exposed to MoO_3 NPs (100, 200, 300, 400, 500, 600, 700 or 800µg/mL) for 24 hours and compared to a vehicle control. Cytotoxicity was assessed by MTT and LDH assays. A concentration of 400µg/mL MoO_3 NPs was further evaluated (~LC_{50}). Capsase 1 and 3 protein levels were also measured in both groups. In addition, hamsters were exposed via inhalation and divided into four groups: 1) no exposure, 2) exposure to aerosolized water for 4h/day for 8 days, 3) exposure to 5mg/m^3 MoO_3 NPs for 4h/day for 8 days (*5-NP*) and 4) a group given a recovery period of one week (*5-REC*) following a *5-NP* exposure. Cultures of RPMCs treated with MoO_3 NPs had increased levels of: LDH (178%), caspase 3 (14%) and caspase 1 (29%) as compared to a control. BALF from the *5-NP* group had increased: total protein levels (62%), total cell counts (58%), neutrophils (870%) and multinucleated macrophages (465%) as compared to controls. BALF from the *5-REC* group had displayed parameters similar to controls, but had an increase of lymphocytes (938%) compared with controls. Tissue sections from the lungs of MoO_3 NPs treated groups of hamsters had membrane blebbing and hyperplasia of the airway epithelia with areas of cell proliferation at the periphery of the lung. Hamsters of the *5-NP* group had increased TUNEL positive cells in airway epithelia. Results from this study indicate cytotoxicity in RPMCs treated with 400µg/mL MoO_3 NPs may be mediated by both oncosis and apoptotic pathways. Animals exposed to 5mg/m^3 MoO_3 NPs had an initial acute inflammatory reaction as indicated by an alteration of BALF cells and protein levels that resolved to a chronic reaction with increased lymphocytes and hyperplasia in the airways. Cellular membrane blebbing in airway epithelia and an increase in TUNEL positive cells in hamsters exposed in the *5-NP* group support apoptosis as a possible pathway of injury.

PS 2162 *In Vivo* Lung Toxicity Associated with Boron Nitride Nanotubes with Different Purities

X. Xin[1], M. Barger[1], K. A. Roach[1], L. Bowers[1], V. Kodali[1], M. B. Jakubinek[2], K. Kim[2], S. Dénommée[2], M. G. Wolfarth[1], S. S. Leonard[1], D. W. Porter[1], A. D. Erdely[1], and J. R. Roberts[1]. *[1]NIOSH, Morgantown, WV; and [2]NRC Canada, Ottawa, ON, Canada.*

Boron nitride nanotubes (BNNTs), a newly emerging nanomaterial with enhanced physicochemical properties, are increasingly incorporated into industrially relevant applications. Currently, commercial production of BNNTs is synthesized with 30-60 % residual compounds and impurities. The goal of this study was to assess the lung toxicity associated with *in vivo* exposure to BNNTs with various purities. Three BNNT samples with a gradient of purity were provided by the National Research Council, Canada, to assess lung toxicity *in vivo*: a low purity as-produced sample with ~50% BNNT (BNLP), an intermediate purity sample (BNMP), and a highly purified sample with >90% BNNT (BNHP). Hexagonal boron nitride (h-BN, <100 nm in diameter) was used as a control material for one of the by-products during synthesis affecting the purity of the BNNT material. All BNNT samples tested were shown to be agglomerated bundles of BNNTs (~3 to 5 walls/tube) with boron and h-BN as the primary impurities. Sample purity was confirmed by electron microscopy (EM). The BNNT samples prepared in dispersion medium (DM) were 0.5-1.5 µm in length and 5-30 nm in diameter. Male C57BL/6 mice were exposed by oropharyngeal aspiration to 4 or 40 µg of sample/mouse dispersed in DM or DM alone on day 0. Animals were euthanized at 4 h, 1 d, 7 d, 1 m, and 3 m post-exposure and lung lavage was performed to evaluate lung injury and inflammation. At 4 h post-exposure, lactate dehydrogenase (LDH) activity and neutrophils influx, indicators of lung injury and inflammation, were significantly increased by high dose of BNMP and BNHP. At 1 d and 7 d post-exposure, the effects were greatest in the high dose of all three tested BNNT samples, with BNHP>BNMP>BNLP, and persisted in the BNHP group up to 1 m post-exposure. Irritant response, indicated by eosinophils increase, was observed in the high dose of BNNT groups at 1 d and 7 d post-exposure, with BNHP>BNMP>BNLP. Lung lymphocytes continued to increase in the BNHP group up to 1 m post-exposure. The results indicated that the tested BNNT samples induced acute toxicity and inflammation only at high concentration and the effects were more pronounced with increasing purity. The reference material used to represent one of the by-products of synthesis, h-BN, did not show significant lung toxicity, suggesting lung effects where present may be due primarily to BNNTs.

PS 2163 Analysis of Nanoparticle Uptake by Disease Vector of Economic Importance

T. Ameh[1], K. Zarzosa[2], T. Varzeas[1], B. Sharp[1], M. Gibb[1], C. Sayes[1], and E. Braswell[2]. *[1]Baylor University, Waco, TX; and [2]USDA Animal and Plant Health Inspection Service, Edinburg, TX.*

The spread of vector-borne pathogens by arthropod hosts continue to cause human, animal and plant diseases of public health and economic importance. Using the integrated vector management approach, this study utilizes nanoparticles as potential targeted anti-pathogenic agents for the control of citrus greening disease. *Candidatus Liberibacter asiaticus*, the bacterial pathogen of citrus greening disease is spread by the Asian citrus psyllid (*Diaphorina citri Kuwayama*). Symptoms of the disease include blotchy mottle, yellow shoots, and improperly developed fruits. The significant decrease in edible

fruit production caused by the disease has led to decreased productivity of citrus farms which in turn causes negative significant economic loss to the citrus industry. Silver nanoparticles were synthesized, and surface functionalized with charged and uncharged groups. The resulting nanoparticles were characterized for size and shape measurements using dynamic light scattering (DLS), transmission electron microscopy (TEM) and atomic force microscopy (AFM). Ultraviolet-visible spectroscopy (UV-Vis) of nanoparticles was done to characterize the differences in surface coating of the nanoparticles followed by Fourier-transform infrared (FTIR) analyses for functional group characterization. Exposure studies carried out on the psyllid vector show differential accumulation of silver nanoparticles based on surface coating. Inductively coupled plasma mass spectrometry (ICPMS) show that negatively charged silver nanoparticles coated with citrate had the highest accumulation concentration (8.27 µg/L) after 96 h of exposure through an artificial feeding media compared to positively charged and uncharged silver nanoparticles. The result obtained from this study are indicative that other arthropods would have similar responses to nanoparticle exposure and that this approach of disease control may be translatable to other vectors of pathogenic diseases.

2164 An In-Depth Multi-'omics Investigation on Different Nanomaterials: A Promising Tool to Support Nanomaterial Grouping

A. Bannuscher[1], I. Karkossa[2], R. Hubaux[3], F. Debacq-Chainiaux[4], P. Nollau[5], J. Laloy[4], M. Stan[6], A. Dinischiotu[6], A. Bahl[1], B. Hellack[7,8], M. Wiemann[9], A. Luch[1], K. Schubert[2,10], M. von Bergen[2,11], and A. Haase[1]. *[1]Bundesinstitut für Risikobewertung (BfR), Berlin, Germany; [2]Helmholtz Centre for Environmental Research GmbH (UFZ), Leipzig, Germany; [3]StratiCELL, Les Isnes, Belgium; [4]Université de Namur, URBC-Narilis, Namur, Belgium; [5]Research Institute Children's Cancer Center and Department of Pediatric Hematology and Oncology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany; [6]Universitatea din București, Bucharest, Romania; [7]Institute of Energy and Environmental Technology (IUTA) e.V., Duisburg, Germany; [8]German Environment Agency (UBA), Dessau, Germany; [9]IBE R&D gGmbH, Institute for Lung Health, Münster, Germany; [10]Kennedy Institute of Rheumatology, University of Oxford, Oxford, United Kingdom; and [11]Universität Leipzig, Leipzig, Germany.*

Nanomaterials (NMs) can be manufactured in plenty of variants demanding for alternative approaches for hazard assessment such as grouping and read-across. Multi-omics analyses are useful for establishing grouping and to justify read-across as they provide detailed insights into NM mode of action (MoA). Here we applied a multi-omics approach considering metabolomics, proteomics and transcriptomics for 12 different NMs including seven SiO_2 variants with a systematic variation of particle size, structure, surface charge and hydrophobicity as well as five other NMs, i.e. two organic pigments, TiO_2 NM-105, Graphene oxide and Mn_2O_3. All NMs were extensively characterized with respect to their physico-chemical properties. Toxicity was assessed *in vitro* in two different rat lung cell models, RLE-6TN rat lung epithelial cells and NR8383 rat alveolar macrophages, using several well-established assays. In addition, selected NMs were investigated *in vivo* in rats using short-term inhalation and instillation studies. Moreover, a multi-omics approach including proteomics, metabolomics and transcriptomics was applied for *in vitro* and *in vivo* samples. Our results demonstrate that NMs can be easily categorized based on changes in the profiles of the individual omics layers but a higher confidence was achieved in an integrated approach. Overall categorization was quite similar in both cell models and largely consistent with categorization based on well-established toxicity data. However, NM MoA was strongly cell-type specific. Overall, our approach appears to be very useful for NM grouping and we provide first examples how to integrate information on NM MoA.

2165 Do Impurities in Boron Nitride Nanotube Material Influence Toxicity?

J. Hubczak[1], V. Kodali[2], M. Shoeb[2], L. Bowers[2], A. Stefaniak[2], N. Yanamala[2], X. Xing[2], K. Frasier[1], T. Eye[2], M. Barger[2], K. Roach[1], M. Jakubinek[3], S. Dénommée[3], K. Kim[3], M. Wolfarth[2], S. Leonard[2], D. Porter[2], J. Roberts[2], and A. Erdely[2]. *[1]West Virginia University, Morgantown, WV; [2]NIOSH, Morgantown, WV; and [3]NRC Canada, Ottawa, ON, Canada.*

Boron nitride nanotubes (BNNTs) have applications in a wide array of industries. Prior BNNT toxicity findings vary and could be attributed to the many manufacturing processes by which BNNTs are produced. These manufacturing processes result in BNNTs with a divergent array of physicochemical characteristics, but commercial processes share a common challenge of having 30-60 % residuals and impurities. Here we evaluated the impact of these impurities on the toxicological profile of BNNT materials. Four BNNT samples made by induction thermal plasma process with a gradient of BNNT purity levels (~50-~90% pure) were used to assess toxicity. Hexagonal boron nitride (h-BN) (~100 nm in diameter) was used as a reference material. Electron micrographs confirmed a decrease in impurities and an increase in tubular structures across the gradient. The BNNTs dispersed in dispersion media decreased in as-produced dimensions and had a length of ~0.5-1.5 µm, diameter of ~5-30 nm, hydrodynamic diameter of 284-396 nm, surface area of 23-150 m^2/g and density of 0.01-0.27 g/cm^3. Electron paramagnetic resonance showed no change in acellular oxidative stress potential among the BNNTs of various purities. Cytotoxicity, proliferation, cellular oxidative stress, NF-κB-based induction of inflammation, and inflammasome activation were assessed in differentiated human monocytes (THP-1) at a concentration range of 0-100 µg/mL. There was a small increase in cytotoxicity and membrane damage with the highly purified BNNT materials, which decreased as the purity of the mixtures decreased. Oxidative stress measured by 4-hydroxynonenal expression, NF-κB by NF-κB-SEAP-expressing THP-1 cells, inflammasome activation by cellular caspase-1 and supernatants for IL1β and IL18 showed a dose-dependent increase with increasing BNNT purity. At all measured end points there was minimal effect with h-BN at the measured concentrations. Computational modeling was used to identify the physicochemical characteristics that altered biological response. This work shows that BNNT mixtures manufactured through the plasma process have low toxicity in general; the increase in toxicity with increasing purity shows that the impurities have minimal role towards the toxicity endpoints measured.

2166 Characterization of Nanoparticle Transformations in Physiologically Relevant Fluids

L. R. Pitts, M. R. Mulenos, and C. M. Sayes. *Baylor University, Waco, TX.*

Nanoparticles are increasingly used in biomedical applications due to their high surface area to volume ratio, ease of surface functionalization, and inherent ability to be excreted. Metal nanoparticles of like surface charge have been shown to display repulsive tendencies; but at physiologically relevant pH, these same particles form a double layer enabling particle stability. When nanomaterials travel through the body to their target site, they encounter many different aqueous environments which may alter colloidal stability. We hypothesize that nanoparticles will become increasingly unstable as the physiologically-relevant fluid they encounter becomes increasing complex. Specifically, the stability of the nanoparticles will be directly related to (1) pH, (2) the concentration of proteins in the biofluid, and (3) the ionic strength of the surrounding matrix. To test this hypothesis, we compared three different surface-functionalized silver nanoparticles that result in positive, negative, and neutral surface charge, which was confirmed through electron microscopy and spectroscopic techniques. Each particle system was incubated in different physiologically-relevant environments: acidic stomach fluid, neutral blood serum, and basic surfactant fluid. Negatively charged particles were noted to undergo the most significant transformations, whereas the particles with neutral surface charges were seen to have the least transformation. The information obtained from these studies will provide crucial insight into colloidal stability of biotransformed nanoparticles, provide read-across comparisons between metal-based and polymeric-based nanoparticles, and aid in filling the literature gap in nanoparticle colloidal stability and how it affects nanoparticle biotransformation.

2167 Polymer Assisted *In Situ* Synthesis of Silver Nanoparticles with Epigallocatechin Gallate (EGCG) Impregnated Wound Patch Potentiate-Controlled Inflammatory Responses for Brisk Wound Healing in Both Normal and Diabetic Condition

A. K. Kar, A. Singh, N. Dhiman, M. P. Purohit, D. Singh, D. Ghosh, and S. Patnaik. *CSIR-Indian Institute of Toxicology Research, Lucknow, India.*
Sponsor: K. Ansari

Diabetic patients often come up with complications such as delayed skin wound healing due to markedly enhanced inflammatory phase. Similarly, non-diabetic patients may also suffer from chronic wounds without proper dressing which fails in maintaining the cycle of inflammation, proliferation, and remodeling of skin wounds. Although various clinically proven dressing materials are available, yet the scope of developing better efficacious materials, will help the patient's centric medicare. Embarking on the same philosophy, we have designed hydrogel wound patches based on biopolymer, Guar gum, and the proven microbicidal silver NPs to promote the wound environment for accelerated wound healing. Incidentally, modified polymer begets *in situ* synthesis of silver NPs of 6 to 12nm size, besides lending ionic surface

charges and impregnated antioxidant epigallocatechin gallate (EGCG) favors a controlled inflammatory response. The wound patches possess apt tensile strength, porosity, and swellability for absorbing wound exudates. Further, *in vitro* studies endorsed them as non-cytotoxic towards the skin Keratinocytes MSC-P5 and the post agent effect following exposure to the patch showed an unbiased response to *E. coli* K12 and *B. subtilis*. High-fat diet (HFD) induced C57 BL-6 diabetic mouse model along with Wistar rats for non-diabetic group was opted. Sub-cutaneous wounds were created and time dependent (3,6,9,12 and 15 days) wound closure validates its accelerated healing through better wound contraction (more than 3 folds compared to control), enriched cell proliferation around wound area by enhanced expression of KI 67, more blood vessels formation, promoted collagen deposition and enhanced vascularisation compared to commercially available wound dressing material (skin graft) Neuskin-F®. The synthesized formulation showed time dependent enhancement in VEGF, a key regulator in promoting re-epithelialization and suppression in key inflammatory cytokines IL-6 and IL-10. Toxicity assessment were also performed in terms of hematological, liver, and kidney functional parameters signifying the non- toxic nature of hydrogel wound patches.

PS 2168 Acute Toxicity of Perfluorinated Alkyl Substances toward Mahi Mahi (*Coryphaena hippurus*) Embryos

K. Y. Gebreab, and J. Berry. *Florida International University, Miami, FL.*

Perfluoroalky substances (PFASs) are persistent organic contaminants that have been detected in wildlife, humans and the environment. They have been associated with diverse negative health effects including cancers, neurotoxicity, thyroid malfunction, reproductive problems, immunotoxicity, lung toxicity, and hepatotoxicity. Previous studies have demonstrated toxicity PFAS in the zebrafish embryo, as a toxicological model system. In the present study, we developed toxicity assays for mahi-mahi (*Coryphaena hippurus*), as an environmentally relevant pelagic marine fish species, and applied these assays to determine acute toxicity of perfluorooctanoic acid (PFOA), as a "legacy" PFAS, and perfluoro-3,6-dioxadecanoic acid (PFPrOPrA, or "GenX") as a next-generation PFAS, and possible environmental toxicant of concern. Bioassays demonstrated acute (24 h) toxicity, in the form of lethality, for both PFAS toward mahi-mahi embryos, and determined median lethal concentrations (LC_{50}) for both compounds. Probit analysis specifically determined mean 24-h LC_{50} values for PFOA and GenX to be 56 and 83 mg/L, respectively. Compared to zebrafish, mahi-mahi are significantly more sensitive to both PFAS, based on lethal concentrations (i.e., LC_{50} at 24 h of 56 versus 96 mg/L for PFOA, and 83 versus 126 mg/L for GenX, in mahi-mahi and zebrafish, respectively). This study showed that mahi-mahi represents a good environmentally relevant model for assessing environmental toxicants and reveals a higher sensitivity relative to zebrafish as an established laboratory model.

PS 2169 Comparison of Routine Clinical Pathology Parameters of Cynomolgus Monkeys and Rhesus Macaque Monkeys

G. Lei, S. McPherson, M. Chen, and Z. Chengen. *Wuxi AppTec, Suzhou, China.*

Nonhuman primates are excellent models for studying biomedical research and routinely used in preclinical toxicity testing because of their genetic similarity to humans. Only a small number of species, such as macaques of the Cercopithecidae family of Old World monkeys, are well suited and established as translational models for drug testing. From this family, rhesus macaque monkey (*Macaca mulatta*) and cynomolgus monkey (*Macaca fascicularis*) are the most common nonhuman primate animal models today. Although closely related, these two species show distinct phenotypic differences, morphology, behavior, and physiology. A comparison of common hematology and clinical pathology parameters between rhesus macaque monkeys and cynomolgus monkeys were performed. The results from the two data sets were analyzed using rhesus macaque monkey (*Macaca mulatta*) as reference control point. Analysis of the hematology data showed slightly higher white blood cell count (WBC), including absolute count of lymphocytes (LYMP), monocytes (MONO), and eosinophils (EOS, for males only) and slightly lower reticulocyte count (RET) in both sexes of cynomolgus monkeys when compared to rhesus macaque monkeys. Differences in clinical chemistry were restricted to relatively higher alanine aminotransferase (ALT) in cynomolgus monkeys relative to rhesus macaque monkeys. Whilst the data showed no major differences in parameters between cynomolgus monkeys and rhesus macaque monkeys it is strongly recommend that separate data sets are maintained for the interpretation of clinical pathology data.

PS 2170 Continuous Tissue Glucose and Telemetric Cardiovascular Measurement in the Conscious, Freely Moving, and Socially Housed Cynomolgus Monkeys

M. Niehoff[1], T. Bartko[2], J. Luft[1], M. Luetjens[1], and J. Nichols[2]. [1]*Covance Preclinical Services GmbH, Muenster, Germany; and* [2]*Covance Laboratories Limited, Madison, WI.* Sponsor: G. Weinbauer

The Abbott FreeStyle Libre is the first for human use FDA approved (2017) continuous glucose monitor (CGM) that requires neither calibration with fingerstick measurements nor surgery. The device was used in combination with a small (13.7 g) cardiovascular telemetry devise (M11 PhysioTel®) for measurement of systemic blood pressure, body temperature and electrocardiogram. The goal of this study was to evaluate the feasibility of the device for the use in freely moving cynomolgus monkeys, and to evaluate the impact of restraint training on cardiovascular (heart rate) and glucose endpoints as potential stress biomarker. Four female cynomolgus monkeys (3.0 to 3.8 kg) minimal invasively implanted with the PhysioTel® M11 device for telemetric cardiovascular measurements were equipped with an external FreeStyle Libre CGM. Cardiovascular endpoints, body temperature and tissue glucose were measured in parallel while animals were repeatedly freely moving or physically restrained (infusion chair). Due to an unsuccessful tissue glucose measurement in all but one animal in the first instance, the experiment was repeated; thus phase I and phase II data were also compared. As expected, heart rate (HR) and tissue glucose increased during physical restraint. Mean HR were 130-150 bpm while animals were freely moving, and increased to up to 200 bpm during restraint, respectively. No HR acclimation was observed with repeated physical restraint. Mean tissue glucose increased transiently from 4 mmol/L when animals were freely moving to up to 8 mmol/L upon initiation of restraint. This pattern was repeatedly observed during independent phases I and II data collections suggesting full reproducibility. The Abbott FreeStyle Libre CGM is feasible for continuous monitoring of tissue glucose in freely moving cynomolgus monkeys for up to 8 days. Consistently increased cardiovascular and tissue glucose values as potential stress endpoints indicated a lack of any positive training effects. The study design did not clearly distinguish whether the increase in glucose levels was attributed to stress or more likely caused by increased muscle activity under restraint.

PS 2171 Genetics of Global Göttingen Minipigs Colonies

L. F. Mikkelsen[1], H. Simianer[2], H. D. Pedersen[1], and C. Reimer[2]. [1]*Ellegaard Göttingen Minipigs A/S, Dalmose, Denmark; and* [2]*Georg-August-Universität Göttingen, Göttingen, Germany.*

Selecting the correct nonrodent or large animal species for toxicology testing of pharmaceuticals in animals is very important to maximize human safety, clinical benefit, and animal welfare. Several factors should be considered in the large animal species selection process, including available scientific information and the need to balance scientific, ethical, and legal constraints. Göttingen Minipigs are a well-recognized large animal species balancing all needs for a translational animal model. This also includes a strict breeding management program ensuring genetic identity between the global Göttingen Minipigs breeding colonies in Europe, North America and Asia. The purpose of the presented study was to evaluate the efficacy of the breeding management program and to identify potential differentiation between the different breeding colonies due to genetic drift or unrecognized divergent selection of breeders in the five isolated breeding colonies. The study used whole genome re-sequencing of two representative DNA-pools per colony to access genomic variation within and differentiation between colonies. The data were completed with sequence data from 13 other pig breeds from public data repositories. An F-test was performed to reveal significantly differentiated allele frequencies between colonies; further, a pathway analysis was conducted. Variation within colony was quantified as expected heterozygosity. The results show that Göttingen Minipigs are easily discriminable from all other breeds, but with minor differentiation between the Göttingen Minipigs colonies. The differentiation results suggest that the underlying mechanisms for the minor differentiation are drift events rather than directed selection and limited to neutral genome regions. We conclude that the breeding management program maintains genetically stable and comparable colonies and shows no need for exchange of breeders between the colonies.

2172 Highly Sensitive Detection of Human Aspartate Aminotransferase Protein by AlphaLISA Is a Useful Way for Evaluating Hepatotoxicity in Humanized Liver Mice

H. Suemizu, N. Yoneda, Y. Higuchi, S. Uehara, and K. Kawai. *Central Institute for Experimental Animals, Kawasaki, Japan.*

There are differences in drug metabolism, pharmacokinetics, and toxicity between humans and nonhuman species. To overcome these species differences, we developed a humanized liver (huLiver) mouse in which the hepatocytes of the host mouse liver were replaced with human hepatocytes. The huLiver mouse will be a valuable *in vivo* model for predicting hepatotoxicity in humans. However, since mouse hepatocytes remain in huLiver mouse, it is not possible to evaluate the degree of injury in human hepatocytes by alanine aminotransferase (ALT) activity because of the lack of species specificity. Therefore, we had been using human ALT, soluble keratin 18 protein, and circulating mRNA as human-specific biomarkers of liver injury. However, we could not observe the changes over time in these methods because of the requirement of a large amount of plasma (at least 50 µL/assay) caused by lower detection sensitivity. In this study, we aimed to establish a sensitive method applicable to huLiver mice. The AlphaLISA immunoassay kit for human aspartate aminotransaminase (AST) (PerkinElmer) was examined as a possible method to evaluate the hepatotoxicity in huLiver mice. We initially checked the species specificity of the human AST AlphaLISA detection kit using human and mouse samples. The AlphaLISA results for human AST showed slight cross-reactivity (<10%) against mouse plasma only in samples with high AST activity (>1,000 U/L). We administered a single intraperitoneal dose of thioacetamide (TAA, 200 mg/kg) to huLiver and control TK-NOG mice and analyzed routine parameters (ALT and AST activity) and AST protein levels in plasma at 0, 3, 7, and 24 hours. Overall, AST activities were correlated well with the activity of hepatic enzyme ALT in the corresponding samples (r^2 = 0.8088). In all cases, AST protein levels were higher in the huLiver mice groups than in the control TK-NOG mice groups. The kinetics of human AST protein was similar to AST activity in both huLiver (r^2 = 0.7464) and TK-NOG (r^2 = 0.7849) mice models. Furthermore, AlphaLISA could detect a significant increase of AST protein at 3 hours (5.5-fold) after TAA treatment in only the huLiver mice group with only 1 µL of plasma samples. Thus, human AST AlphaLISA can be a highly sensitive quantitative evaluation method for evaluating hepatotoxicity in a humanized liver mouse model.

2173 Comparative Toxicity of CD40 Antibodies in CD40/FcγR Humanized Mice and in Monkeys

S. Ruepp[1], G. H. Cantor[1], R. Jain[2], P. Strop[2], B. Lehman[1], Y. Callejas[1], D. Bounous[1], W. Freebern[3], B. Wang[3], and B. Barnhart[2]. *[1]Bristol-Myers Squibb Company, Princeton, NJ; [2]Bristol-Myers Squibb Company, Redwood City, CA; and [3]Bristol-Myers Squibb Company, New Brunswick, NJ.*

CD40 is constitutively expressed on antigen presenting cells and its activation leads to upregulation of costimulatory molecules, adhesion molecules and secretion of proinflammatory cytokines, and represents a promising approach to enhance anti-tumor responses. CD40 agonists have demonstrated clinical activity in patients with advanced solid malignancies, but treatment-related adverse effects, including thrombosis, cytokine release syndrome (CRS) and liver enzyme elevations were limiting escalation to potentially more efficacious doses. Identification and characterization of an improved and safer CD40 antibody relies on the availability of reliable non-clinical and models. Typical CD40 agonist antibodies bind to cynomolgus monkey, but not to mouse CD40 and some agonists also require cross-linking via Fc receptors for activity. Recently mice humanized for CD40 and Fc receptors were described and we used these mice to evaluate how they and cynomolgus monkeys informed risk assessment of CD40 agonists. For benchmarking purposes we generated a biosimilar version of a clinical stage agonist anti-CD40 antibody and tested this antibody in CD40/FcR humanized mice and in monkeys. When humanized CD40/FcgR mice were given a single iv dose of 0.5 mg/kg of this antibody (clinical MTD 0.2 mg/kg) decreased platelet counts and microthrombi in the liver and lung were detectable within 24 hours. CD40/FcR transgenic mice also provided mechanistic insight for the clinically observed hepatic effects and indicated ALT increases and hepatocellular damage were secondary to platelet activation, thrombus formation and infarcts. In contrast, when the same antibody was dosed to cynomolgus monkeys up to 5 mg/kg iv no ALT increases or thrombi were detectable. We obtained similar results with a number of BMS CD40 agonist antibodies; there were clear pharmacodynamic effects in monkeys, but no thrombosis or hepatotocicity. In contrast, CD40/FcR transgenic mice successfully identified safety concerns at relevant doses, including thrombosis and hepatotoxicity. These results support the value of using rationally selected humanized mouse models to enhance nonclinical safety assessment.

2174 Ovariectomy in an Animal Model Exposed to Environmental Toxicant Increases Susceptibility to Colon Polyp Development

K. J. Harris[1], A. E. Archibong[1], M. K. Washington[2], J. M. Amos-Landgraf[3], S. E. Adunyah[1], and A. Ramesh[1]. *[1]Meharry Medical College, Nashville, TN; [2]Vanderbilt University, Nashville, TN; and [3]University of Missouri, Columbia, MO.*

Colorectal cancer (CRC) is the third most common diagnosed cancer and the third leading cause of cancer-related deaths in the United States. The incidence of colorectal cancer and mortalities due to this disease are higher in men than in women. Epidemiological evidence revealed estrogens as protectors against the development of colon cancer in postmenopausal women treated with hormone replacement therapy. Previously, our lab has shown that male animal models develop twice as many polyps in the colon than female animals when exposed to the environment toxicant, Benzo(a)pyrene [B(a)P]. In addition, we have also shown that female animals exposed to B(a)P have an increased protein expression of the phase II drug metabolizing enzyme, Glutathione S-Transferase (GST) when compared to male animals suggesting the female sex hormones may regulate metabolism. The aim of this study was to determine whether ovariectomy in a female Polyposis in Rat Colon (PIRC) model increases B(a)P-induced colorectal tumorigenesis and whether tumorigenesis is reduced by estrogen supplementation after ovariectomy. Here, we show that ovariectomy in B(a)P treated (50 µg/kg bw) female PIRC rats increased colon polyp development compared to the vehicle. Our results also confirm that exogenous estradiol supplementation to ovariectomized female PIRC animals exposed to B(a)P significantly attenuates the development of colon polyps. This mechanism could involve the metabolism of the parent compound, B(a)P, by Glutathione S-Transferase and this pathway could be regulated by estradiol. *This research was funded by NIH grants 5R25GM059994-3, U54CA163069-04, G12MD007586-29, and 5RO1CA142845-04.*

2175 Aerosol Treatment for Ariway Hyperreactivity and Inflammation with an Inhibitor of Soluble Epoxide Hydrolase in a Murine Model of Asthma

X. Li[1,2], C. Zhang[3], K. Tsuji[4], J. Yang[1], J. Chen[1], C. Wu[1], S. M. Mack[1], W. Li[2], K. E. Pinkerton[1], and B. D. Hammock[1]. *[1]University of California Davis, Davis, CA; [2]Shandong University, Jinan, China; [3]Shandong Provincal Qianfoshan Hospital, Jinan, China; and [4]Kyoto Sangyo University, Kyoto, Japan.*

Asthma affects more than 300,000,000 people in the world today. An inhibitor of soluble epoxide hydrolase(sEH) is a potential method for the treatment of asthma. We studied the efficacy of an inhibitor of sEH, 1-trifluoromethoxyphenyl-3-(1-propionylpiperidin-4-yl) urea (TPPU). The goal of this study was to determine whether inhalation of TPPU could attenuate mucin secretion and airway hyper-responsivity in a murine model of asthma. To investigate an efficient method for the treatment of airway hyper-reactivity and inflammation, TPPU (1mg/ml) was administered by inhalation. Male BALB/c mice were given ovalbumin (OVA) by intraperitoneal (IP) injection on days 0 and 14 of the study as a means to sensitize them to allergen. Nebulized OVA (1%) was subsequently administered six times, every other day beginning on day 28 of the experiment, to provoke allergic inflammation and airway reactivity. Four treatments groups were tested: 1) PBS negative control, 2) OVA positive control, 3) OVA+TPPU (2h), 4) OVA+TPPU (6h). Pulmonary function was measured using a Flexivent system while applying increasing doses of methacholine, a potent bronchoconstrictor. At necropsy lung tissues were collected for quantitative measurements of lung inflammation, airway bronchoconstriction and the volume of intracellular airway mucosubstances. Semi-quantitative and morphometric measurements demonstrated following inhalation of TPPU for either 2 or 6 hours, a significant reduction in lung inflammation ($p<0.05$), intracellular mucosubstance volume ($p<0.05$) and airway contraction ($p<0.05$) in OVA-exposed mice. The average volume of intracellular mucosubstances per basal lamina surface area in OVA-treated mice was 0.0100±0.0007µm^3/µm^2. TPPU reduced mucosubstance volume by more than five-fold and four-fold following 2 or 6 hours of TTPU inhalation, respectively. The severity of airway constriction was three-fold lower in mice that inhaled TPPU for 2 or 6 hours, compared to the positive control. TPPU given by inhalation directly reduced airway hyper-reactivity, lung inflammation and mucin hypersecretion in this murine model of asthma. These findings suggest TPPU may be an effective treatment for asthmatic symptoms.

2176 Opioid-Induced Multi-Organ Necrosis in Ferrets

J. Tressler, L. Jennings, J. Johnson, S. Pierce, E. Pueblo, A. Dukes, S. Stone, M. Racine, B. McCranor, and B. Wong. *US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.*

Opioids are linked to both acute and chronic renal and hepatic damage following overdose exposures. Necrotic tissue lesions may be observed following opioid exposure in ferrets. A pharmacokinetics study was conducted in ferrets in which animals received multiple serial subcutaneous injections of the potent opioid carfentanil. Following each injection, study animals were monitored in whole body, unrestrained plethysmography chambers for 4 hours. During this time, the animals experienced multiple periods of apnea and respiratory depression, which causes hypoxemia and tissue hypoxia. Subsequent studies in ferrets monitored by telemetry have also demonstrated systemic hypotension associated with carfentanil exposure. Animals were kept on study for approximately 11 weeks and received a total of 3 or 4 injections of carfentanil. Gross findings at necropsy included multiple nodules on the surface of the kidneys, pancreas, small intestine, omentum, and peripancreatic fat. Microscopically, the nodules were composed of necrotic, saponified fat surrounded by a chronic-active inflammatory infiltrate. Nodules specifically overlying the pancreas were associated with areas of coagulative pancreatic necrosis. Saponified fat is commonly associated with pancreatic enzyme leakage following acute necrotizing pancreatitis. Additionally, diffuse acute and chronic renal tubular degeneration and necrosis with interstitial fibrosis were also observed, suggesting multiple cumulative incidents of acute kidney injury. Overall, multi-organ necrosis is hypothesized to be the result of tissue hypoxia caused by opioid-induced respiratory depression and systemic hypotension, and may be exacerbated in the kidney due to decreased renal blood flow.

2177 Aconitine Affects Behavioral Changes of Zebrafish Embryos via 5-HT Receptor

H. Chen[1], F. Wang[1], X. Ni[1], R. Yi[1], J. Yang[1], Y. Bai[1], L. Xu[1], X. Zhang[1], K. W. Kwok[2], J. Deng[3], and W. Dong[1]. *[1]Inner Mongolia University for the Nationalities, Tongliao, China; [2]Hong Kong Polytechnic University, Hong Kong, China; and [3]Zunyi Medical University, Zunyi, China.*

Caowu (*aconite*) is a traditional Chinese medicine. Its main active ingredient is *aconitine*. Because it causes serious damage to the nervous system, it is regulated and used with caution. This experiment used zebrafish embryos as an animal model to investigate the neurotoxicity of aconitine to zebrafish embryos in early development. Experimental results showed that 100 μM aconitine can increase the number of coiling frequency in zebrafish embryos by 8-10 times, 5-HT1A receptor agonist 8-OH-DPAT also caused similar behavioral changes, however, when the 5-HT1A receptor selective antagonist WAY100635 was added, the increased coiling frequency behavior was inhibited. Exposure to aconitine also significantly increased serotonin receptor *5-htr1ab* and *5-htr1bd* mRNA expression. When the *5-htr1ab* mRNA is overexpressed alone, the zebrafish embryo also exhibits a significantly increased coiling frequency. Conversely, when the *5-htr1ab* gene is knocked down; the zebrafish embryo retrieval frequency is inhibited. Moreover, the protein expression of the serotonin receptor was reduced by a factor of 0.5 in the 96hpf (hour past fertilization) zebrafish embryo. The results suggest that the neurotoxicity caused by aconitine is mediated through the 5-HT receptor in the brain of the zebrafish embryos, which in turn changes the coiling behavior.

2178 A Nine-Month Inhalation Study to Investigate the Atherogenic Effect of Cigarette Smoke in Apolipoprotein E-Deficient Mice

M. Matsuda, H. Ozaki, K. Oishi, K. Sano, H. Suzuki, and T. Mine. *Japan Tobacco Inc., Yokohama, Japan.* Sponsor: S. Ito

Atherosclerosis is one of the major causes of cardiovascular disease (CVD), including myocardial infarction, heart failure, and stroke. It has been reported that cigarette smoking is one of the risk factors for CVD and that smoking cessation results in a decline in the risk of CVD development. However, the atherogenic effect of cigarette smoke is not fully understood due to the lack of animal models available to investigate the effect of cigarette smoke on atherosclerosis development. To develop the model for the investigation on the atherogenic effect of mainstream cigarette smoke (MCS), female apolipoprotein E knockout (ApoE KO) mice were exposed to MCS for 9 months. In addition, mice were exposed to filtered air (FA) after MCS exposure to investigate the effect of smoking cessation on MCS-induced atherogenic changes. ApoE KO mice were exposed to FA or MCS generated from 1R6F Kentucky reference cigarette (600 μg total particulate matter/L) for up to 9 months using a whole body exposure system. In the cessation group, mice were exposed to MCS for 3 months before switching to FA for up to 6 months. ApoE KO mice were subjected to biological analysis at 3, 6, 8, or 9 months. Results showed that MCS exposure marker concentrations, such as COHb, nicotine and cotinine, in the blood of the MCS group were significantly increased, while those of the cessation group were similar to those of the FA group. No significant differences were seen in total plasma cholesterol and triglyceride concentrations between the groups at any time point. En face analysis showed that plaque surface areas in the aortic arch were significantly increased in the MCS group at 6, 8, and 9 months. In the cessation group, the aortic plaque surface area was significantly decreased compared with those in the MCS group at 8 months. In summary, this murine model could detect the acceleration of aortic atherosclerosis development caused by chronic MCS inhalation and smoking cessation retarded MCS-induced atherosclerotic progression in this murine model. These findings indicate that this model will be useful to investigate the effect of cigarette smoke on atherosclerosis development.

2179 Histopathological Characteristics in the PXB Hepatic Chimeric Mice: Comparison with SCID Mice

A. Moriyama[1], Y. Sasaki[1], Y. Saito[2], Y. Komohara[2], K. Kobayashi[1], and H. Tsusaki[1]. *[1]Shin Nippon Biomedical Laboratories Ltd., Kagoshima, Japan; and [2]Kumamoto University, Kumamoto, Japan.*

PXB-mice are human hepatocyte chimeric mice originating from transgenic SCID mice generated by crossing urokinase-type plasminogen activator-transgenic mice with SCID mice. More than 70% of the liver of PXB-mice consists of human hepatocytes. When developing compounds for which clinical toxicity is difficult to predict by animal studies, PXB-mice may exhibit PK/TK profiling that is closer to that of humans than non-chimeric mice. Therefore, PXB-mice are expected to be used for toxicity studies in future. In order to conduct toxicity studies using PXB-mice, it is important to know the characteristics of this animal model. Histopathological examination was conducted in typical organs and tissues for toxicity studies in male PXB-mice (n=6, 23 to 24 weeks). The results were compared with those from male SCID mice (n=100, 12 to 20 weeks) that were the origin of the PXB strain. Many of the spontaneous histopathological findings in PXB-mice were also observed in SCID mice. Hypoplasia of the lymphoid organs was observed in both strains. A characteristic change in all PXB-mice was vacuolation in the hepatocytes, which was observed to various degrees. These were lipid vacuoles, and the vacuolated cells coincided with the human-derived cell region. There were no differences in the incidence and the degree of vacuolation among the hepatic lobes. In mouse-derived hepatocytes, no vacuolation was observed, although those were slightly larger than the average size of hepatocytes of SCID mice. In addition, the aorta of PXB-mice showed the focal intimal thickenings with an incidence of 50%. One PXB-mouse showed lymphoma in the various organs and tissues, and another PXB-mouse showed thymic lymphoma. PXB-mice, as well as SCID mice, were considered to be susceptible to thymic lymphoma. Based on the above results, it was suggested that PXB-mice are useful for an evaluation of toxicity, since there were no notable spontaneous lesions which hindered the assessment of hepatotoxicity risk in humans, except for 1 case of lymphoma.

2180 Comparison of Two Intravenous Infusion Methods in Freely Moving Beagle Dogs

J. Vein, C. Camillerapp, L. Basset, C. Thirion Delalande, and P. Singh. *Charles River Laboratories Montréal ULC, Evreux, France.*

We compared two methods of ambulatory infusion in group-housed beagle dogs for feasibility and reproducibility. A catheter was surgically implanted in the femoral or jugular vein in four non-naïve female beagle dogs, and connected to an Instech® Orchestra ambulatory pump placed in the back pouch of a Ludomed® jacket worn by each dog. Sterile saline was continuously infused for 10 days (4.0 mL/hour). Saline bags were changed daily and the administered volumes were recorded. The dogs were group-housed and monitored daily for health status and to check integrity of the infusion system. Body weight and food consumption were recorded. The animals were euthanized on day 11, and a complete macroscopic examination was performed. Injection sites were examined microscopically at three sites: catheterized vein, tip of catheter and non-catheterized vein (1 cm from the catheter tip). At the femoral vein infusion site, both dogs showed iliac lymph node enlargement, with red discoloration or endothelial thickening. Minimal hemorrhaging was also noted in adjacent fat. These changes were considered to be non-adverse and consistent with commonly recorded findings at infusion sites. At the jugular vein infusion site, various microscopic findings were observed, including endocardial ulceration/hyperplasia, mononuclear/mixed inflammatory cell

infiltrates and myocardial/endocardial edema at the tip of the catheter and in the noncatheterized vein, both located in the right atrium. In addition, intimal thickening, endothelial ulcer and lymphoid cell/macrophage infiltrates in the vascular wall or thrombus and hemorrhaging in the endocardium were observed. In conclusion, implantation of an ambulatory catheter was well tolerated in the femoral vein, but implantation in the jugular vein caused local intolerance. Based on the findings from this study, it is considered that femoral vein catheterization provides a better method than use of the jugular vein and that this method is in line with the improvement of animal welfare during continuous infusion.

PS 2181 Clinical Pathology and Histopathology Parameters in Juvenile and Adult Guinea Pigs: A Comparative Study

Y. Lu[1], B. Borders[1], B. Walling[1], J. Stinson[2], N. Hayward[3], J. Ross[1], B. Roche[1], and N. Makori[1]. *[1]Charles River, Ashland, OH; [2]Charles River Laboratories, Ashland, OH; and [3]eXIthera Pharmaceuticals, Westborough, MA.*

The guinea pig (GP) is a valuable animal model for nonclinical studies. Adult GPs express the human homologous *Kcnh$_2$* gene which encodes KCNH2 (or hERG1) protein, the major molecular target for QT interval regulation and drug-induced arrhythmias. The KCNH2 mediated cardiomyocyte repolarization is relatively unimportant in other traditionally used rodent animal models (rat and mouse), which renders the GP a valuable model for cardiovascular function evaluation in nonclinical studies. Additionally, for test articles that are pharmacologically inactive in other rodent models, the GP serves as an appropriate alternate. Also, the GP is one of the most suitable animal models for respiratory and otological nonclinical studies. One of the limitations of using GPs is the paucity of historical reference data. In this study, clinical pathology parameters from juvenile (8-10-week old; 22-155 males (M) and 22-148 females (F)) and adult GPs (30-week old; 5M and 5F), as well as histopathology evaluations from these two groups (juvenile: 5M and 5F; adult: 10M and 9F) were collected and compared. Compared to the juveniles, both male and female adult GPs have markedly higher total white blood cell (1.96-fold: M; 1.61-fold: F), lymphocyte (1.78-fold: M; 1.85-fold: F), monocyte (3.77-fold: M; 2.22-fold: F), basophil counts (7.73-fold: M; 6.09-fold: F), and fasting blood glucose level (2.08-fold: M; 1.86-fold: F), lower platelet count (0.57-fold: M; 0.62-fold: F), and shorter prothrombin time (0.74-fold: M; 0.76-fold: F) and activated partial prothrombin time (0.76-fold: M; 0.75-fold: F). Common histopathology findings in both juvenile and adult GPs include cardiomyocyte vacuolation, pigmented macrophages in cecum lamina propria, and inflammatory cell infiltration in multiple tissues. Of note, the prevalence of adipocyte infiltration in various tissues were observed only in adult GPs, i.e., brain ventricle (90%), salivary gland (89%), thymus (67%) and pancreas (67%), but not in juveniles. In summary, this study contributes to building a robust valuable historical control reference data set to aid in the planning for nonclinical studies. In addition, this study assures more accurate interpretation of findings when evaluating clinical pathologic and histopathologic parameters in juvenile and adult GPs.

PS 2182 Immunogenicity Study of HPV16L1/RG1 Chimeric Particles in Rabbits

M. Lindeblad, K. Kabirov, Y. Chen, U. Bhat, E. Glaze, and A. Lyubimov. *University of Illinois at Chicago, Chicago, IL.*

The primary objective of this pilot study was to determine and compare immunogenicity of HPV16L1/RG1 Chimeric Particle vaccines from two sources in rabbits (n=3/vaccine group). The vaccines were administered intramuscularly into the quadricep muscles of the hind legs on Days 1, 15, and 29. Blood samples collected from the rabbits on Days 15, 29 and 43 were analyzed for antibody production to HPV16L1 and HPV16L2 using the MSD platform. The titers of anti-HPV16L1 antibodies and *in vitro* neutralizing effect of these antibodies were greater with the vaccine produced by Paragon compared with the vaccine produced by Kirnbauer. The production of antibodies to HPV16L2 was lower compared to HPV16L1 in both vaccine products. Animals administered vaccines showed time-dependent increased levels of antibody production on Days 15, 29 and 43. The highest Ab titres were seen on Day 43. The vaccine produced by Paragon showed neutralizing activity for all three tested HPV subtypes (HPV16, HPV45, and HPV58) with the highest activity seen for HPV16. The neutralizing effect of the antibodies was confirmed in a mouse passive transfer assay. The rabbit antibodies fully protected (100% inhibition) all mice against HPV16, with the exception of one rabbit sera. Partial protection was observed for HPV45 and HPV58 subtypes; however, the viral load that the mice were challenged with was likely too large to allow for a thorough analysis of these results. In a separate study, different manufacturing processes of the vaccine where compared whereby one vaccine was subjected to the process of disassembly and reassembly (modified) to increase purity and the second vaccine was unmodified. The results indicated that the unmodified vaccine L1 antigen produced higher antibody levels on Day 43 after vaccination compared to the L1 in modified vaccine. L2 produced more comparable induction of antibodies following either of two vaccine immunization. In conclusion, both vaccines produced effective neutralizing antibodies for HPV16, as well as partial protection against HPV45 and HPV58. However, the Paragon vaccine appeared to be more effective in the production of antibodies (HPV16 L1/L2) compared to the Kirnbauer vaccine, based on the small number of animals in this study. In addition, the unmodified version had higher titers for L1 than the modified vaccine.

PS 2183 Differences in Survival, Incidence of Spontaneous Neoplasms, and Neoplastic Onset in Two-Year Carcinogenicity Studies Conducted in Crl:CD(SD) Rats and Crl:WI(Han) Rats

M. A. Morse[1], D. G. Stump[2], and S. J. Bulera[3]. *[1]Charles River, Spencerville, OH; [2]Charles River, Ashland, OH; and [3]Charles River, Reno, NV.*

Two commonly used rat strains in pharmaceutical development programs are the Charles River Crl:CD(SD) rat or CD®IGS rat, and the Crl:WI(Han) (Wistar Han IGS) or Wistar Han rat. To compare the performance of these two strains, the survival, incidence of major neoplasms that impact survival, and onset of these neoplasms in 2-year carcinogenicity studies were compared from data compiled from multiple Charles River Safety Assessment facilities from 2006 to 2018. These data show that the survival rate in CD®IGS rats has been declining from 2006 to the present. From 2006 to 2008, all carcinogenicity studies conducted in CD®IGS rats at Charles River facilities completed 95 weeks of dosing and 73% of these studies completed 104 weeks of dosing. However, from 2013 on, only 49% of carcinogenicity studies conducted in CD®IGS rats completed at least 95 weeks of dosing and just 15% of studies completed 104 weeks of dosing. In contrast, from 2006 to 2018, all carcinogenicity studies conducted in Wistar Han rats at Charles River Safety Assessment facilities completed the intended duration of 104 weeks of dosing. In fact, survival in Wistar Han rats at the end of Week 104 in 2-year studies is quite comparable to the survival of CD®IGS rats at the end of Week 80 in 2-year studies. Major neoplastic causes of death in CD®IGS rats include pituitary adenomas in males and females and mammary adenocarcinomas and fibroadenomas in females. In Wistar Han rats, the incidence of pituitary adenomas was 59% (females) to 65% (males) of that observed in CD®IGS rats, and the incidences of mammary adenocarcinomas and mammary fibroadenomas in females were 31% and 65%, (respectively) of those observed in CD®IGS rats. In addition, the onset of these neoplasms was two to four months later in Wistar Han rats compared to CD®IGS rats; as many of these neoplasms tend to result in early death late in the second year of a carcinogenicity study, this delayed onset confers a definite survival advantage to Wistar Han rats. These strain differences in survival and neoplastic incidence and onset strongly favor the use of Charles River Wistar Han rats in drug development programs in which eventual carcinogenicity testing in rats is anticipated (e.g. small molecule development programs).

PS 2184 A Simple Large-Animal Whole-Body Inhalation Exposure System to Study Environmentally Relevant Toxicant Exposures

C. M. Santana Maldonado, P. Gauger, D. R. Magstadt, D. Kim, D. Shrestha, C. Charavaryamath, and W. K. Rumbeiha. *Iowa State University, Ames, IA.*

We developed a simple custom-made whole-body exposure chamber to study inhalation exposure to environmentally relevant concentrations of toxicants and/or infectious agents in a large animal model. Most whole-body inhalation exposure systems are designed for use in small animals such as rodents and rabbits. This is a limitation to research as exposures in non-rodent models is sometimes required, especially for translational studies. Minipigs have been recognized as potential animal models for human diseases. Currently, most large animal inhalation studies use anesthetized animals. However, anesthesia affects animal welfare, may confound research outcomes, and anesthetic gases are hazardous to investigators. To overcome these challenges, most inhalation studies in mini pigs utilize masks, which does not replicate real life exposure conditions. This is also challenging for prolonged exposures. In order to replicate real life conditions, we developed a whole-body inhalation chamber large enough to fit six 3-week-old Yorkshire Crossbred Isowean piglets. The 30 ft^3 transparent polystyrene exposure chamber is 76 cm W X 122 cm L X and 84 cm H. The chamber is fitted with valves to input breathing air or test gases/vapors, an exhaust valve to remove test and waste gases from the chamber. Animals have access to water and feed *ad libitum* and allows

for real-time measurement of chamber temperature, relative humidity, and oxygen. The clear chamber allows for behavioral evaluation during exposure. Using this chamber, we investigated the effects of low-level hydrogen sulfide (H_2S), an environmental stressor, on the pathogenicity of influenza A virus (IAV) in swine in a BSL2 facility. Thirty-five 3-week old pigs were exposed six hours daily for 12 days to either breathing air (BA) or H_2S in the chamber. On the seventh day, pigs were inoculated with placebo (NC) or IAV (C). Test groups were: BA/NC, BA/C, 0.5ppm/C, 5ppm/C, 50ppm/NC, and 50ppm/C. Results showed that pigs exposed to H_2S and inoculated with IAV had statistically significantly increased dyspnea, viral load, and microscopic lung injury compared to BA/C and reactive nitrogen species compared BA/NC group. However, there was a significant decrease in pro-inflammatory cytokines in lungs of pigs exposed to higher levels of H_2S. This novel custom-made whole-body exposure chamber can be adapted to study the effects of volatile toxicants, toxic gases, or infectious agents with appropriate containment in pigs.

PS 2185 Blood Sampling for Clinical Pathology in Rats: Retro-Orbital Sinus Sampling versus Jugular Vein Sampling

J. Latour, H. Stegeman, M. van Tuyl, and H. Emmen. *Charles River, Den Bosch, Netherlands.*

Clinical pathology plays an important role in evaluating the potential toxicity of a test compound in a safety study. In these studies, at the end of the treatment with the test compound, blood is sampled from rodents (rats and mice) at to evaluate the effect of the test compound on haematology, coagulation and clinical chemistry parameters. Blood sampling via the retro-orbital sinus under isoflurane anesthesia was traditionally the method for clinical pathology blood sampling in rats. Recovery from the anesthesia can impact animal well-being and may impact the outcome of study endpoints. Blood sampling from the jugular vein without anesthesia has been considered an animal-friendly alternative method compared to retro-orbital sinus blood collection. As both methods have been used for collecting clinical blood samples, it is valuable to determine if differences in clinical pathology parameters are caused by the different blood collection methods in untreated animals. This study gives an overview of the normal ranges of clinical pathology parameters in untreated rats after blood sampling via the retro-orbital vein or jugular vein in different strains of rats (Wistar Han and Sprague Dawley). Differences in ranges between the two blood collection methods are discussed considering the differences in blood sampling location. This overview can be used to interpret differences in clinical pathology parameters in rat studies using these different blood collection methods.

PS 2186 Twenty-Eight-Day Continuous Intravenous Infusion in Mice: Use of Externalized Magnetic Ports and Tethers to Achieve Study Endpoints and Enhance Animal Welfare

T. R. Gleason, J. D. Bultman, B. J. Zillig, and G. A. Murphy. *Charles River, Ashland, OH.*

Continuous intravenous (IV) infusion in mice presents many challenges. The model requires intricate surgery and catheter size is limited due to vessel size. In addition, traditional tether security devices such as jackets, harnesses or tail-cuffs need to be continually checked and adjusted for proper fit. Improper fit of jackets or harnesses can lead to irritation, skin lesions, and swelling of the anterior body. Tail-cuffs can cause swelling and lesions where they are secured with steel suture. If the devices are too loose, the mouse can escape and destroy the exteriorized catheter, leading to patency issues and potential infection. A validation study was conducted comparing continuous infusion of 0.9% Sterile Saline for Injection (saline) and 20% hydroxypropyl-beta-cyclodextrin (HBC) in sterile water. Twenty-five CD1 male mice implanted with jugular catheters attached to an externalized port were purchased. Male mice were used since gender differences were not expected. The ports of 20 mice (10 per group) were connected to a magnetic tether/swivel assembly mounted to a counterbalance arm on the cage lid. The animals were infused at a rate of 2 mL/kg/hr for 27 or 28 consecutive days. Due to toxicity in 5 animals and a blocked catheter in 3 animals between days 5-10 in the 20% HBC group, the surviving and replacement animals were placed on a saline dosing holiday followed by dosing the remaining 10 or 17 days with 10% HBC. Animals were observed daily, and body weights, food weights and detailed physicals were collected weekly. Blood was collected for hematology and serum chemistry at the time of scheduled necropsy and histopathology was conducted on select tissues. All animals were patent for 27 or 28 days of dosing; 90% and 57% of the saline / HBC groups (respectively) were patent for blood draw at necropsy. There were no clinical, gross necropsy or histological signs of infection and white blood cell counts were normal. When both groups were compared to the historical reference, mean AST, ALP, SDH, and A/G ratio were slightly higher while mean globulin was slightly lower. The tether/port connection remained intact for all animals throughout the study and only one animal had a skin scab around the port beginning on day 14. The use of an externalized magnetic port and tether system proved successful in this 28-day continuous IV infusion study and was an improvement in animal welfare when compared to the use of jackets, harnesses, or tail-cuffs.

PS 2187 Adaptive Regulation of Bile Acid and Cholesterol Transporters in Mouse Kidney and Intestine during Alpha-Naphthylisothiocyanate (ANIT)-Induced Cholestasis

Y. Tanaka[1], T. Ikeda[2], H. Ogawa[2], and T. Kamisako[1]. *[1]Kindai University, Osakasayama, Japan; and [2]Tezukayama Gakuin University, Sakai, Japan.*

Cholestasis is a decrease in bile flow that leads to accumulation in serum and liver of bile constituents such as bilirubin, bile acids, and cholesterol. It is known that cholestasis is associated with a decrease in biliary excretion of bile acids and alterations of bile acid metabolism and transport genes. We hypothesize that cholestasis results in an increase in non-biliary excretion of bile acids and cholesterol and alteration in the expression of bile acid and cholesterol metabolism related genes also occur in intestine and kidney. To test this hypothesis, eight-week-old male C57Bl/6 mice were administered alpha-naphthylisothiocyanate (ANIT) (75 mg/kg po) and liver, duodenum, jejunum, ileum, kidney, blood, urine, and fecal samples were collected 72 hours later. Serum levels of total bilirubin, total bile acid, total cholesterol, and ALP were elevated after ANIT. Hepatic bile acid and cholesterol concentrations were increased after ANIT. These results indicate that ANIT induces both cholestasis and hypercholesterolemia. Furthermore, fecal and urinary cholesterol and urinary bile acid concentrations were increased 72 hours after ANIT, whereas fecal bile acids were reduced. In liver, ANIT increased mRNA expression of sinusoidal efflux transporters Mrp3 and Mrp4 but decreased mRNA expression of Cyp7a1, Cyp27a1, Ntcp, Oatp1a1, Oatp1b2, and Bsep. In duodenum, ANIT increased mRNA expression of Mrp2 and the FXR target genes, Fgf15, Asbt, Ost-alpha, and Ost-beta. In jejunum, ANIT increased mRNA levels of FXR, Ost-beta, and the cholesterol uptake genes SR-B1 and LDL receptor, and decreased mRNA expression of Mrp3, Abca1, and Abcg5. In ileum, ANIT increased Mrp2 mRNA and decreased Mrp3 mRNA. In kidney, ANIT increased Mrp2, 3, and 4, Ost-alpha, and Ost-beta, and tended to increase SR-B1 and Abcg8. These changes in liver, kidney, and intestine may be an adaptive response to ANIT-induced cholestatic liver injury. Intestinal induction of LDL receptor and SR-B1, renal induction of Mrp2 and Mrp4, and increased tendency in renal SR-B1 and Abcg8 may promote fecal cholesterol, urinary bile acid, and urinary cholesterol excretion, respectively. These responses may facilitate alternative route for bile acid and cholesterol excretion during cholestasis.

PS 2188 Characterization of Glomerular Filtration Rate and Renal Blood Flow in Diabetic Miniature Swine

E. M. Walters[1], S. E. Boley[2], D. F. Brocksmith[1], and G. F. Bouchard[2]. *[1]Sinclair Bio Resources, Auxvasse, MO; and [2]Sinclair Research Center LLC, Auxvasse, MO.*

People with type I diabetes (T1D) can have renal complications such as hyperfiltration and vascular restructuring that can potentially result in renal failure. The objective of this study was to determine if the induction of T1D in miniature swine impacted renal function by evaluating the glomerular filtration rate (GFR) and renal blood flow (RBF). Yucatan males (> 6 months old) were chemically induced into a diabetic state using alloxan. Three diabetic and three control animals were fasted overnight then administrated iodohippurate (15 mg/kg) and Iohexol (1.25 mg/kg), independently, via an intravenous injection. Blood samples were obtained prior to dosing and at 6 time points following dosing to evaluate the clearance rate of either iodohippurate (RBF) or iohexol (GFR). In the diabetic miniature swine, there was a 48% increase in GFR and a 43% increase in RBF, compared to control swine. The GFR increase suggests there may be a hyperfiltration phenotype in the alloxan-induced diabetic miniature swine, similar to what has been noted in patients with T1D. Furthermore, the increase in renal blood flow also suggests there may be some vascular restructuring occurring in the animal model. While further investigation into the correlation between renal dysfunction and diabetes will be needed, these preliminary data suggest the alloxan-induced diabetic miniature pig may be a good translational model for T1D renal function research.

2189 Combination of Lacto-*Bacillus* Formulation with Cyclosporine A Completely Prevents Disease Progression in a Murine Model of Inflammatory Bowel Disease

R. Samadfam[1], D. Poulin[1], W. Finlayson[2], S. Coulson[2], K. Ralston[2], N. Pichon[2], and C. DeBakker[2]. [1]*Charles River, Senneville, QC, Canada; and* [2]*Servatus Limited, Sippy Downs, Australia.*

Ulcerative colitis (UC) is characterized by chronic digestive track inflammation and immune system malfunction. We investigated the efficacy of Lacto*Bacillus* (3 strains combined) in an *in vivo* model of DSS colitis. Stool consistency, blood in the stool and body weight were evaluated and a total disease activity index (DAI) was calculated. Colons were collected for cytokine and histopathology evaluation. Bacterial dosing was performed daily at $1.5x10^{10}$ cfu/mL alone or in combination with Cyclosporin A (CsA). Fecal samples for microbiome analysis were collected. Treatment with both CsA and live bacteria significantly lowered DAI score when compared to control, consistent with improvements in the colon length and composite histopathology score. The combination of live bacteria + CsA had superior effect on in-life scoring and histopathology findings. Majority of animals assigned to this group had no signs of inflammation or disease in colon. Decreases in anti-inflammatory cytokines including IL-2, Il-6, Il-17, KC/GRO and TNF were observed in colon of animals receiving live bacteria formulation or CsA alone. Consistent with in-life scoring and histopathology, additive effects were observed for combined therapy (live bacteria + CsA). Changes in fecal microbiome have been observed during the course of the study. There is an apparent slight improvement, where an apparent shift towards baseline microbiome composition was observed in treated animals compared to DSS control. Our data clearly indicate treatment of mice with live therapeutics by oral gavage significantly prevents development of DSS-induced colitis in mice with no significant safety concern. Combination of live therapeutics with a standard of care compound (CsA) had an additive effect with almost a complete prevention of the disease. These bacterial strains alone or combined with SOC present an alternative approach in treatment of colitis in clinic.

2190 Cerebrospinal Administration in the Juvenile CD1 Mouse Using the Intracerebroventricular Route

A. Saumure Di Fruscia, J. Douville, F. Emond, C. Foucault, M. Halle, and F. Goulet. *Charles River, Senneville, QC, Canada.* Sponsor: M. Vezina

An increasing number of molecules targeted to address neurological diseases and deficiencies are in development. As these are often larger molecules which fail to reach their target due to low penetration of the blood-brain barrier and/or have short half-life in circulation, targeted administration of these drugs directly into the central nervous system is often indicated. Neurological disorders often appear or develop during childhood and there is a heightened interest in conducting nonclinical studies in juvenile animals to mimic the age and development stage of the target population. Administration into the intrathecal space is more difficult than routine approaches regardless of species, but these challenges are greater when attempting these in smaller species such as the mouse, and more so in a juvenile population. In order to circumvent the technical limitations for intrathecal administration due to the size and delicate anatomy of the juvenile mouse, our laboratory developed an approach to conduct repeated intracerebroventricular (ICV) injection in CD1 mice of 21 days old. Anesthetized mice were restrained, and dosing was guided using stereotaxic table and predetermined coordinates to target the right ventricular area. During trials, a portion of mice were used for confirmation of successful injection. Diluted ink or saline was injected in the ventricle, and accuracy was evaluated visually following euthanasia and extraction of the brain from the skull and performing a coronal cut. Following this confirmation, an additional subset of mice was injected again 7 days later to assess tolerability of repeated anesthesia and injection. These animals were then maintained for an additional week. This subset was then euthanized, the brain was collected and histopathological evaluation was performed in order to characterize accuracy of the injection, and any procedure-related findings. There were no abnormal clinical signs and no changes in body weights or food consumption noted following the first or second injection. Animals recovered well from the procedures, and histopathology evaluation showed only minimal background findings. These results demonstrate that the ICV route of administration can be successfully used for safety assessment studies using cerebrospinal delivery in the juvenile mouse.

2191 Impact of Anesthesia on Rat Clinical Pathology

B. Lundell, K. Nkhata, and V. Wichmann Miller. *WuXi AppTec, Saint Paul, MN.* Sponsor: D. Fuhrer

Clinical pathology is a critical endpoint for preclinical systemic toxicity studies. In 2017, AAALAC recommended reducing the flow rate of CO_2 to a 10-30% displacement rate when anesthetizing rats. This may impact clinical pathology values. The objective of this study was to evaluate clinical pathology parameters using different anesthetics prior to terminal blood collection in rats. Thirty Sprague Dawley® rats were randomized to three groups. Ten animals (5 M/ 5 F) were evaluated per group. Rats were fasted and placed in an induction chamber using: 1) 4% isoflurane in O_2, 2) CO_2 with a 30% cage volume displacement per minute (30% CO_2) or 3) CO_2 with a 70% cage volume displacement per minute (70% CO_2). Following anesthesia, blood was collected by cardiac puncture into EDTA and SST™ Vacutainer® tubes (BD, Franklin Lakes, NJ). Whole blood was assayed for hematology parameters using the Hemavet 950 (Drew Scientific Inc, Miami Lakes, FL). Serum was assayed for clinical chemistry parameters using the Vet Axcel® (Alfa Wassermann Diagnostic Technologies, LLC, West Caldwell, NJ). Results were compared among groups using multiple unpaired t-test. Probability (p) values < 0.05 were considered statistically significant and biological relevance was evaluated. Statistically significant differences were observed among groups for the time to accomplish anesthesia. Exposure time in minutes was shortest for 70% CO_2 (4.2 ± 0.4), followed by 4% isoflurane (5.2 ± 0.8) and finally 30% CO_2 (6.0 ± 0.5). Compared to isoflurane, 30% CO_2 had a statistically significant impact on at least 11 clinical chemistry parameters, with glucose, phosphorus, potassium (all increased) and chloride (decreased) having biologic relevance. These parameters were also impacted when 70% CO_2 was used, but to a lesser magnitude. Prolonged exposure time at the lower CO_2 flow rate created a respiratory acidosis leading to electrolyte imbalance. Anesthesia with 30% CO_2 had no significant impact on hematology parameters. A trend of decreased leukocyte count was observed. A larger group size is needed to fully determine biologic relevance. Hematology parameters were similar at 30% and 70% CO_2. Choice of anesthesia must be considered when comparing clinical pathology data among laboratories. Artifact produced by preanalytical variation must be considered. Since clinical chemistry parameters collected under isoflurane were closer to published ranges, and CO_2 anesthesia resulted in some values incompatible with life, isoflurane is recommended when evaluating clinical pathology endpoints.

2192 A Mouse Model of *In Utero* Ultrafine Particulate Matter Exposure and Infant Respiratory Syncytial Virus Disease

C. H. Lau, R. Shore, D. Pendleton, J. Behlen, T. Mustapha, D. Garcia-Rhodes, A. Myers, A. Brar, T. Vargas, J. Secrest, Y. Li, R. Zhang, A. Rodrigues Hoffmann, N. Harvey, and N. Johnson. *Texas A&M University, College Station, TX.*

In utero exposure to particulate matter (PM) air pollution has been associated with increased lower respiratory tract infections (LRTIs) in infants. Despite the known sensitivity of the fetus to environmental pollutants and epidemiological evidence correlating prenatal PM exposure and LRTI morbidity, mechanisms of PM enhanced pathogenesis are relatively unexplored in immunologically immature populations. Moreover, the role of ultrafine particles (UFP, ≤ 0.1 μm) in the etiology of childhood respiratory disease are limited. To clarify the impact of *in utero* UFP exposure on LRTI morbidity, we exposed time-mated C57BL6/N mice to 100 μg/m^3 ultrafine particulate matter (LD), 500 μg/m^3 ultrafine particulate matter (HD) or filtered air (FA) for 6-h daily from gestational day 0-18. At 5 days of age, offspring were challenged with culture media (sham control) or a chimeric strain, rA2-19F, of respiratory syncytial virus (RSV) previously shown to elicit an aberrant immune response similar to infant infection. At 3 and 11 days of age, offspring were examined for pulmonary inflammation, via histologic and bronchoalveolar lavage (BAL) fluid analysis, pulmonary T cell profiles, and viral load (3 dpi). Blinded histologic examination revealed an increased inflammatory response within the RSV dosed offspring, with a subjectively heightened inflammatory response of the HD and LD exposed mice in comparison to the FA exposed mice. Within RSV dosed offspring, LD exposed offspring had significantly increased total leukocytes within BAL fluid compared to FA exposed mice. Eosinophilia varied within and between all exposure and dosing groups, with no significant trends. Viral load and flow cytometry analysis is ongoing. In conclusion, it appears the PM exposed, RSV dosed offspring exhibit an increased inflammatory response.

2193 The Value of History of Use within the Safety Assessment of New Dietary Ingredient Notifications (NDins)

L. T. Steen, T. Dao, E. Enongene, and A. Abdel-Rahman. *US FDA/CFSAN, College Park, MD.*

The Federal Food, Drug, and Cosmetic Act (FD&C Act) requires that manufacturers and distributors of a dietary supplement containing a new dietary ingredient (NDI), that has not been present in the food supply as an article used for food, submit a premarket safety notification to the FDA at least 75 days prior to introducing the ingredient to the market. The codified rules for the data required to be in a New Dietary Ingredient Notification (NDIN) (21 CFR 190.6) include a "history of use or other evidence of safety establishing that the dietary ingredient, […] will reasonably be expected to be safe…" The safety assessment within an NDIN review can be viewed as a modified hazard assessment where the history of use (HOU) serves as the exposure assessment and also provides insight into hazard identification. Specifically, a well-documented history of safe use serves several functions within the NDIN safety assessment: 1) provides documentation of historical consumption for comparison between the proposed conditions of use of the notified ingredient or supplement product to documented historical values; 2) helps to identify the data gaps which can be filled with other evidence of safety or safety studies; and 3) can be used to modify the safety factors used in safety calculations. New dietary ingredients vary from those with well-documented histories extending hundreds of years to those which have no history of use. Therefore, the data submitted for these ingredients will vary significantly depending on the HOU data available. A majority of the unique NDINs' received since 2014 contain HOU data in addition to other evidence of safety, but the HOU does not have the same substantive value in all NDINs. Among NDINs which were acknowledged without objection since 2014, approximately 38% contained a HOU which contributed to the safety review conclusion by modifying safety factors from pre-clinical animal data or establishing a reasonable expectation of safety based on historical consumption. Case studies of how history of use data affected the safety assessment and ultimately the conclusion of the NDIN review will be presented. While often it is a balance of both history of use data and other evidence of safety data that results in a reliable basis for an expectation of safety, the history of use, whether representing years of marketing success or centuries of experience, plays a necessary and significant role in the conclusion of the NDIN safety assessment.

2194 Screening Hazard Information for Low-Priority Substance Chemicals under the Toxic Substances Control Act (TSCA)

M. S. Nahar[1], C. Mitchell[1], L. Sweet[1], C. Rudisill[2], M. Riccardi[2], J. Melia[2], and C. Davies[1]. *[1]US EPA, Washington, DC; and [2]SRC Inc., Syracuse, NY.*

Under the Frank R. Lautenberg Chemical Safety for the 21st Century Act amendments to the Toxic Substances Control Act (TSCA), the US Environmental Protection Agency (EPA) is directed to prioritize existing chemicals in the TSCA Inventory as either high-priority substances for risk evaluation or low-priority substances for which risk evaluations are not warranted at the current time. The statute required EPA to designate 20 low-priority substances and 20 high-priority substances by December 2019. EPA created a fit-for-purpose literature search and review approach to transparently identify and document relevant and reasonably available information to support the risk-based screening review of the low-priority substances. Here, we outline EPA's approach for identifying, screening, evaluating, and integrating hazard (human health and environmental) and fate information to support the first 20 TSCA low-priority substance designations. Specifically, we describe sources, tools, inclusion/exclusion criteria, and data quality metrics used to identify relevant references for the screening reviews. For each chemical, EPA searched for hazard information using five search engines to access peer-reviewed literature (e.g. PubMed, Web of Science) and more than 20 "grey" literature and additional sources (e.g. online data repositories). All references were managed using the Health & Environmental Research Online (HERO) database and DistillerSR software during title/abstract screening, full text screening, and data evaluation steps. If data for human health or environmental endpoints were of insufficient quality or were unavailable for the target chemical, modeling data were used to fill data gaps or analogs were identified for read-across. Analog references were evaluated using a selective application of the same screening and evaluation strategy used for grey literature and additional sources. From the title/abstract screening, full text screening, and data evaluation steps, on average 3%, 43%, and 60% of references were included. Of the acceptable sources used for final designation, approximately 79% were from grey literature sources and 21% were from primary data sources. The approach described above was used to support the first 20 low-priority substance designations under TSCA and provides insight on the data that supports assessment of low-hazard chemicals.

2195 Nonclinical Regulatory Guidelines Development: EU, USA, and Australia—Regulatory Point of View

I. Algayadh, and R. Almadany. *Saudi Food and Drug Authority, Riyadh, Saudi Arabia.*

Preclinical studies, also known as the preclinical development and nonclinical studies, is a phase of research that begins before clinical trials, and during which important feasibility, iterative testing and product safety data are collected. The aim of this study is to highlight the most important well-established regulatory nonclinical guidelines and create the way for other researchers across the globe to investigate these guidelines and regulations. Also, promote harmonization of the preclinical studies to support human clinical trials and reduce differences between regions. A review was done on the updated guidelines of the following: European Medicines Agency (EMA), United States Food and Drug Administration (US FDA), and Therapeutic Goods Administration (TGA) of Australia. The content was reviewed and analyzed**.** Based on the collected information from multiple regulatory authorities with a wide range of stringency in terms of preclinical regulatory guidelines, it was noticed that most of the regulations referred to the International Council for Harmonization (ICH) guidelines. In summary, the findings indicate the need for more harmonization to standardize the guidelines across the globe. In addition, studies and collaborations are necessary in the area of nonclinical to reduce the requirements, efforts and therefore maintain the resources and unify the regulatory themes.

2196 Toxicology Studies to Support a Clinical Trial Using [^{68}Ga]-Labeled Radiotracers for PET Imaging

T. Kissner[1], A. Dudda[1], M. Wagner[1], L. Johansson[2], S. Pierrou[2], and O. Eriksson[2]. *[1]Sanofi, Frankfurt, Germany; and [2]Antaros Medical AB, Uppsala, Sweden.*

During last years, the Positron Emission Tomography (PET) tracer technology is becoming more of interest to be used in clinical and preclinical investigational studies. Some typical questions to be answered with this technology are imaging of tissues (e.g. tumors) specifically targeted with the radiotracer, bio-distribution of new radiolabel drugs or occupancy assessment of drug target receptors. In our case, two new [^{68}Ga] gallium-labeled PET radiotracer compounds (binding and active agonists at GLP-1 or Glucagon receptor) were intended to be used in a clinical study to investigate the receptor occupancy of a dual GLP1/GCG receptor agonist. Structurally, the radiotracers consist of a peptide strain which bound to a DOTA chelator which acts as the complex binding side for the [^{68}Ga] gallium isotope. The dual agonist will be given during a 4-week dosing period by daily SC administration and each of both PET radiotracers will be administered to the human subjects as short IV infusion once at base line and a second time at the end of the 4-week dosing period. PET scans will be performed after radiotracer administrations. A meeting with Swedish Medical Product Agency (MPA) took place in advance of the non-clinical testing to discuss the appropriate toxicology study design. Sanofi proposed both compounds would fall under the micro-dosing approach according to ICH M3 (R2) guideline and discussed specifically the micro-dosing requirements to be fulfilled for clinical radiotracer testing: total dose given ≤ 100 µg; total dose ≤1/100th of NOAEL (in mg/kg); total dose ≤1/100th of pharmacologically active dose (scaled in mg/kg). Further, Sanofi proposed to use unloaded tracers (neither loaded with labeled [^{68}Ga]$^{+3}$ or Ga^{+3}) to be tested in each of the extended single IV dose toxicity rat studies in the rat and use dose levels of the unloaded tracer which correlated to a 10-, 100-, or 1000-fold of the intended clinical dose of radiotracer. Agency agreed to the use of unloaded tracers molecules for animal testing; also to the proposed toxicology study design and to the strategy that radiotracers - in our clinical study setting - would fall under micro-dosing approach number 1 of ICH M3 (R2) guideline requiring extended single dose toxicity study.

2197 First Results of Developmental Neurotoxicity (DNT) Testing in the Extended One-Generation Reproductive Toxicity Study (EOGRTS) under the REACH Regulation

I. Bichlmaier, O. Leppäranta, D. Simon, V. Sihvola, and H. K. Huuskonen. *European Chemicals Agency, Helsinki, Finland.*

REACH (Registration, Evaluation, Authorisation and Restriction of Chemicals) is a regulation of the European Union, to protect human health and the environment from the risks that can be posed by chemicals, while enhancing the competitiveness of the EU chemicals industry. Under REACH, the EOGRTS

(OECD TG 443) is an information requirement for higher tonnage substances. The EOGRTS design is concern-driven and specified to meet risk assessment and classification and labelling needs. The DNT cohorts 2A and 2B of EOGRTS are required if the available information on a substance indicates a particular concern on (D)NT. Evidence supporting these concerns could originate from existing information derived from *in vivo* or non-animal approaches, from the knowledge of relevant mechanisms or modes of action of the substance itself, or from information on structurally analogous substances. Since the implementation of EOGRTS, the first results from requested studies with DNT cohorts have become available for the following substances: (A) diethanolamine, (B) 2-ethylhexanoic acid, (C) the oligomerisation and alkylation reaction products of 2-phenylpropene and phenol, (D) 2-(4-tert-butylbenzyl) propionaldehyde, (E) 4,4′-propane-2,2-diyldiphenol, polymer with 2-methyloxirane, (F) biphenyl, and (G) 3,5-dimethylpyrazole. Effects were observed for substances A, C, D and F. For substance A, adverse clinical observations, impaired auditory startle response and corresponding neuropathological findings were observed. For substance C, morphometric evaluation of the brains of Cohort 2A rats revealed lower hippocampus thickness values in high-dose males, and lower Cornu Ammonis thickness values in high-dose females (both when measured unilaterally). For substance D there were some small effects on brain weight, and altered auditory startle response. For substance F some effects on grip performance were reported for high-dose animals. These are the first results of DNT-triggered testing under REACH based on a limited number of studies for which results have become available on ECHA's dissemination website. Additional data is generated because DNT cohorts are requested in approximately 25% of ECHA decisions.

PS 2198 Developing a Defined Approach for Eye Irritation Testing

N. Choksi[1], A. J. Clippinger[2], S. Gehen[3], M. Corvaro[4], S. N. Kolle[5], K. Bentley[6], A. Hofstra[7], M. T. Inforzato[8], N. Ryan[9], E. Webb[9], W. Casey[10], and D. G. Allen[1]. *[1]Integrated Laboratory Systems Inc., Research Triangle Park, NC; [2]PETA International Science Consortium Ltd., London, United Kingdom; [3]Corteva Agriscience, Indianapolis, IN; [4]Corteva Agriscience, Rome, Italy; [5]BASF SE, Ludwingshafen, Germany; [6]FMC Corporation, Newark, DE; [7]Syngenta Canada Inc., Guelph, ON, Canada; [8]Syngenta Crop Protection LLC, Greensboro, NC; [9]Bayer AG, St. Louis, MO; and [10]NIEHS/NICEATM, Research Triangle Park, NC.*

Regulatory acceptance and implementation of new approach methodologies depend on public-private partnerships, which allow communication and cooperation among federal agencies and the private sector. To that end, the PETA International Science Consortium Ltd., the Interagency Coordinating Committee on the Validation of Alternative Methods, the National Toxicology Program Interagency Center for the Evaluation of Alternative Toxicological Methods, and CropLife America companies are collaborating on a three-phase evaluation to assess the applicability of *in vitro* eye irritation test methods to assess eye irritation potential for agrochemical formulations. Six formulations with existing *in vivo* data, classified as non-irritating (US Environmental Protection Agency [US EPA] Category IV) or severely irritating (US EPA Category I) were tested in Phase 1. The formulations were tested in the bovine corneal opacity and permeability (including histopathology), neutral red release, isolated chicken eye (including histopathology), EpiOcular (eye irritation test and time-to-toxicity protocols), and porcine cornea reversibility test methods. Each method predicted the same category as the rabbit test for most of the tested formulations, showing promise for further testing. Ten additional agrochemical formulations with *in vivo* data, representing a wider range of eye irritation classifications (US EPA Categories I, II, III, and IV), were evaluated in Phase 2. While none of the methods directly correlated with the *in vivo* results, several methods showed potential for use in a defined approach to assess agrochemical formulations. Phase 1 and 2 results will be used to identify which methods will be evaluated in Phase 3 and can form the basis of a defined approach for testing of agrochemical formulations for eye irritation potential. *This project was funded with federal funds from the NIEHS, NIH under Contract No. HHSN273201500010C.*

PS 2199 Integrated Regulatory Strategy to Prioritize Per- and Polyfluoroalkyl Substances (PFAS) of High Concern and Define Risk Management

F. Broeckaert, P. G. Karamertzanis, J. Peltola-Thies, J. Caley, Z. Kloslova, S. Lapenna, I. Gonzalez Rodriguez, and N. Andersson. *European Chemicals Agency, Helsinki, Finland.*

The European Chemicals Agency (ECHA) Integrated Regulatory Strategy aims to ensure the coherent implementation of the regulatory processes and supports authorities in addressing substances of concern. Coherent regulatory processes also contribute to meeting the 2020 goals of the World Summit on Sustainable Development. Therefore, with the support from Members States, ECHA has moved from a substance-by-substance assessment to assessment of groups of structurally and/or functionally similar substances. Per- and polyfluoroalkyl substances (PFAS) constitute a large group of substances widely used in various consumer and industrial applications. A few PFAS and salts of PFAS have recently been the subject of regulatory action in Europe, including harmonised classification as developmental toxicants, identification as substances of very high concern (SVHC) and restriction. In order to clarify common structural and developmental toxicity properties and to propose regulatory strategies for groups of PFAS, we mapped these chemicals within the chemical universe of REACH registered substances (chemical universe) and also substances notified in the C&L inventory. Algorithms were developed using a set of specific chemical features. Any notified or registered substance for which ECHA has at least one dossier with a composition that contains a constituent, impurity, or additive with a molecular structure that contains at least one C-F bond was located. Currently, the focus is on PFAS substances mapped in about 30 structurally-related subgroups. The analysis shows that the complex toxicity profile of PFAS is better understood at a subgroup level, provided that some data are available. The analysis attempts to determine the presence of structural alerts in some PFAS and to apply read-across for some subgroups, to investigate whether exposure to structurally similar PFAS results in similar health effects in order to facilitate an integrated regulatory strategy. These finding may also support informed substitution. Additional studies on the critical effects will facilitate read-across and may avoid regrettable substitutions.

PS 2200 Rethinking Carcinogenicity Assessment for Agrochemicals

G. M. Hilton[1], G. Akerman[2], J. Baldassari[3], M. Battalora[3], R. Buesen[4], A. J. Clippinger[1], D. Geter[5], A. Lowit[2], S. Melching-Kollmuss[4], T. Kormos[6], S. Papineni[7], R. C. Peffer[8], B. Williamson Riffle[9], N. Ryan[6], N. Visconti[6], and D. C. Wolf[5]. *[1]PETA International Science Consortium Ltd., London, United Kingdom; [2]US EPA, Washington, DC; [3]FMC Corporation, Newark, DE; [4]BASF SE, Ludwigshafen am Rhein, Germany; [5]Syngenta Crop Protection LLC, Research Triangle Park, NC; [6]Bayer US LLC, Research Triangle Park, NC; [7]Corteva Agriscience, Indianapolis, IN; [8]Rich Peffer Toxicology Consulting LLC, Greensboro, NC; and [9]BASF Corporation, Research Triangle Park, NC.*

For the past 40 years, questions have been raised about the relevance and regulatory utility of rodent cancer bioassays in human health risk assessment. As a result, a working group of experts from different sectors have formed the Rethinking Carcinogenicity Assessment for Agrochemicals Project (RECAAP) to determine the appropriateness of and criteria for waiving rodent cancer bioassays for the registration of food-use pesticides. A weight of evidence (WoE) reporting framework, which outlines a suggested assessment of publicly available information, was used to draft carcinogenicity study waivers to determine if sufficient information was available to perform a health protective chronic risk assessment without conducting rodent cancer bioassays. Information used in the WoE include exposure, mode-of-action, physiochemical properties, metabolism, and sub-chronic toxicological data from standard risk assessment endpoints. Using this framework, RECAAP evaluated 29 pesticides registered over the past ten years with the chemical distribution spanning 15 tumor types, 28 chemical classes, and eight cancer classifications (including subclasses). The reporting framework criteria and example carcinogenicity waivers will be presented. This effort has established criteria for when the mouse and/or rat cancer bioassay can be waived while ensuring that pesticide human health risk assessments are protective.

PS 2201 Assessing the Impact of Expert Knowledge on ICH M7 (Q)SAR Predictions. Is Expert Review Still Needed?

N. L. Kruhlak, P. S. Jayasekara, L. E. Woodard, S. K. Skanchy, M. T. Kim, G. Kumaran, B. E. Mugabe, J. Yang, and A. J. Zych. *US FDA/CDER, Silver Spring, MD.*

The ICH M7(R1) guideline recommends the use of complementary (Q)SAR models to assess the mutagenic potential of drug impurities as a state-of-the-art, high-throughput alternative to empirical testing. Additionally, it includes a provision for the application of expert knowledge to increase prediction confidence and resolve conflicting calls. Expert knowledge, which includes structural analog searching and mechanistic interpretation, has been particularly valuable in situations where models return an indeterminate (equivocal) result or are unable to generate a prediction due to a lack of relevant training set analogs (out-of-domain). Recently, a retrospective analysis was conducted by FDA's Center for Drug Evaluation and Research to assess the impact of

applying expert review to (Q)SAR predictions for 1002 drug impurities evaluated in new and generic drug applications between April 2017 and April 2019. Expert knowledge overturned the default predictions for 26% of the impurities and resolved 96% of equivocal predictions and 75% of out-of-domain calls. Of the 261 cases where expert knowledge overturned the default prediction, 15% were upgraded to equivocal or positive and 79% were downgraded to equivocal or negative. Furthermore, the chemical classes where this effect was most pronounced were polycyclic aromatic systems (68% overturned), aldehydes (39% overturned), aromatic amines (35% overturned), and Michael-reactive acceptors (33% overturned). Collectively, the results suggest that a modified workflow that triages predictions could be used to improve (Q)SAR review efficiency, and that the application of expert knowledge still plays an important role in an ICH M7 (Q)SAR prediction workflow.

PS 2202 Phage Therapy as a Viable Treatment Option to Overcome Drug Resistance: Nonclinical Regulatory Progress and Scientific Perspectives

R. C. Dumitrescu[1], and G. Krishna[2]. *[1]Parexel International Corporation, Bucharest, Romania; and [2]Parexel International Corporation, Bethesda, MD.*

Superbugs that are immune to multiple drugs are a concern with more frequent use of antibiotics. Phage therapy is considered as an alternate to overcome bacterial multiple-drug resistance (MDR), yet there is no guidance in making this a reality. Aim of this presentation is to review the evolution of phage therapy and to share the lessons learned (educational) by the authors' "nonclinical regulatory" experience. To this end, pertinent literature was reviewed, expert opinions were pursued, and authors' personal experiences discussed. Results showed: phage therapy is enlisted as biologic, but there are differences from "biologics", i.e., phage is a living and replicative virus, generally non-toxic/well tolerated, which targets directly and specifically bacterial envelope, uses the host bacteria to multiply, is self-dosing (multiplication linked to bacterial population dynamics) and does not trigger a significant immune response to itself (as opposed to live viral vaccines). However, there is a toxicological concern such as risk of toxic shock as result of dead bacterial debris and release of toxins. Proof of efficacy in *in vitro* and pharmacology models, limitations of animal toxicology studies considering the 3R-principles have strengthened the relevance of alternative models as pivotal for pharm/tox regulatory pathway to a marketed drug. With technological advancements, particularly in Good Manufacturing Practices, there has been an increasing trend in clinical studies of patients with severe bacterial infections, successfully treated with phages as compassionate-use, providing last hope for patients suffering from MDR infections. Increased rate of clinical success raised awareness in the stakeholders, so workshops were held by both EMA (2015) and FDA (2017) to exchange information with the medical and scientific community about the issues associated with bacteriophage therapy. Recent reviews on this topic highlight a strategic collaborative effort globally to improve this with a rationalized scientific approach. Despite the rapid increment in finding relevant *in vitro* and *in vivo* pharmacological models, alternative toxicity testing with clinical relevance and continuously expanding clinical applications, a specific regulatory guidance on this topic is needed. As such, the interaction with regulatory bodies is currently a "negotiation" process, using scientific arguments. Based on authors' experience (up to 5), it is concluded that such interactions have helped/will help charter a pathway to bring phage therapy as a valuable treatment option to the patient.

PS 2203 A Retrospective Study on EU Harmonized Classifications for Carcinogenicity to Guide Future Research

C. Terry, J. Z. Yan, M. Corvaro, and S. Gehen. *Corteva Agriscience, Indianapolis, IN.*

Under European Regulation (EC) No 1272/2008 (CLP), chemicals can be defined as carcinogenic if they induce tumors, increase tumor incidence and/or malignancy, or reduce the time to tumor development. In January 2019, 149 reports considering the carcinogenicity classification of chemicals under CLP were identified on the ECHA website, covering two Carc. 1A chemicals ("known to have carcinogenic potential for humans"), 24 Carc. 1B ("presumed to have carcinogenic potential for humans"), 44 Carc. 2 ("suspected human carcinogens") and 79 chemicals not classified for carcinogenicity. The general features of these ECHA opinions were considered. Human carcinogenicity data resulted in two chemicals being classified as Carc. 1A, and supported the classification of 29% of Carc. 1B substances. Most (71%) Carc. 1B chemicals induced tumors in more than one species (mainly rodent, but also human, data). For 29%, tumors in a single rodent species were sufficient for 1B classification in WoE assessments (e.g. also considering genotoxic potential). For Carc. 2 classifications, 59 and 41% were based on tumors in a single species or in two rodent species, respectively. Of the chemicals not classified for carcinogenicity, 11% had no relevant data available, while others were not classified based on substance-specific or read-across data indicating a lack of effect (66%). A further 23% had indications of carcinogenicity in rats and/or mice which were not considered relevant to humans. Carc. 1B chemicals most frequently induced tumors in the rat lung (33%) or nasal cavity (25%), and/or the mouse lung (38%) or liver (33%). For Carc. 2 chemicals, the most frequently affected organ was the liver (32% of Carc. 2 chemicals in rats, 30% in mice), and Leydig cell tumors were also very commonly induced in rat testes (27%). In mice, besides the liver, the most common target was the lung (16%). Twelve of the chemicals not classified for carcinogenicity produced tumors in rats; four affected the liver, four the thyroid, two the testes and two the mammary gland, while the preputial gland, blood and adrenals were affected by one chemical each. In mice, six 'not classified for carcinogenicity' chemicals induced tumors in the liver, while the thyroid, lung and Harderian gland were affected by one chemical each. Based on summarized MoAs linked to cancer classification, an assessment of the different tumor sites affected by the 44 Carc. 2 chemicals was conducted to present prioritized areas for future MoA-based research.

PS 2204 Assessment Strategy for the Identification of Endocrine Disruptors

N. Andersson[1], M. Arena[2], D. Auteri[2], S. Barmaz[2], E. Grignard[3], A. Kienzler[3], P. Lepper[1], A. M. Lostia[2], S. Munn[3], J. M. Parra Monte[2], F. Pellizzato[1], J. Tarazona[2], A. Terron[2], and S. Van den Linden[1]. *[1]European Chemicals Agency, Helsinki, Finland; [2]European Food Safety Authority, Parma, Italy; and [3]Joint Research Centre, Ispra, Italy.*

For the first time, ECHA and EFSA have jointly published a Guidance document [1] on how to identify endocrine disruptors in accordance with the scientific criteria for the determination of endocrine disrupting (ED) properties applicable to the Biocidal Products (BPR) and the Plant Protection Products (PPPR) Regulations. The ED criteria are unique in that they are the first translation of the WHO/iPSC definition of an endocrine disruptor into regulatory requirements. According to the criteria a substance shall be considered as having ED properties: if it shows an adverse effect, if it shows endocrine activity, and if there is a biologically plausible link between the adverse effect and the endocrine activity (i.e. it has an endocrine mode of action). They require a weight of evidence approach for reaching the conclusion that includes taking into account all available information and conducting a mode of action analysis (which includes assessing essentiality, consistency and specificity). Separate conclusions are required on whether the ED criteria are met with respect to humans and non-target organisms. Depending on the available information, additional data might need to be generated on order to reach these conclusions. The data requirements of the BPR and PPPR contain more mammalian studies that may be informative on ED properties than studies on other taxonomic groups. Thus, in line with the general principle to avoid unnecessary animal testing, the assessment strategy in the guidance recommends to strive for a conclusion on the ED properties with regard to humans first, followed by a conclusion on mammals as non-target organisms based on the same data set. Only when the ED criteria are not met for mammals as non-target organisms, there will be a need to proceed to other taxonomic groups. First experiences with the practical application of the ED Guidance are discussed including the outcome of the first ED conclusions on active substances. *Reference: [1] Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009 https://doi.org/10.2903/j.efsa.2018.5311.*

PS 2205 Current and Future Risk Assessment Considerations for Genotoxic and Nongenotoxic Carcinogens

G. M. Woodall. *US EPA, Research Triangle Park, NC.*

The National Academies of Science risk assessment paradigm includes both qualitative hazard identification and quantitative dose-response assessment, which are combined with exposure assessments to render a risk characterization to inform risk decisions. An often-mischaracterized aspect of cancer dose-response assessment is in the latitude for risk model selection between genotoxic versus non-genotoxic carcinogens. The 2005 EPA Cancer Guidelines recommend a health-protective default assumption of a linear low-dose model where any exposure poses some risk; the question is then what level of risk is acceptable. Typically, risks lower than one-in-a-million ($1:10^6$) are deemed to be acceptable; however, higher risk levels may sometimes be deemed acceptable considering technical feasibility to reduce exposures, and social, cultural and economic factors. The most often proposed alternative "non-linear" risk estimation models assume a threshold exposure level to be achieved and maintained in order to induce cancer. In a thresh-

old model, any exposures below a certain level are assumed to not increase cancer risk, and estimations of risk are then similar to estimates for non-cancer risks. A common misconception is that the Cancer Guidelines (EPA, 2005) assume a linear low-dose model only if a carcinogen is active through a genotoxic mechanism, and a non-linear (e.g., threshold) model if it causes cancer through a non-genotoxic mechanism. In actuality, critical mechanistic evidence is needed before replacing the default assumption of linearity with any other model to estimate risks, regardless of whether a genotoxic or non-genotoxic mechanism is the putative cause. Several examples in completed cancer risk assessments will be presented to illustrate aspects of these considerations. As greater understanding is gained on the specific mechanisms leading to cancer and those individual mechanistic steps are combined to create credible adverse outcome pathways (AOPs), it is anticipated that the evidence to either support or reject the default linear assumption will be enhanced. These considerations also need to be made in the context of exposures of populations to many agents contributing to overall cancer risk, including occupational exposures as well as exposures in ambient air, drinking water and food.

2206 Comparison of Flavor Chemicals and Cytotoxicity of Authentic and Counterfeit Refill Fluids Purchased Worldwide

E. Omaiye[1], W. Luo[2], J. Pankow[2], and P. Talbot[1]. *[1]University of California Riverside, Riverside, CA; and [2]Portland State University, Portland, OR.*

Electronic cigarettes (ECs) expose consumers to nicotine, flavor chemicals, metals and reaction products that can negatively impact the health of users. Recently, the use of ECs has been linked to vaping-associated pulmonary illness (VAPI). To examine the relationship between flavor chemicals and VAPI, we identified and quantified flavor chemicals and nicotine in EC products that were manufactured by one company and purchased in four countries, and we compared flavor chemicals in authentic and counterfeit products. We identified cytotoxic refill fluids using the MTT assay and further observed their effects on cell growth using live cell imaging. We then tested authentic standards of pure flavor chemicals that may contribute to the cytotoxicity of the refill fluids. Total flavor chemical concentration was ≥ 1 mg/ml in 76% of the refill fluids and ≥ 10 mg/ml in 34%. Of 130 flavor chemicals identified, 28 were ≥ 1 mg/ml in at least one sample and 6 of these were ≥ 10 mg/ml. The total number of flavor chemicals in each product ranged from 0 - 50. For authentic refill fluids, products purchased in different countries were similar in type and concentration of flavor chemicals. However, counterfeit "Menthol" and "Bright Tobacco" products contained twice the concentration of flavor chemicals as their authentic counterparts. Identical products purchased in different countries induced similar cytotoxic responses in the MTT assay and cell growth inhibition in the live cell imaging assay. However, counterfeit "Bright Tobacco" inhibited cell growth more than its authentic counterparts. Ethyl maltol, furaneol, and eugenol contributed to toxicity. For specific authentic products, the flavor chemicals used, their concentrations, and their cytotoxicity did not vary with country of origin. Cytotoxicity was attributed to specific flavor chemicals that were present in high concentration, which often exceeded those in other consumer products. Flavor chemical concentrations in counterfeit products exceeded those in their authentic counterparts, supporting the idea that counterfeit products can contribute to VAPI. Safety of these products could be improved by regulation of their flavor chemicals.

2207 The Key Characteristics of Carcinogens

K. Z. Guyton[1], and M. T. Smith[2]. *[1]IARC, Lyon, France; and [2]University of California Berkeley, Berkeley, CA.*

The key characteristics of human carcinogens were recently introduced to provide a uniform approach for searching, organizing, and evaluating mechanistic evidence to support cancer hazard identification. The key characteristics comprise the properties of known human carcinogens, including their ability to be genotoxic; be immunosuppressive; or modulate receptor-mediated effects. They differ from the hallmarks of cancer, which are the properties of cancer cells. The key characteristics have been applied in evaluations of more than 50 mechanistically diverse chemicals and complex exposures classified into Groups 1, 2A, 2B, and 3 by IARC Monographs expert Working Groups since 2015. Because they are based on empirical observations of the properties associated with known carcinogens rather than an *a priori* hypothesis about a mechanism of action, the key characteristics provided an agnostic and unbiased survey of the mechanistic literature. This improved uniformity across evaluations of mechanistically diverse agents. It also improved transparency, revealing strengths as well as gaps in evidence, and highlighting mechanistic similarities and differences. However, some challenges, including in interpreting evidence on individual key characteristics, were also identified. In 2019 amendments, the IARC Monographs Preamble has adopted an approach based the key characteristics. The Preamble addresses some of the identified challenges, and also emphasizes study quality considerations in the review of evidence relevant to the key characteristics. These are important advancements to prepare for future advances in molecular research aimed at identifying the causes of human cancer, the first step in cancer prevention.

2208 Comparative Risk Assessment of Regulated vs. Unregulated Cannabis Concentrate Aerosol ("Vape") Products

R. Rucker, and E. Rufer. *PAX Labs Inc., San Francisco, CA.*

The recent epidemic of vaping-related lung injuries has focused attention on risks associated with illicit cannabis "vape pens." In a series of studies, we quantified some of the risks associated with illicit vape products, relative to regulated ones. Although regulated markets for cannabis products exist in 33 states, the unregulated, illicit market still accounts for the majority of cannabis consumed in the US. Cannabis products sold outside of regulated channels are not subject to testing for potency, impurities or contaminants. Three important differences distinguish regulated products from unregulated: the hardware, the cannabis content, and diluents. Poor manufacturing processes may introduce toxic heavy metals into cartridge components, which may leach into cannabis oils. Unsafe cultivation processes can introduce pesticides, which are concentrated during the process of extracting and distilling cannabis. Components of comparable regulated and unregulated hardware products were subjected to elemental analysis. Two common diluents -- MCT oil (sometimes used in regulated products) and Vitamin E acetate (often used in unregulated products) -- were aerosolized and tested for chemical composition. Finally, regulated and unregulated products were tested for pesticides and potency. Exposure to these substances was assessed using a new model of cannabis concentrate aerosol consumption ("vaping"). This model was based on usage data from tens of thousands of regulated cannabis users that opted-in to sharing their data were collected via a mobile app connected to a digital vaporizer. We conclude that regulated products present a lower risk to the end user than unregulated products. These results have important implications for public health policy makers, as they develop strategies to address the safety risks from illicit vapor products.

2209 Systematic Assessment of Cellular Gene Network Modulation by Valproic Acid Analogues for Biological Read-Across

N. G. Vrijenhoek[1], L. Wijaya[1], M. J. Moné[1], M. Wehr[2], S. E. Escher[2], and B. van de Water[1]. *[1]Leiden Academic Centre for Drug Research, Universiteit Leiden, Leiden, Netherlands; and [2]Fraunhofer Institute for Toxicology and Experimental Medicine, Hannover, Germany.*

Chemical read-across is commonly evaluated without particular knowledge about the biological mechanisms leading to the observed adverse outcomes in *in vivo* studies. The integration of data showing a shared mode of action in humans will strengthen the read-across assessment. Here we used a large panel of valproic acid (VPA) analogues to include detailed mode-of-action (MoA) data as a proof-of-concept for read across. In rodents, VPA and some of its analogues cause hepatic steatosis, whereas other analogues do not. Previous studies showed a predictive value for stress pathway response activation for the hepatotoxic potential of VPA analogues. Here, we look into the transcriptomic response of HepG2 cells stimulated for 24 h by the analogues in a dose response range to be able to predict steatotic potential *in vivo*. We used TempO-Seq targeted high-throughput screening assay to assess the differential expression of more than 3000 genes, referred as the S1500+ geneset, that reflects all biological pathways. Dose response analysis revealed clustering of steatotic-positive versus steatotic-negative VPA analogues. To quantitatively define biological read-across of VPA analogues we used both pathway analysis and our in-house primary human hepatocyte (PHH) TXG-MAPr tool, a novel gene expression visualization tool based on weighted gene co-expression network analysis of the Open TG-GATEs database. VPA responses in HepG2 cells displayed high similarity in gene network modulation compared to responses in PHH. Steatotic VPA analogues demonstrated similar pathway activation. Quantitative gene network analysis allowed ranking of biological similarity of VPA analogues. Importantly, free fatty acid synthesis modulation was highly affected by all steatotic VPA analogues, but not by *in vivo* negative analogues. We defined the most representative genes that reflect steatosis responses in both HepG2 and PHH that could be generally used as markers for steatosis onset. In summary, by studying the MoA on a transcriptional level, we anticipate to support risk assessment by providing quantitative and mechanistic biological information to corroborate a robust read-across approach. *This work was part of the EU-ToxRisk project and received funding of the European Union's Horizon 2020 research and innovation program under grant agreement No 681002.*

2210 Evaluation of Risk Associated with Heavy Metals in *Carica papaya* (Pawpaw) from Three Waste Dump Sites in Rivers State, Nigeria

L. P. Karikpo[1], I. K. Ekweozor[1], M. Miebaka[1], and O. K. Yemitan[2]. [1]*Rivers State University, Port Harcourt, Nigeria; and* [2]*Lagos State University, Lagos, Nigeria.*

The fruit of *Carica papaya* (Papaya) is popularly consumed worldwide; but in addition, the leaves and root decoction of the plant are also used for various medicinal purposes in Africa. In this study, the risk associated with heavy metals (Cr, Cd &Pb) in *Carica papaya* (CP) from three local Government refuse sites in Rivers, Nigeria, was measured and assessed. The leaf, root and fruit samples of CP were collected and transported to the laboratory for six months, at intervals of six weeks. The concentrations of the heavy metals in the samples were analysed using the Atomic Absorption Spectrophometer. The potential risk associated with consumption of these metals was evaluated in terms of Estimated Daily Intake (EDI), Target Hazard Quotient (THQ) and Hazardous Index (HI). The EDI values (mgkg-1day1) of Cr, Cd &Pb, respectively, were as follows; for Leaf: station1 (7.82×10-4, 8.99×10-5, 9.65×10-4), station2 (7.92×10-4, 6.16×10-5, 1.10×10-3), station3 (6.83×10-4, 7.32×10-5,1.12×10-3); Root: station1 (6.19×10-4, 4.33×10-5, 1.03×10-3), station2 (3.78×10-4, 4.65×10-5, 6.57×10-4), station3 (3.99×10-4, 6.82×10-5, 8.07×10-4); and Fruit: station1 (3.26×10-4, 3.16×10-5, 7.69×10-4), station2 (3.61×10-4, 2.0×10-5, 2.70×10-4), and station3 (9.15×10-5, 3.83×10-5, 4.46×10-4). DerivedTHQ values were: Leaf, in station1 (0.52, 5.99, 0.69), station2 (0.53, 4.12, 0.79), station3 (0.46, 4.82, 0.80), for Root: station1 (0.41, 2.89, 0.74), station2 (0.25, 3.10, 0.47), station3 (0.27, 4.55, 0.58); and Fruit: station1 (0.22, 2.11, 0.55), station2 (0.24, 1.33, 0.19), station3 (0.06, 2.55, 0.32), respectively. Computed HI for Leaf in station1 (7.2), station2 (5.44) & station3 (6.08); Root, station1 (4.04), station2 (3.82), & station3 (5.4); and for Fruit, station1 (2.88), station2 (1.76) & station3 (2.93), respectively. The study revealed that Cr, Cd &Pb were bioconcentratedin CP with values higher than WHO/FAO safety limits. Therefore, consumption of *Carica papaya* plant parts may pose heavy metal health risk in the study locations.

2211 Categorical Read-Across Assessment of Cancer and Noncancer Endpoints for Amino-Dinitrotoluenes

D. D. Petersen. *US EPA, Cincinnati, OH.*

For some chemicals to which we are all exposed, rich data sets incorporating chronic, reproductive and developmental bioassays are available. However, most chemicals are "data-poor", hindering the identification of toxicity thresholds. 4-Amino-2,6-Dinitrotoluene (4-ADNT), and 2-Amino-4,6-Dinitrotoluene (2-ADNT), collectively, ADNTs, are members of a category of compounds known as nitroaromatics. The two ADNTs are the main human urinary metabolites of trinitrotoluene (TNT). There are no repeat-dose toxicity studies for the ADNTs, however, both are active in most genotoxicity tests. A categorical read across (RA) process was used to identify a surrogate for the derivation of a toxicity value for noncancer effects, and an RA process using several SAR tools was used in the weight of evidence analysis of carcinogenic effects. Three similarity contexts (structural, metabolic, and toxicitylike) were utilized to facilitate the final noncancer analogue chemical selection. Six structural analogues with published toxicity values were identified (TNT, 2-Methyl-5-Nitroaniline, Isopropalin, Pendimethalin and Trifuralin). Whereas analogues other than TNT do not share common metabolites, all analogues share metabolic features such as reduction of nitro-groups to amino-groups during metabolism. Toxicity profiles of the analogues in animal studies show that all produce methemoglobinemia and related blood effects. Only isopropalin failed to produce hepatic effects. This suite of toxic effects, beginning with reactive oxidant species (ROS) produced in red blood cells resulting in oxidation of hemoglobin (methemoglobin), red blood cell destruction, splenic effects from damaged RBC processing and Kupffer cell and other liver effects subsequent to ROS, and other effects from damaged RBCs are common features of organic and inorganic nitrate exposure. TNT proved to be the most appropriate analogue, in terms of structural, metabolism and toxicity. In the carcinogenicity analysis, analogues were identified through structural clustering with known carcinogens (ChemACE). ADME, genotoxicity, and carcinogenic data were evaluated and a SAR analysis was performed on the target and potential analogues for structural alerts known to be associated with carcinogenicity. Based on similarities across these data streams, we determined that ADNTs could reasonably be expected to lead to carcinogenicity. *The views expressed in this abstract are those of the author and do not necessarily reflect the views and policies of the US EPA.*

2212 Evaluation of Serum and Urine Metabolites Perturbed in Hyperglycemia Induced by Bisphenol S Exposure in Wistar Rats

K. Mandrah[1,2], V. Jain[1,2], J. A. Ansari[1,2], and S. K. Roy[1,2]. [1]*CSIR-Indian Institute of Toxicology Research, Lucknow, India; and* [2]*AcSIR, Ghaziabad, India.* Sponsor: D. Parmar

Bisphenol S (BPS) is an industrial chemical and widespread in the environment causing detrimental effects proportionally similar to its congener substance bisphenol A (BPA). Earlier studies have been focused on its estrogenic potential. Based on the available literature, we hypothesized that it may perturb the expression of endogenous metabolites in several biochemical pathways. In the present study, we have characterized perturbed metabolites in serum and urine of male Wistar rats. Experimentally, BPS was administered orally at doses of 0.05, 0.5 and 5 mg/kg bw (low, medium and high) for 90 days. The oral glucose tolerance test (OGTT) and insulin tolerance test (ITT) showed an elevated level of glucose in exposed animals at medium and high doses, indicated the manifestation of hyperglycemia. Further, GC-MS/MS analysis identified 24 and 9 differential metabolites in serum and urine, respectively, consisted of amino acids, sugars, and organic acids. In addition, multivariate data of differential metabolites were obtained by reprocessing of GC-MS/MS data using metaboanalyst software; comprising ANOVA data of individual metabolites, principle component analysis (PCA) and partial least square discriminant analysis (PLS-DA) data. Where, variance in different groups explained in foremost two PCs with 32.1 % and 15.5 % of PC1 and PC2, respectively. Furthermore, perturbed metabolites were explored to identify the altered pathways by Kyoto Encyclopedia of Genes and Genomes (KEGG) based analysis. The result showed amino acid, glycolysis, pyruvate metabolism, and other pathways affected due to BPS exposure. Conclusively, the study showed perturbed metabolites promisingly revealing BPS exposure induce hyperglycemia.

2213 The Impact of the Seasonal Biorhythms on Hematotoxicity in Rats by Treatment of Cyclophosphamide, Methotrexate, and 5-Fluorouracil

V. N. Rakitskii, and S. V. Skupnevskii. *F.F. Erisman Federal Scientific Center of Hygiene, Mytischchi, Russian Federation.* Sponsor: V. Rakitskii, EUROTOX

The same doses of xenobiotics are administered at different times of the day or seasons may be accompanied by variability in the amplitude of the toxic effects. The investigation of chronotoxicological regularity for pollutants contributes to a more accurate determination of toxicological properties, which ultimately facilitates to identify and reduce environmental health risks of chemicals. The aim was to determine chronotoxicological profile of combination the cytostatics CMF by marker parameter - count of leukocytes. 84 male *Wistar* rats aged 90 ± 5 days were used in the work. The experiment was carried out during a year, two equal randomized groups were formed every two months. Housing and feeding conditions were standard for vivarium. Experimental design: control group - solvents; the experimental group - intraperitoneally cyclophosphamide 100 mg/m^2 (once a day for two weeks), methotrexate 40 mg/m^2 and 5-fluorouracil 600 mg/m^2 on the first and eighth days. The administration time was 11:30. 24 hours after the last injection the animals were euthanized (CO_2 chamber), blood sampling with an anticoagulant (heparin) was analyzed *ex tempore* on Erma PCE-210 automated hematology analyzer (Japan). Statistical processing was based on Student's *t*-test. Administration to experimental animals a complex of cytostatics was accompanied by the expected decrease in the total number of white blood cells (WBC) - on the average of 73%. The mean annual count of WBC in control animals was 5.9 ± 0.8 x 10^9 /L. In August (the bathyphase) it decreased to 4.8 ± 0.8 × 10^9, in February (the acrophase) it increased to 6.8 ± 0.4 × 10^9 ($p<0.01$). The range of values between the extreme points was 29%. In animals of the experimental groups the average annual number of WBC was 1.6 ± 0.3 x10^9/L. The minimum was detected in August - 1.0 ± 0.2 x10^9, the maximum - in October and December - 1.8 ± 0.2 x10^9 which defines a 180% increase ($p<0.001$). The wide variability in the hematotoxic effect of the used chemicals (CMF) reveals the modulating action from seasonal biorhythms, which in modeled pathology are manifested by a larger amplitude of the body's response reactions. This circumstance should be taken into account in procedures for assessing acute and chronic toxicity of testing substances to increase the veracity of the information received.

2214 Proposal for a Health-Based Occupational Exposure Limit for Trichloramine by the Nordic Expert Group

G. Johanson[1], G. Wastensson[2], and K. Eriksson[3]. *[1]Karolinska Institutet, Stockholm, Sweden; [2]Göteborgs Universitet, Gothenburg, Sweden; and [3]Umeå Universitet, Umeå, Sweden.*

The Nordic Expert Group for Criteria Documentation of Health Risks from Chemica (NEG) is a collaboration for production of criteria documents on chemicals as basis for setting occupational exposure limits (OELs) in the Nordic countries (1). A criteria document on inorganic chloramines, including a health-based OEL proposal for trichloramine, was recently published (2). Trichloramine is formed as one of several disinfection byproducts when chlorine reacts with nitrogen containing compounds. Trichloramine is immiscible with water and evaporates easily from water into air. Trichloramine may aggravate asthma symptoms in individuals with existing asthma, however, NEG concludes that the risk of developing asthma following long-term exposure to trichloramine cannot be evaluated at present. No data on genotoxic, carcinogenic, reproductive or developmental effects were located. Based on several studies on indoor swimming pool workers the critical effect is judged to be irritation, starting at approximately 0.4 mg/m^3 (stationary measurements). Applying assessment factors (AF) to account for extrapolation from LOAEC to NOAEC (AF 2) and from stationary to personal measurements (AF 2), NEG recommends a health-based OEL of 0.1 mg/m^3 (8-h TWA), corresponding to 0.2 mg/m^3 for stationary measurements in swimming pool facilities. No short-term exposure limit (STEL) is recommended. For comparison, the World Health Organization (WHO) in 2006 recommended a maximum trichloramine level of 0.5 mg/m^3 as a comfort value in indoor swimming pool air (3). *References: (1) https://www.av.se/en/the-nordic-expert-group/. 2215 An Integrated Approach of Dietary Exposure and Physiologically Motivated Toxicokinetic Modeling for Probabilistic Risk Assessment of Nitrate and Nitrite through Vegetable Consumption

Y. Lin[1,2], C. Cheng[1], and Z. Lin[2]. *[1]Institute of Food Safety and Health Risk Assessment, National Yang-Ming University, Taipei, Taiwan; and [2]Institute of Computational Comparative Medicine, Kansas State University College of Veterinary Medicine, Manhattan, KS.*

Food safety of nitrate and nitrite in vegetables has been a concern of many regulatory bodies and researchers. This study aimed to determine the concentrations of nitrate and nitrite in vegetables and to estimate the potential dietary risk of nitrate and nitrite due to vegetable consumption based on internal dose in a probabilistic manner by integrating dietary exposure assessment with physiologically-motivated toxicokinetic (TK) modeling. In this study, the concentrations of nitrate and nitrite in 21 vegetables were determined based on the massive consumption database from the Nutrition and Health Survey in Taiwan (NAHSIT) covering all ages. We optimized a previously established TK model, validated our new model using human data, and incorporated Monte Carlo simulations to account for variability across human populations for different age groups. High levels of nitrate were detected in leafy vegetables with the means ranging from 545.33 to 1641.17 mg/kg. Nitrite contents of vegetables were generally low with the means ranging from 1.27 mg/kg in potato to 8.20 mg/kg in sweet potato vines. The major sources contributing to the average nitrate and nitrite exposures across age populations were cruciferous leaf vegetables and cabbage. The assessment results were found to be different between based on external vs. internal dose, suggesting that it is critical to include the kinetic process of the endogenous formation of nitrite into risk assessment of nitrate and nitrite. Our results suggest that nitrate and nitrite exposure from vegetables is unlikely to result in appreciable safety risk for most age populations, but may be a potential concern for preschoolers. This is the first study integrating dietary exposure assessment, a TK model in humans, with probabilistic approach to predict the internal dose for estimating the dietary risk caused by nitrate and nitrite in vegetables. Our method can be applied to obtain more reliable exposure estimates and to improve risk assessment of nitrate and nitrite.

2216 *In Vitro* and *In Vivo* Identification of a Soluble Epoxide Hydrolase (sEH) Metabolite, 14,15-DHET, as an Early Doxorubicin (DOX) Cardiotoxicity Biomarker and Screening of sEH Inhibitors for Medical Intervention

J. M. Santos, A. Joiakim, D. Kaplan, D. Putt, and H. Kim. *Detroit R&D Inc., Detroit, MI.*

Approximately 610,000 cancer-related deaths were estimated for 2018 in US. Chemo therapy is the most common treatment given to cancer patients. However, the treatment may induce cardiac dysfunction. Detection of early biomarkers that predicts cardiac dysfunction offers opportunities to adjust an individual's treatment during chemo therapy. Attenuation of the conversion of epoxyeicosatrienoic acids (EETs) to dihydroxyeicosatrienoic acids (DHETs) by inhibiting the activity of sEH has been tested as a therapeutic approach for treating cardiovascular diseases. The aims of this study are to find whether 14,15-DHET is an early biomarker to predict DOX-induced cardiotoxicity using cell media of DOX-treated H9c2 rat cardiomyocytes and serum of DOX-treated female Sprague-Dawley rats and to screen inhibitors, which may prevent the sEH-dependent cardiotoxicity. H9c2 cells were incubated with and without 1 μM DOX for 2 hr and cells and media were collected after 2, 6 and 26 hr recovery periods. H9c2 hypertrophy (cell area and BNP expression) and 14,15-DHET levels in cell media by ELISA were assessed. Cellular hypertrophy was detected only after 6 and 24 hr of recovery period following DOX treatment and not after 2 hours. Levels of 14,15-DHET increased after 2 hr recovery period prior to detection of cellular hypertrophy and 14,15-DHET remained elevated after 6 and 24 hours. sEH expression in the cells was confirmed by 2.6- and 4.5-fold elevated 14,15-DHET levels in cell media after treatment with and without 1 and 5 μM EET, respectively. Honokiol, a component of magnolia bark, and AUDA, a synthetic sEH inhibitor, inhibited sEH activity in a reconstituted system with recombinant sEH. The result obtained with H9c2 cells was confirmed using a rat serum with and without DOX treatment (3 mg/kg /week for 2 weeks) (no recovery group) and after a 2-week recovery period (recovery group). After two weeks of DOX treatment, when cardiotoxicity was not detected, levels of 14,15-DHET were increased compared to the control group. The results suggest that 14,15-DHET is an early biomarker to predict DOX-induced cardiotoxicity. Early diagnosis of patients to predict cardiac dysfunction is necessary to adjust the anti-cancer drug treatment protocol. Moreover, inhibition of sEH may ameliorate the chemotherapy-induced cardiotoxicity. *Supported by NHLBI SBIR Phase I Contract HHSN261201600028C.*

2217 Dihydroxyacetone Exposure Alters NAD$^+$/NADH-Inducing Mitochondrial Stress and Autophagy in HEK293T Cells

K. R. Smith, F. Hayat, J. Andrews, M. E. Migaud, and N. R. Gassman. *University of South Alabama Mitchell Cancer Institute, Mobile, AL.*

Dihydroxyacetone exposure alters NAD$^+$/NADH inducing mitochondrial stress and autophagy in HEK293T cells. Dihydroxyacetone (DHA) is the triose precursor to dihydroxyacetone phosphate (DHAP). DHA is used as the active ingredient in sunless tanning products (STPs) where its reaction with amines in the skin produces the STPs browning effect. DHA is also a by-product generated by the heat-driven oxidation of glycerol, a component of e-cigarette flavoring. Human exposure to DHA has been increasing as the popularity of STPs and electronic cigarettes has grown. Little is known about systemic effects of exogenous DHA exposure through absorption or inhalation. This present study uses HEK 293T cells in investigation of systemic effects of exogenous DHA exposure. HEK293T cells were sensitive to consumer-relevant doses of DHA, with an IC_{50} value of 2.4 ± 0.3 mM. In order to evaluate acute exposure effects, we have kept our dosing concentration at the IC_{90} value of 5 mM DHA. Flow cytometry and propidium iodide staining revealed cell cycle arrest, with the G2/M fraction doubling at 48 h, then increasing out to 72 h. TMRE staining indicated reduced mitochondrial function over time, while assays for ATP levels showed ATP reduction beginning at 24 h. In addition to reduced function, mitochondria also exhibited morphological changes viewed by super resolution microscopy. Auto-fluorescent imaging and NAD+ biosensors revealed an imbalance in the redox cofactors NAD+/NADH within 24 h of exposure. Assays for levels of reduced and oxidized glutathione showed a decrease in reduced glutathione and an increase in oxidized glutathione, suggesting reduced cellular capacity for handling reactive species. A decrease in the ratio of LC3B I/II at 48 h, along with increases in SIRT1 expression over time, indicated autophagy as a driver of cell death. Despite DHA's ability to be converted to DHAP and integrated into metabolic pathways, the metabolic dysfunction and starvation responses observed in the HEK293T cells indicate that DHA does not readily contribute to the energetic pool in these cells.

2218 Dietary Arsenic Risk Assessment and Risk Management

R. A. Schoof. *Ramboll, Seattle, WA.*

Regulatory limits in dietary arsenic have so far focused on specific foods without adequate consideration of overall dietary intake. Concerns about dietary inorganic arsenic (iAs) have focused on rice, and especially on rice-based foods for infants; however, other food groups typically contribute more to daily intake, with vegetables and fruits contributing over 50% of the daily intake for a typical American compared with less than 20% from rice. Beer, wine and other grains are estimated to contribute another 20% of intake. Due to the lack of reliable data on iAs concentrations in most foods, daily iAs intake estimates are quite variable. For Americans, the mean iAs intake from food has been estimated to be 0.05 µg/kg b.w./day. The European Food Safety Authority estimated higher daily intakes, with mean adult intakes ranging from 0.09 to 0.38 µg/kg and 95th percentile dietary intakes ranging from 0.14 to 0.64 µg/kg; however, these estimates include drinking water intake and assumed iAs was 70% of total arsenic for most foods. These intake estimates also do not consider cooking losses and reduced bioavailability from some foods. Most recent studies show a correlation between urine arsenic and high iAs foods; however, epidemiology studies generally have not had adequate exposure data to support assessment of impacts on disease burden. Using the current USEPA slope factor, average dietary iAs would be associated with unacceptable increases in cancer risk, and several schemes are being proposed to reduce arsenic exposure by intervening at multiple levels in the food supply chain. Many of the proposed interventions could have significant implications for the food supply of people in developing countries who rely heavily on rice. It has recently been proposed that cancer induction by inorganic arsenic has a threshold drinking water concentration of 100 ug/L (with a range of 50-150 µg/L). For a 70 kg adult consuming 2 L/day at 100 µg/L, the safe daily intake would be 2.9 µg/kg. If drinking water only contains 10 µg/L, a dietary intake of 1.7 µg/kg would be safe. This estimate exceeds high end dietary intake estimates by a substantial margin. If this threshold is accurate, iAs should not be a source of health risk for people without elevated drinking water arsenic. Exceptions might be intakes for infants consuming largely rice-based diets and populations consuming certain seaweeds with very high iAs. Given potential disruptions to the food supply and possible associated adverse effects from attempts to control iAs exposure, it is imperative that arsenic risks be accurately characterized.

2219 Filling the Gap between Regulation and Public Health Risk Characterization: Case Study in Lead ALE Sites in Michigan

X. Che, J. Gray, and S. Crider. *Michigan Department of Health and Human Services, Lansing, MI.*

Lead is one of the most ubiquitous toxic substances and can be found in all parts of the environment including air, soil, and water. Lead in pipes can enter drinking water when the pipes corrode or break down. US EPA established the Lead and Copper Rule (LCR) in 1991 to monitor and reduce lead in drinking water. LCR requires public water supplies to sample water and test lead at customer taps. A lead action level exceedance will trigger required actions which includes adjusting corrosion control and delivering customer notice. In June 2018, Michigan made a step forward and adopted the country's most strict LCR to further reduce exposure to lead from drinking water. Along the protections in the Michigan's revised LCR, Michigan Department of Health and Human Services (MDHHS) reaches out to residents and conducts sequential samplings. Results from sequential sampling are used to identify lead sources in plumbing and to adjust flushing time recommendations. The results provide more information on the lead exposure levels for exposure assessment and risk characterization in different scenarios. The estimated levels were then entered into US EPA IEUBK model to estimate the health risk. It is indicated that the action of flushing for right amount of time would effectively reduce lead exposure from drinking water and lower the probability for children to have an elevated blood lead level (>5 µg/dL). MDHHS is also engaged in various types of public health actions to protect people against exposure to other lead sources.

2220 Risk Assessment of the Flame Retardant Chemical Tetrabromobisphenol A (TBBPA)

X. Chen[1], C. Bevington[1], S. J. Harrad[2], and M. A. Babich[1]. *[1]Consumer Product Safety Commission, Rockville, MD; and [2]University of Birmingham, Birmingham, United Kingdom.*

TBPPA (79-94-7) is the highest production volume organohalogen flame retardant (OFR) chemical. The purpose of this study is to conduct a preliminary risk assessment for TBBPA by using the currently available exposure data and key toxicity studies. TBBPA has been detected in indoor dust and air, and in human tissues. The TBBPA concentration in plastic enclosures of TVs and computer monitors ranges from 11 percent to 27 percent, based on XRF, GC-MS, and LC-MS analysis of discarded products. The NTP 2-year bioassay indicates TBBPA can cause cancer in animals; the unit cancer risk of TBBPA is 0.002 $(mg/kg\text{-}d)^{-1}$. based on uterine cancer. TBBPA was consistently reported to inhibit thyroid function in both reproductive and developmental and repeated-dose toxicity studies. The acceptable daily intake is 0.6 mg/kg-d, based on the reduction of T4 thyroid hormone levels. Human biomonitoring data and environmental monitoring data from indoor dust, indoor air, diet, and hand-wipes were used to estimate TBBPA exposures. Estimated TBBPA average daily exposures ranged from 1 $x10^{-6}$ to 2.4 $x10^{-2}$ mg/kg-d. This results in hazard indices of 2 $x10^{-6}$ to 4 $x10^{-2}$ and lifetime excess cancer risks of 2.1 $x10^{-9}$ to 5 $x10^{-5}$. TBBPA exposures derived from environmental monitoring overlap with, but do not fully explain, the range of data observed in human biomonitoring. For example, one human biomonitoring study conducted with 140 volunteers in south China suggests much higher exposures and risks than modeled exposures. In summary, these analysis indicate more research, including human biomonitoring studies for the US population, and migration studies for TBBPA containing consumer products, are needed to better assess the health effects of TBBPA.

2221 Aflatoxin-Related Immunotoxicity: A Dose-Response Assessment

N. Saha Turna, and F. Wu. *Michigan State University, East Lansing, MI.*

Aflatoxins are toxic compounds produced by the fungi *Aspergillus flavus* and *A. parasiticus*. In warm climates, these fungi frequently contaminate food commodities such as maize and peanuts. In many parts of the developing world, especially in sub-Saharan Africa, people are co-exposed to dietary aflatoxin and multiple infectious agents in food, water, and the environment. There is evidence suggesting that aflatoxin exposure may lead to immune dysfunction, which could increase infectious disease risk in vulnerable populations. Our aim was to conduct a dose-response assessment on a non-carcinogenic endpoint of aflatoxin - immunological effects - beginning with a review of human and animal studies on the association between aflatoxin exposure and immune system impairment. We sought to determine a non-carcinogenic tolerable daily intake (TDI) of aflatoxin, based on the existing data surrounding aflatoxin and immunological effects. In our literature search on PubMed and Google scholar databases, human, animal, and *in vitro* studies were considered relevant if they included aflatoxin exposure and measurement of at least one marker of immune function. Reference lists of the included studies were also screened to identify additional relevant studies. For the dose response assessment, we found several mammalian studies with sufficient dose-response data to derive dose-response curves and benchmark doses. We selected one pig study (Meissonier et al. 2008), in which 3-week-old weaned pigs received a control diet or diets contaminated with 385, 867 or 1807 µg pure AFB_1/kg feed, and the pro-inflammatory cytokine IL-6 was measured. We generated a dose response curve and determined the benchmark dose lower confidence limit (BMDL). The BMDL was divided by the product of uncertainty factors (UF) to determine the TDI. We have assumed two different UFs for interspecies extrapolation: 2 and 10 (as this study was done in pigs) and found TDI_{20} = 4.65 µg/kg bw/day and TDI_{100} ~ 1 µg/kg bw/day. The latter TDI is identical to that for fumonisin (1 µg/kg bw/day), estimated by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 2011. There is considerable evidence that aflatoxin exposure alters immunological markers. As aflatoxin is a genotoxic carcinogen, international risk assessment bodies such as JECFA have not established a TDI for aflatoxin. Aflatoxin exposure data exist in the literature, upon which the non-carcinogenic risk of aflatoxin can be assessed in the future.

2222 Risk Assessment Studies of the Impact of Occupational Exposure of Pharmaceutical Workers in Baddi on the Development of Antimicrobial Drug Resistance

N. Verma[1], and S. Kumar[2]. [1]*Chitkara University, Baddi, India; and* [2]*ABESIT College of Pharmacy, Ghaziabad, India.*

Pharmaceutical workers involved with the production of antimicrobial drugs are exposed to various antimicrobial chemicals in different steps of manufacturing such as grinding, sieving, compression, granulation, mixing and filling. These exposures may lead to the development of multidrug resistance (MDR) in bacteria. Scientific reports on the occupational health hazard of pharmaceutical workers involved in manufacturing antibiotics are scarce. The present study aimed to compare the degree of bacterial resistance in pharmaceutical workers in Baddi, India to that of individuals not involved in the pharmaceutical field. Twenty male workers from five local pharmaceutical companies and twenty male subjects not involved in the pharmaceutical field (non-pharmaceutical subjects) were randomly selected. Nasal fluid, mucus/cough and stool specimens were collected from each subject and were cultured separately at 37°C for 24 hours to obtain bacterial growth. The cultured species were then identified, isolated and subjected to microbial sensitivity testing against 18 different antibiotics from eight different groups by the disk diffusion method. *Staphylococcus* spp., *Pseudomonas* spp. and *Escherichia coli* were identified and isolated from the culture of nasal fluids, mucuses and stools, respectively. All the isolated species of bacteria exhibited significant enhancement of the degree of MDR in pharmaceutical workers compared with non-pharmaceutical subjects. Workers with a longer working history had greater degree of antibiotic resistance and vice versa. It can be certainly considered that the exposure of pharmaceutical workers to antibiotic agents resulted in a high incidence of multidrug resistance. Effective steps should be taken to minimize inherent exposure of pharmaceutical workers to antibiotics during work to prevent antimicrobial drug resistance. Further a computational model/QSAR can be developed for antibiotic for multidrug resistance.

2223 Derivation of an Oral Reference Dose for Methyl *tert*-butyl Ether (MTBE) with a Comparative Analysis of Toxicokinetic Data in Rats and Humans

B. J. Lampe. *NSF International, Ann Arbor, MI.*

In chronic two-year drinking water studies, exposure to methyl *tert*-butyl ether (MTBE) in rats is associated with a wide range of kidney effects, including increased severity of chronic progressive nephropathy and increased incidence of kidney tumors. Due in part to its historical use as a gasoline additive, exposure to MTBE via drinking water can also occur in humans as a result of contaminated wells and drinking water supplies. The aim of the current research was to identify an oral reference dose for MTBE and to consider whether the available toxicokinetic data in rats and humans allow for the use of a chemical-specific adjustment factor (CSAF) for extrapolation of the point of departure (POD) from a rat-specific dose to a human-equivalent dose. As interpretation of the kidney effects in male rats are confounded by a male rat-specific mode of action (alpha-2μ globulin nephropathy), the critical effect was identified from the most sensitive kidney effect in female rats: increased relative kidney weight with histopathological correlates of increased incidence of renal tubular hyperplasia, papilla mineralization, and pelvis mineralization. The available toxicokinetic data were subsequently reviewed to determine the feasibility of deriving a CSAF for interspecies extrapolation. In rats, plasma area under the curve (AUC) values for both MTBE and its primary metabolite *tert*-butyl alcohol (TBA) have been predicted from a physiologically-based pharmacokinetic (PBPK) model for a wide range of doses (~50 - 1,200 mg/kg-day) based on a 91-day exposure. Conversely in human subjects, plasma AUC values were measured in subjects exposed singly to only one comparatively low dose level (0.15 mg/kg). Recognizing that the differences in exposure level and duration associated with the predicted rat AUC values and the measured human AUC values preclude valid comparisons, we concluded that the available toxicokinetic data are insufficient to derive a CSAF. Instead, the default US EPA dosimetric adjustment method was utilized for the interspecies extrapolation. A POD of 156 mg/kg-day was derived from the lower confidence limit on the human-equivalent benchmark dose ($BMDL_{HED}$) associated with the critical effect, using a benchmark response rate of one standard deviation above the control mean. Based on an uncertainty factor of 30 (3x for intraspecies differences, 10x for interspecies differences), the reference dose is 5 mg/kg-day. Expansion of the existing rat PBPK model to allow for predicting relevant TK parameters in humans at similar dose levels as rats will be useful for refinement of the oral reference dose for MTBE.

2224 QIVIVE (Quantitative *In Vitro* to *In Vivo* Extrapolation) in Practice: A Comparative Assessment of Emerging and Conventional Risk Assessment and Associated Interpretive Opportunities

K. A. Magurany[1], V. Bhat[1], D. Allen[2], X. Chang[2], and S. S. Ferguson[3]. [1]*NSF International, Ann Arbor, MI;* [2]*Integrated Laboratory Systems Inc., Research Triangle Park, NC; and* [3]*NIEHS/NTP, Research Triangle Park, NC.*

The wealth of *in vitro* data that have been generated as part of the Tox21 and ToxCast initiatives or that may be generated in the future using New Approach Methodologies provides an opportunity to refine the science of risk assessment. Such an approach fills data gaps, reduces animal usage, provides human relevant data that increases confidence and reduces uncertainty compared to conventional approaches, and reduces the time and costs necessary to generate safety data, thus advancing opportunities to innovate while effectively protecting public health. Ideally within this process, adverse outcome pathways (AOPs) that identify key events necessary for adverse apical outcomes are aligned to a battery of *in vitro* assays. Reverse dosimetry, or QIVIVE, of the assay activity concentration at cutoff (ACC) using compound-specific parameters within pharmacokinetic (PK) models provides an estimated human daily equivalent administered dose (EAD) that would result in a plasma concentration corresponding to the *in vitro* ACC, the "lowest effect level" for assay activity. In this study, oral EADs for two suspected estrogen receptor agonists, *p-tert*-butylphenol (CAS# 98-54-4) and benzophenone (CAS# 119-61-9) were derived from active *in vitro* assays and compared to points of departure (PODs) from the available two-generation reproductive toxicity studies in rats. One compartment (1C) and three-compartment (3C) PK models were applied to estimate oral EADs using the NTP Integrated Chemical Environment (ICE) tool and the median ACC_{ER}. For *p-tert*-butylphenol, EADs were estimated as 69 mg/kg-day (1C) and 2.2 mg/kg-day (3C, 100 days). In comparison to the two-generation study with a human equivalent LOAEL of 48 mg/kg-day, use of the 1C model provides a comparable POD; however, the apical endpoints were not consistent with estrogen agonism. For benzophenone, EADs were estimated as 85 mg/kg-day (1C) and 5.6 mg/kg-day (3C, 100 days), where the 1C EAD was comparable to the human equivalent NOEL of 38 mg/kg-day (the highest dose tested) from the two-generation study in rats; however, evidence for estrogenic effects was not observed in the two-generation study. Further evaluation of interpretive opportunities for the assays, including consideration of thresholds of adversity, apical endpoints, components of the PK models, and the value of reference chemicals, are presented.

2225 Notification Level Recommendations for Perfluorooctanoic Acid and Perfluorooctane Sulfonate in California Drinking Water

C. N. Banks, I. Flores-Avila, A. Soshilov, C. Steinmaus, E. Khan, D. Ting, M. Marty, and L. Zeise. *Office of Environmental Health Hazard Assessment, Sacramento, CA.*

Notification levels (NL) are non-regulatory health-based advisory levels for chemical contaminants in California drinking water that do not have regulatory standards or Maximum Contaminant Levels. NLs of 5.1 parts per trillion (ppt) for perfluorooctanoic acid (PFOA) and 6.5 ppt for perfluorooctane sulfonate (PFOS) were set by the California State Water Resources Control Board (SWRCB), based on recommendations by the Office of Environmental Health Hazard Assessment (OEHHA). OEHHA conducted a focused evaluation of recent animal and human toxicity studies of PFOA and PFOS, emphasizing known hazards (hepatotoxicity, immunotoxicity, reproductive toxicity, thyroid toxicity, and carcinogenicity). Epidemiology studies were evaluated and observed to support hazard evaluations but not included in the final dose response assessment because there were no identified studies suitable for point of departure determination. Using OEHHA's risk assessment methodology and human clearance values derived by the US EPA, OEHHA developed cancer reference levels (RL) of 0.1 ppt for PFOA based on increased incidences of pancreatic and hepatic tumors in male rats exposed orally for 2 years, and 0.4 ppt for PFOS based on increased incidences of hepatic tumors in male rats administered PFOS in the diet for 2 years. Cancer RLs represent the concentration of the chemicals in drinking water estimated to not pose more than a one in one million cancer risk over a lifetime. RLs for non-cancer endpoints were also developed: 2 ppt for PFOA based on biomarkers of liver toxicity in female mice; and 7 ppt for PFOS based on immunotoxicity in male mice. Because the cancer RLs are below quantifiable levels of detection in water, OEHHA recommended setting the NLs at the lowest levels at which PFOA and PFOS can be reliably detected using available and appropriate techniques.

2226 Risk Assessment of the Drinking Water Treatment Chemical 2-phosphonobutane-1,2,4-tricarboxylic acid (PBTC)

M. G. LaFramboise, and K. A. Magurany. *NSF International, Ann Arbor, MI.*

Use of 2-phosphonobutane-1,2,4-tricarboxylic acid (PBTC) as a corrosion and scale inhibitor in drinking water treatment may result in PBTC residual of drinking water. Dermal exposures to PBTC also occur predominantly through the use of industrial and consumer cleaning products containing PBTC. An oral risk assessment was undertaken to establish allowable drinking water levels. Due to inadequate human health effects data, hazard identification relied upon laboratory animal data. No adverse effects were seen after dietary PBTC exposure up to the highest tested doses of 461 and 513 mg/kg-day for male and female Wistar rats, respectively, after 90 days, the longest-term data identified. High LD_{50} values > 10,000 mg/kg also suggest a low toxicity profile for PBTC. The available *in vivo* and *in vitro* genetic toxicity studies for PBTC suggest low concern for genotoxicity. No reproductive studies were identified and the one developmental gavage study in Wistar rats showed no adverse effects up to the highest tested dose of 1000 mg/kg-day. Since the subchronic key study was unpublished and secondary sources poorly characterized the test substance, the NOAEL was adjusted based upon the commercial percentage of PBTC typically used (~40%) to an adjusted human equivalent $NOAEL_{HED}$ of 42 mg/kg-day as the point of departure. A 3x rather than default 10x study duration uncertainty factor is supported by the free-standing NOAEL combined with the high-water solubility and the apparent rapid elimination which is supported by the low toxicity. The lack of tested analog or surrogate compounds limited the ability to apply read-across to fill in data gaps. Using a 1000x composite uncertainty factor (3x interspecies, 10x intraspecies, 1x LOAEL to NOAEL, 3x study duration, 10x database), an oral RfD of 0.04 mg/kg-day was determined for PBTC resulting in a Total Allowable Concentration in drinking water of 1 mg/L assuming 0.032 L/kg-day adult water intake and a 80% relative source contribution to account for other non-drinking water routes of exposure.

2227 Evaluation of the Carcinogenic Potential of Baclofen after Dose Titration in rasH2 Mice

G. Chevalier[1], N. Aubert[2], C. Thirion Delalande[1], B. Palate[1], P. Singh[1], and R. Forster[1]. *[1]Charles River, Evreux, France; and [2]Ethypharm SA, Saint Cloud, France.*

Baclofen, a selective gamma-aminobutyric acid-B receptor agonist, has emerged as a promising drug for long term treatment of alcohol dependence. We evaluated the carcinogenic potential of Baclofen in a 26-week study by the oral route (gavage) in male and female CB6F1-TgrasH2 transgenic mice at dose levels of 45, 90 and 180 mg/kg/day. Dose titration of Baclofen is necessary before chronic treatment, so the animals were given three increasing dose levels of Baclofen for 5 days each before starting the 26 week treatment period. Vehicle control (0.5% methylcellulose aqueous solution) and positive control (N-methyl-N-nitrosurea) groups were included in the study. Toxicokinetics were evaluated concomitantly in non-transgenic CB6F1-nonTgrasH2 (wild type) satellite mice. Health status, central nervous system activity, food consumption, body weight and the possible onset of masses were monitored. Designated organs were microscopically examined. Survival rates were not affected by treatment. Maximum plasma Baclofen concentrations were reached at 0.5h on day 1 and at 0.75h on day 25, and no accumulation was observed on day 25. Clinical signs, body weight loss and low food consumption were noted in the high dose group on the first 3 days at the highest titration dose level and during the first 2 weeks of the treatment period; values were similar to controls from week 3, thus demonstrating habituation to Baclofen. There were no treatment related palpable masses or neoplastic findings after Baclofen administration up to week 26. Treatment related non-neoplastic findings were limited to non-adverse increased lymphoid atrophy in the thymus (females at 45 or 90mg/kg; males and females at 180 mg/kg). In conclusion, based on the conditions of this study, with titrated dose levels prior to the beginning of the study, Baclofen was considered to be non-carcinogenic after oral administration in CB6F1-TgrasH2 transgenic mice.

2228 Risk Assessment of the Phosphorothioate Antisense Oligonucleotide Drug Class and Thrombocytopenia

J. J. Hawes[1,2]. *[1]US FDA/NCTR, Jefferson, AR; and [2]US FDA/CDER, Silver Spring, MD.*

Thrombocytopenia serious adverse events, including fatality, have occurred in clinical trials with systemically administered phosphorothioate (PS) antisense oligonucleotide (ASO) therapeutics; however, class-relatedness and predictability have remained unclear and a topic of debate. To address these uncertainties, all systemically-administered PS ASOs with past and ongoing clinical trials in the US were examined for clinical thrombocytopenia events and dose margins were determined at the no observed adverse effect level (NOAEL) for thrombocytopenia in non-human primate (NHP) studies. The data indicate that thrombocytopenia is a class-related effect that can be predicted by the NHP NOAEL for thrombocytopenia, with generational trends on safety margins. Based on the current available clinical and nonclinical data, a safety margin threshold for thrombocytopenia risk is proposed, which may be used to guide risk hazard assessments and clinical monitoring programs.

2229 Adequacy of Available Data to Derive Provisional Oral Toxicity Values for 2-nitropropane

P. Kaiser[1], K. Zaccaria[2], M. Odin[2], J. Reid[1], and S. Wesselkamper[1]. *[1]US EPA, Cincinnati, OH; and [2]SRC Inc., North Syracuse, NY.*

The adequacy of epidemiologic, toxicologic, and mechanistic data was assessed for deriving a provisional oral reference dose (RfD) for 2-nitropropane (2-NP). No oral subchronic or reproductive/developmental studies are available for 2-NP, and the chronic oral database is limited to a single 16-week gavage study in rats with a single dose level and limited reporting on nonneoplastic endpoints. Available short-term and acute oral studies include 14- to 28-day studies in rats that only evaluated clinical signs, body weight, and liver endpoints and 1- to 14-day studies in rats that only evaluated renal and/or liver endpoints. These studies demonstrate toxicity of 2-NP to the liver, but effects on other organs are unknown due to a lack of relevant information. Data from inhalation and injection studies that investigated a wider range of endpoints, however, clearly identify the liver as the most sensitive toxicity target of 2-NP. Supporting mechanistic studies suggest that hepatic damage is secondary to oxidative stress due to generation of reactive intermediates during denitrification of 2-NP in the liver (e.g., N-nitro compounds and oxygen radicals), and genotoxicity studies provide strong evidence for oxidative DNA damage in the liver following exposure to 2-NP. Therefore, while available oral studies are too limited in scope and/or duration to support derivation of provisional RfDs for 2-NP, the data are adequate for derivation of a screening subchronic p-RfD. The 4-week oral study provides sufficient data on several liver endpoints to perform dose-response analysis. However, this less-than-subchronic study is considered inadequate to develop a screening chronic p-RfD for 2-NP, because it is not known if the critical effect observed in the short-term study will increase in severity or provide a more sensitive basis for dose-response analysis following longer treatment duration. While there are no longer-term oral data available, inhalation data suggest that sensitivity to hepatic toxicity may increase with exposure durations >6 months. Ultimately when evaluating the adequacy of a database for deriving reference values, it is crucial to consider various lines of evidence. *The views expressed are those of the authors and do not necessarily reflect the views and policies of the US EPA.*

2230 Oral Risk Assessment of Polyethylene Glycol: Low Molecular Weight Compound as Conservative Analog for Class

S. L. Hamilton, and V. S. Bhat. *NSF International, Ann Arbor, MI.*

The general population may be orally exposed to polyethylene glycol (PEG) polymers via ingestion of treated drinking water due to its use as a formulation ingredient in drinking water treatment chemicals. Other commercial applications that may result in human exposure to PEG include direct or indirect food-contact uses, contact with consumer products, direct medical treatment, or occupational exposures. The dataset encompasses PEG compounds with molecular weights (MW) ranging from 200 to greater than 100,000. A low MW compound, PEG-400, was selected as a conservative read-across analog for the class-based evaluation. Collectively, studies in both humans and animals indicate that absorption of PEG and polymer MW are inversely related. Lower MW polymers, such as PEG-400, may be orally absorbed in contrast to higher MW polymers which undergo little to no absorption. Polymers of lower MW may also undergo partial metabolism, potentially via alcohol dehydrogenase,

resulting in the generation of diacid and hydroxyacid metabolites. It has been suggested that this *in vitro* oxidation of PEG into carboxylic acid metabolites is the most probable pathway for polymer degradation. Due to the anticipated low bioavailability and lack of metabolism of higher MW PEG compounds, toxicity data on a low MW compound, PEG-400, was used to derive an oral reference dose (RfD) for the class. The RfD is based on a NOAEL of 1128 mg/kg-day identified from a 13-week gavage study in Fischer 344 rats given PEG-400. Clinical signs suggestive of altered renal function, such as increased urinary protein, bilirubin, and NAG, were observed at the LOAEL of 2820 mg/kg-day. The potential osmotic effects of PEG itself, or secondary to the very high bolus dose in general, may ultimately contribute to the renal effects seen in the identified animal studies, rather than inherent hazard potential. A comparable NOAEL from chronic exposure suggests a lack of temporal progression of the critical effects or their potency. Using a 100x uncertainty factor to account for (10x) intraspecies and (3x) interspecies variability, as well as (3x) database deficiencies that consist of a lack of standardized developmental toxicity data in a rodent and non-rodent species, an RfD of 3 mg/kg-day was determined for PEG compounds. This corresponds to a Total Allowable Concentration of 20 mg/L in drinking water.

2231 Rethinking Carcinogenicity Assessment for Agrochemicals

S. Papineni. *Corteva AgriScience, Zionsville, IN.*

The two-year cancer bioassay in rodents has been considered the gold standard to assess carcinogenicity for chemicals across multiple sectors including agrochemical industry. Cancer bioassays are known to be animal and resource intense studies using at least 400 animals per study. However, the need to conduct the bioassay as a default data requirement has been questioned over the years with increased understanding of biology and cancer pathogenesis and availability of other appropriate methods to obtain information to determine the carcinogenicity potential. Specifically, with the limitations presented by the rodent cancer bioassay because of both qualitative and quantitative differences in cancer causing mechanisms, age-dependent windows of susceptibility, and target organ susceptibility. Scientific advancements leading to better technology and efficient ways to evaluate the mechanism of actions could offer alternate testing strategies for carcinogenicity evaluation. This shift in thought process of rethinking carcinogenicity initiated an effort within the agrochemical sector to conduct a retrospective analysis assessing all the data available to determine carcinogenicity potential for pesticides. As part of this effort, Corteva Agriscience™ has been conducting weight of evidence analysis for their chemistries. The weight of evidence analysis conducted on two synthetic auxin herbicides will be presented as case studies 1) florpyrauxifen-benzyl and 2) halauxifen-methyl. In this retrospective analysis, chemical properties (pH, P_{ow}, and solubility), metabolism (ADME and Toxicokinetics), and toxicity (acute, short term, genotoxicity, reproductive, endocrine, and immunotoxicity) for any indication of carcinogenic potential were considered. The outcome of this retrospective analysis was then compared to the results of the available cancer bioassays for the respective active ingredients to determine the predictivity and identify any gaps. Collectively, this exercise demonstrated that available data for these two herbicides including short term testing can be predictive of their carcinogenicity potential and thus conduct of cancer bioassays did not add scientific value to human health risk assessment. Thus, emphasizing that carcinogenicity evaluation should be based on a weight of evidence analysis considering all the lines of evidence instead of a default approach of conducting rodent cancer bioassay on every pesticide.

2232 Oral Reference Dose for Non-Essential Elements in Drinking Water: Dietary Impact on the Relative Source Contribution

B. J. Hughes, K. D. Cox, and V. S. Bhat. *NSF International, Ann Arbor, MI.*

Establishing oral reference doses (RfDs) for naturally occurring elements with high dietary and water intakes is difficult. Case in point, Rubidium (Rb), found naturally in the environment as the 16th most abundant element has a general population exposure that can occur via leaching from cement materials with potable water-contact applications. The primary route of human exposure occurs naturally in the diet. Evaluation of Rb is complicated due to 1) human and animal data confounded by baseline levels of Rb in the diet, 2) similarity of biological action with potassium (K) in the body, and 3) lack of guideline toxicity studies. Dietary Rb ingestion in a typical adult is estimated at 1 to 5 mg/day or 14 to 71 µg/kg-day, while in children ingestion is estimated at 2.34 mg/day (or 78 µg/kg-day) with milk intake accounting for 50% of dietary Rb and other food sources contributing the balance. Rb is a close analog to K and both elements exert similar biological effects, such as Rb and K are interchangeable substrates for Na^{+}/K^{+} ATPase dependent transport in the cell membrane and action potentials. As a former therapy for clinical depression, the mechanism of action involves decreasing the resting potential of the neuron and thus increasing the firing rate and the release of norepinephrine for activating postsynaptic receptors. Recognizing a paucity of data on the genetic or long-term effects of Rb in humans or laboratory animals, Rb is not expected to be DNA-reactive, bioaccumulate, or pose a concern for long-term health effects. The critical effects of Rb are an increase in sensory stimulation in animals and elevated mood in humans. Antidepressant effects in human clinical trials suggest a therapeutic minimal dose of 5 mg/kg-day; therefore, a LOAEL of 5 mg/kg-day was selected as the point of departure. A total uncertainty factor of 300 accounted for uncertainty due to intraspecies (3x), LOAEL to NOAEL (3x), study duration (3x), and an incomplete database (10x). Therefore, the RfD is 0.02 mg/kg-day. The total allowable concentration in water of 500 µg/L assumed a 70 kg adult, and a 2 Liter/day intake as well as a relative source contribution (RSC) of 0.8. The RSC of 0.8 is the EPA's ceiling level and was justified based on the background level of Rb in the patient population via the diet prior to treatment.

2233 Using GreenScreen Benchmark and Sub-Benchmark Scores to Identify Safer Plasticizers

J. Y. Tanir, B. Wang, and M. H. Whittaker. *ToxServices LLC, Washington, DC.*

The GreenScreen® for Safer Chemicals is a hazard assessment framework that assesses chemicals against 18 human health, environmental, and physical hazard endpoints, and based on hazard combinations, assigns a benchmark (BM) score of 1-4, with 1 being most hazardous and 4 being least hazardous. GreenScreen® hazard assessments for 61 plasticizers in the ToxFMD® Screened Chemistry Library were compared to identify safer alternatives and to differentiate among specific hazards. Of the 61 plasticizers, 18% were BM-1 ("Avoid - Chemicals of High Concern"), 49% were BM-2 ("Use but Search for Safer Substitutes"), 15% were BM-3 ("Use but Still Opportunity for Improvement"), and 10% were BM-3DG, due to a data gap (DG) that prevents a BM-4 score (comprising epoxidized fatty esters, glycols, and terephthalates). Across the 61 plasticizers, 59% have a data gap for endocrine activity, 44% for respiratory sensitization, and 34% for neurotoxicity. Because almost half of the 61 plasticizers are scored as BM-2s, the 30 BM-2 plasticizers were studied to see if differentiation in hazard level is feasible. The GreenScreen® framework assigns BM-2 scores due to 7 sub-benchmark scores (a-g). Of the 30 BM-2s, 83% are BM-2e (defined as posing moderate hazards for carcinogenicity, genotoxicity, reproductive toxicity, developmental toxicity, and/or endocrine activity). Further distinction within BM-2e sub-benchmark scores may lead to greater differentiation of higher versus lower hazard BM-2s. Of the 25 BM-2e plasticizers, hazard classifications among 68% have low confidence in hazard classifications, based on modeling, limited or marginal evidence, or conflicting data for reproductive toxicity, developmental toxicity, or endocrine activity. The remaining 8 BM-2e plasticizers (32%) have reliable data supporting a moderate hazard classification for screened hazard endpoints. A higher confidence level in hazard classifications provides stronger support that these 8 plasticizers may pose a higher hazard than BM-2e plasticizers with low confidence levels. Examining trends in BM scores and sub-benchmark scores within a set of plasticizers provides insight into the identification of safer alternatives. Further research into filling data gaps and the use of robust chemical hazard frameworks to inform the design of safer plasticizer molecules can lead to a wider supply of lower-hazard plasticizer alternatives.

2234 A Survey and Quantitative Risk Assessment of PFAS Chemicals in Hair Care Products

K. Towle[1], E. Fung[2], J. Parker[2], and A. Monnot[1]. *[1]Cardno ChemRisk, San Francisco, CA; and [2]Cardno ChemRisk, Aliso Viejo, CA.*

Per- and polyfluoroalkyl substances (PFAS) are a family of chemicals that are used in various industrial and consumer product applications. A recent analysis identified 13 different PFAS in approximately 200 personal care and cosmetic products. Limited information is available regarding potential exposures to PFAS following application of personal care and cosmetic products. Therefore, the purpose of this analysis was to 1) determine the concentration of 23 different PFAS in a survey of hair care products, 2) perform a quantitative risk assessment to calculate potential systemic PFOA exposures associated with these products, and 3) compare these values to potential systemic exposures from shower water containing PFOA. PFOA was selected as the comparison chemical for this quantitative assessment given the available toxicological data. Ten commercially available hair conditioner products were selected for analysis, and the PFAS content was assessed using modified EPA Method 537 Version 1.1. A daily systemic exposure dose (SED) to PFOA was estimated using (1) amount of product applied per application, (2) number of applications per day, (3) PFOA concentration in the product, (4) a retention factor, (5)

surface area of the scalp, (6) dermal absorption of PFOA, and (7) adult body weight. Low (mean amount applied and 2% dermal absorption) and high (95th percentile amount applied and 70% dermal absorption) models were evaluated to assess different parameters. A similar calculation was performed for shower water, accounting for number of showers per day and body surface area. No PFAS were detected in the analyzed products; therefore, we assumed that the hair conditioners contained half the PFOA method detection limit (2 ng/g). For the shower water assessment, we assumed that the water contained PFOA at the EPA health advisory standard (70 ng/g). Margin of Safety (MOS) values were calculated by comparing the SED results to the PFOA oral RfD (0.00002 mg/kg/day). The hair conditioner MOSs ranged from 17,900 to 795,000, while the shower water MOSs ranged from 4,230 to 434,000. Given the above assumptions, potential exposure to PFOA from hair conditioner use was approximately 50-75% lower than exposure to PFOA-containing shower water alone. These findings suggest that potential exposure to PFOA in the examined products is not associated with an increased health risk.

2235 Risk Assessment of Trihalomethanes in the Development of Public Health Goals for Drinking Water in California

I. Flores-Avila, N. Dangleben, A. Soshilov, C. Steinmaus, D. Qiao, E. Khan, D. Ting, M. Marty, and L. Zeise. *Office of Environmental Health Hazard Assessment, Sacramento, CA.*

Disinfection is necessary for the elimination of microbial contaminants in drinking water. However, the disinfection process of chlorination or chloramination produces toxic chemicals, known as disinfection byproducts (DBPs). These DBPs include four thrihalomethanes (THMs): chloroform, bromoform, bromodichloromethane (BDCM), dibromochloromethane (DBCM) that are currently regulated federally and in California. The established federal and state maximum contaminant level (MCL) for total concentration of THMs in drinking water is 80 ug/L. The Office of Environmental Health Hazard Assessment (OEHHA) has proposed Public Health Goals (PHGs) that represent the concentration of each individual THM in drinking water that would not pose significant health risks to the public, including sensitive subpopulations (e.g., infants and children). PHGs are not regulatory standards and are based solely on public health considerations without regard to economic considerations. PHGs are used by the State Water Resources Control Board (SWRCB) to establish California's MCLs for drinking water. The proposed PHGs are: 0.4 ug/L for chloroform based on liver and kidney cancer; 0.5 ug/L for bromoform based on cancer of the large intestine; 0.06 ug/L for BDCM and 0.1 ug/L for DBCM based on liver cancer. OEHHA also developed health-protective concentrations for all four THMs based on noncancer effects.

2236 Risk Assessment of 1,1,1-Trifluoroethane (HFA-143a) as a Potential Impurity in HFA-134a in Metered Dose Inhaler Products

R. Chang, I. Mohar, and T. Lewandowski. *Gradient, Seattle, WA.*

Asthma prevalence in the United States has been steadily increasing in recent decades. According to a survey conducted by the Centers for Disease Control (CDC) in 2017, about 25 million people in the US, or 8% of the population, suffer from asthma. Treatments delivered by pressurized metered dose inhalers (pMDI) are the cornerstone of symptom management among asthma patients. The compound 1,1,1,2-tetrafluoroethane (HFA-134a) is a commonly used propellant in pMDIs. Here, we derived a permissible daily exposure (PDE) of 1,1,1-trifluoroethane (HFA-143a) as a potential impurity in HFA-134a and compared this to the current US Food and Drug Administration (US FDA) accepted specification for HFA-134a. Standard risk assessment methodology was followed, and the PDE was derived in accordance with available International Conference on Harmonisation (ICH) guidance. We determined that HFA-143a is not expected to be mutagenic or carcinogenic based on *in vivo* and *in vitro* mutagenicity and genotoxicity studies and a two-year chronic oral exposure study, in which the no-observed adverse effect level (NOAEL) was > 300 mg/kg bw/day, the only dose tested. No signs of developmental and reproductive toxicity were reported from inhalation exposure to HFA-143a in studies with rodents and rabbits. The most sensitive endpoint was determined to be cardiac sensitization hazard. In an acute inhalation study with beagle dogs, cardiac sensitization responses were observed with a no-observed adverse effect concentration (NOAEC) of 250,000 ppm, equivalent to a delivered dose NOAEL of 3,716 mg/kg. However, the two-year chronic study would provide a more appropriate point of departure for risk assessment given potential chronic pMDI use. Based on a NOAEL of 300 mg/kg determined from the two-year chronic oral exposure study, a PDE of 0.6 mg/kg was derived. We compared this PDE to the US FDA accepted impurity concentration of 20 ppm for HFA-143a in clinical-grade HFA-134a. Assuming an HFA-143a concentration of 20 ppm is delivered in one 50 µL pMDI actuation, a safety margin of 25,510 is derived. These results strongly suggest that the US FDA accepted concentration of 20 ppm for HFA-143a provides appropriate protection against potential adverse health effects caused by HFA-143a as a potential impurity in an HFA-134a pMDI.

2237 Analysis and Comparison of Major Immune Cell Populations in Peripheral Blood of Naïve Cynomolgus Monkeys

M. Patel, A. S. Wong, and T. Rogers. *Altasciences, Everett, WA.*

Changes in major immune cell populations in the peripheral blood of cynomolgus monkeys, as determined by flow cytometry, are routinely used as an immunological endpoint in toxicology studies. However, it is difficult, especially for studies involving small animal groups, to determine a "normal" value that can be used as a guideline. To determine what constitutes a "normal" value for various immune cell populations in the peripheral blood, we analyzed large cohorts of naïve adolescent (total: n=168, males: n=84, females: n=84) and infant (n=33) cynomolgus monkeys. We determined relative percentage and absolute counts of immune cell populations, such as CD3+ total T cells, CD3+CD4+ T cells, CD3+CD8+ T cells, CD3-CD20+ B cells, CD3-CD16+ NK cells, and CD3-CD14+ monocytes. The number of CD3+ total T cells were 3.06±1.25, 3.24±1.35, 2.88±1.12, and 4.97±1.55 x 106 per mL for total adolescent, male, female, and infant cynomolgus monkeys, respectively. The number of B cells (CD3-CD20+) were 1.34±0.75, 1.45±0.90, 1.23±0.56, 1.85±1.01x 106 per mL and the number of NK cells (CD3-CD16+) were 7.59±4.24, 8.56±4.44, 6.63±3.81, 4.48±1.94 x 105 per mL for total adolescent, male, female, and infant cynomolgus monkeys, respectively. The numbers for monocyte counts (CD3-CD14+) were 2.48±1.09, 2.46±1.22, 2.50±0.94, and 4.44±2.08 x 105 per mL for total adolescent, male, female, and infant cynomolgus monkeys, respectively. Our results also indicated statistically significant differences in absolute counts of various cell populations based on the age and sex of cynomolgus monkeys. For example, infants had significantly higher levels of total lymphocytes, CD3-CD14+ monocytes, CD3+ total T cells, CD4+ T cells, and CD3-CD20+ B cells compared to adolescent monkeys ($p<0.005$, Mann Whitney test). The absolute counts of CD3-CD16+ NK cells, were significantly lower in infants compared to adolescent monkeys ($p<0.0001$, Mann Whitney test). In addition, we also observed sex-dependent differences where females had significantly lower counts of CD3+CD4+ T cells and CD3-CD16+ NK cells compared to males (($p<0.001$, Mann Whitney test). Overall, our data helps understand the various immune cell populations present in peripheral blood cynomolgus monkeys. The reported values can also serve as a guideline for improved understanding of the various toxicology related changes introduced by therapeutic treatments during drug development.

2238 Inter-Individual Variability Adjustment Factors for Occupational Exposure Limits

Y. Chervona, E. L. Dahl, J. Gould, and M. J. Olson. *SafeBridge Consultants Inc., New York, NY.*

Using a default adjustment factor of 10 for inter-individual variability (*i.e.*, pharmacokinetic (PK) and pharmacodynamic (PD) variability) is common practice in setting occupational exposure limits (OELs) to protect workers in the pharmaceutical manufacturing environment, though there is some evidence suggesting this value may be unnecessarily conservative. Active Pharmaceuticals Ingredients (APIs) are unique in that they typically have extensive human exposure data, including PK and PD data that can be used to calculate a chemical-specific adjustment factor (CSAF), which may be used in place of the default of 10 in calculating OELs. The purpose of this study was to evaluate the variability in internal exposures, primarily in healthy volunteers, to identify a reasonable default adjustment factor for most healthy workers. From the publicly available data on APIs, the means and standard deviations of exposure data, as area-under-the curve (AUC) after administration of the API, were collected. These data were used to calculate CSAFs for each API, as the mean AUC plus two standard deviations divided by the mean AUC. Using two standard deviations is conservative in that it covers >95% of the upper bound response in the population. The mean of the CSAF values for all the APIs evaluated rounded to 5, indicating that a default adjustment factor of 5 for an API would be representative of inter-individual variability within a subject population. Therefore, an adjustment factor of 5 for inter-individual variability would be appropriate for setting OELs that would protect most workers in pharmaceutical manufacturing. This default would not be recommended for compounds with certain sensitive subpopulations (*e.g.*, asthmatics or variant metabolizers) that are not part of the group assessed for calculation of the CSAF and might be included in the worker population.

2239 Setting Default Health-Based Exposure Limits for Early-Stage Monoclonal Antibody-Based Therapeutic Proteins

H. S. Adragna, J. Gould, K. Sachdeva, and R. Sussman. *SafeBridge Consultants, Inc., New York, NY.*

Health-based exposure limits (HBELs) are developed for active pharmaceutical ingredients to minimize product cross-contamination in GMP manufacturing facilities (acceptable daily exposures, ADEs) and to identify acceptable exposures for worker protection (occupational exposure limits, OELs). In the absence of sufficient data to support a robust, compound-specific assessment and derivation (*e.g.*, early in the development of the drug candidate), default HBELs may be assigned. However, standardized methodologies for the establishment of default limits for biotechnology-derived products such as recombinant proteins and monoclonal antibodies (mAbs) have not been previously described. Robust data sets from 28 marketed mAb-based therapeutic agents were evaluated to derive ADE and OEL values utilizing the lowest therapeutic dose, standard adjustment factors, and adjustment for bioavailability. A comparison of these HBEL values identified three Hazard Categories based on therapeutic target. Recommendations were developed for assigning default ADE and OEL values of 0.1, 1, 10, 100 µg/day or µg/m^3 for early-stage mAb-based therapeutics, taking into account the assigned Hazard Category and potency. The criteria on mechanism of action, potency, and bioavailability should be reviewed by a qualified toxicologist, and the limitations of the assessment should be understood when assigning default values to ensure these are protective of the general population and/or workers, as appropriate. Limitations, including predictability of hazards for novel therapeutic targets and unpredictable adverse effects, should be understood. As the Hazard Category and the human dose may change as more information becomes available, there should be vigilance to ensure the defaults are updated and/or replaced with more robust, compound-specific derivations when sufficient data are generated.

2240 Rapid Evidence Mapping for Health: A Case Study

J. Lam[1], B. Howard[1], K. Thayer[2], and R. Shah[1]. *[1]Sciome LLC, Research Triangle Park, NC; and [2]US EPA, Research Triangle Park, NC.*

Stakeholders in the field of environmental health are increasingly relying on tools and practices from the disciplines of evidence synthesis and systematic review to summarize the literature and identify scientific consensus with respect to potential health risks. Given the ever-accelerating pace of publications in this field, the practice of "evidence mapping" is being increasingly used to identify the key areas of study relevant to a given topic along with gaps in the literature. However, constructing detailed evidence maps can be resource-intensive, limiting their utility for practical implementation, particularly for broader questions of interest. As a result, approaches that increase the speed and reproducibility of evidence mapping are in great demand. Here we outline a process called "rapid Evidence Mapping" (rEM), which we define as a resource-efficient form of knowledge synthesis in which components of the systematic review process are simplified to produce a visual and quantitative representation of the scientific evidence. We show how rapid evidence maps can be created with the aid of Sciome's text-mining and machine learning software, and to illustrate the application of the procedure, we describe a proof-of-concept case study on the topic of low-calorie sweeteners (LCS) with respect to human dietary exposures and health outcomes. The resulting rEM produced similar findings compared to a traditional evidence mapping of the same topic (Wang et al. 2016), but required significantly less time, effort, and resources to create. Furthermore, a sensitivity analysis evaluating the set of studies included at 25% recall (i.e., the point at which the machine learning algorithms predicted we had identified 25% of all relevant references) would have resulted in the same conclusions regarding the current state of the science and existing research gaps. This observation suggests that further efficiency gains can be achieved by mapping only a computer-selected subset of the available literature. rEMs can be used to quickly summarize the available body of evidence relevant to a research question, identify gaps in the literature to inform future research, and contextualize the design of a systematic review within the broader scientific literature, significantly reducing human effort while yielding results comparable to those from traditional methods. The potential time savings of this approach make it a powerful tool for rapidly translating knowledge to inform science-based decision-making.

2241 Setting Permitted Daily Exposures (PDEs) for Pharmaceutical Agents Administered by the Intravitreal Route

T. A. Kimmel, and A. W. Ader. *SafeBridge Consultants Inc., Mountain View, CA.*

The eye is a complex and multilayered organ which possesses three chambers, the largest being the posterior chamber which houses the retina. This chamber is filed with vitreous humor (VH) which, although vascularized, functions independently of blood to eliminate foreign substances. Eyes possess a number of physiological barriers restricting or preventing movement of these substances, including therapeutic agents, between the eye and the general bloodstream. Because of the unique structure and functionality of the eye, existing guidelines for setting health-based Permitted Daily Exposures (PDEs) for pharmaceutical agents administered by the intravitreal (IVT) route have limited applicability. IVT drugs: 1) deliver a small volume of a highly concentrated dose, which may not be presumed to be systemically effective; 2) are formulated/engineered with the intent of causing little to no systemic toxicity; 3) may be formulated to locally target ocular tissues; or 4) may only migrate from the VH into the general bloodstream in very small amounts. Consideration must also be given to the pharmacokinetic behavior of IVT drugs once they have been injected into the VH, and to the actions of intraocular enzymes. For these and other reasons, calculation of an IVT PDE for a drug using direct, volume-based extrapolation from the eyeball to the human body or bloodstream may not be appropriate. Instead, three alternative approaches to setting IVT PDEs are proposed. Two may be described as "compliance- or quality-driven," while the third is dose-driven. The first approach may be applied to setting PDEs for small-molecule drug substances which are given exclusively by IVT injection, the second for small-molecule drug substances given both by IVT injection and systemically, and the third for high molecular-weight drugs, such as monoclonal antibodies and other biologicals. All three approaches are based on a review of readily available data for IVT-administered drugs, and all are considered scientifically supportable. The strengths and limitations of each approach are described. A comparison of the three approaches suggests that PDE values in the range of 1–20 µg/day are appropriate for drug substances present as potential contaminants in an IVT drug to which a patient might be exposed. IVT PDEs may also be used in manufacturing plants to set cleaning limits for shared equipment. This range applies only to pharmaceutical agents and not to other chemicals, for which further investigation is required.

2242 Assessment of the Applicability of Threshold of Toxicological Concern (TTC) for Per- and Polyfluoroalkyl Substances (PFAS)

L. L. Pham[1], C. Thompson[2], and S. Borghoff[3]. *[1]ToxStrategies Inc., Asheville, NC; [2]ToxStrategies Inc., Katy, TX; and [3]ToxStrategies Inc., Cary, NC.*

The presence of low amounts of PFAS have been reported in industrial and consumer products and thus there is potential for human exposure. Most PFAS have little or no toxicity information, thereby necessitating a resource-effective approach to screen and prioritize those that need further safety assessment. The TTC approach proposes a *de minimis* exposure value based on chemical structure and toxicological information from similar chemicals. Herein we test the applicability of the TTC approach to PFAS by incorporating a dataset of no-observable-adverse-effect-level (NOAEL) values for >20 PFAS chemicals into the corrected Munro TTC database. All substances were assigned into Cramer Class III (i.e., 1.5 µg/kg/day), and the cumulative distribution of the NOAELs evaluated. There was no statistical significance in the PFAS enriched distribution compared with the Munro distribution. The derived human exposure level for the PFAS enriched Cramer Class III dataset was >1.3 µg/kg/day. Evaluation of the structural chemical profiles showed that the added PFAS had distinct Toxprint Chemotypes. Dimension reduction techniques such as Principle Component analysis on the Toxprint Chemotypes showed clustering of the additional PFAS chemical away from the Munro TTC dataset. Similar calculations on whole chemical structures using maximum common substructures showed that the PFAS were distinct from the chemicals currently in the Munro dataset. However, the available data shows that PFAS NOAELs cluster within the substance in the Cramer Class III. Consideration of PFAS as a separate TTC class could result in a lower TTC value for these substances; however, at this time the relatively small data set inhibits any additional sub classification. This analysis shows that incorporation of these ~20 PFAS do not significantly change the current TTC Cramer Class III distribution and furthermore, provides an expansion of the chemical space providing support that the TTC approach can be applied to PFAS chemicals.

2243 Proposed Tier-Based Safety Evaluation for Personal Care and Cosmetic Products

A. Monnot[1], E. Fung[2], and K. Towle[1]. *[1]Cardno ChemRisk, San Francisco, CA; and [2]Cardno ChemRisk, Aliso Viejo, CA.*

In the United States, the US Food and Drug Administration (US FDA) is responsible for the regulation of marketed cosmetic products. Currently, there are no laws or regulations that require specific safety testing, nor are companies required to share product safety information with the US FDA. In 2019, two senators introduced the Personal Care and Cosmetics Act, which would increase the regulatory oversight of the US FDA for personal care and cosmetics products; however, this bill contains limited information or proposed testing requirements. In the present evaluation, we propose a tier-based safety evaluation framework for personal care and cosmetic products. The proposed 3-tiered safety evaluation framework was utilized to assess the safety of a personal care product that has reports of adverse events following application. Specifically, Tier 1 involves an ingredient-based assessment to evaluate the safety of individual ingredients in the product and to identify any potential hazards associated with exposure. This includes methods for dermal hazard identification, supply chain analysis, and potential contaminant screening. Tier 2 involves a product mixture based assessment to evaluate the safety of the final formulated product. We present proposed methods for *in vitro* and in use testing for various health outcomes, as well as heat stress degradation of the product mixture following hair styling. Finally, Tier 3 is a population-based assessment that monitors the safety of a product post-market. This tier helps determine potential risk factors associated with reported adverse events and provides an example of a post-market product safety surveillance program. Overall, this testing strategy allows for efficient and focused testing, minimizes cost and time, and provides a comprehensive evaluation of a product and its ingredients.

2244 HGBEnviroScreen: Enabling Community Action through Data Integration in the Houston-Galveston-Brazoria Region

S. Bhandari[1], E. Craft[2], P. G. T. Lewis[2], S. W. Marvel[3], D. M. Reif[3], and W. A. Chiu[1]. *[1]Texas A&M University, College Station, TX; [2]Environmental Defense Fund, Austin, TX; and [3]North Carolina State University, Raleigh, NC.*

The Houston-Galveston-Brazoria (HGB) region faces numerous environmental and public health challenges given the density of industrial facilities and activity associated with being the nation's energy capital. Historically disadvantaged communities most often impacted by natural disasters like hurricanes or industrial events such as chemical fires are limited by their ability to access and utilize big data for advocacy efforts. We developed HGBEnviroScreen, a geospatial tool that integrates data from multiple environmental and public health indicators, to identify and prioritize regions of heightened vulnerability in part to serve communities developing environmental justice action plans. This tool provides valuable information on critical factors driving vulnerability at the census tract level for an 8 county area. While similar in objectives to existing environmental justice tools such as EJScreen and CalEnviroScreen, HGBEnviroScreen is unique in its ability to integrate and visualize national and local data to addresses regional concerns, and serves as an innovative method that could be adapted or scaled for use by other metropolitan areas. For the 1090 census tracts in the HGB region, we accrued data into five domains: (i) social vulnerability; (ii) baseline health; (iii) pollutant exposures and risks; (iv) sources of pollution; and (v) flood risk. We then used the Toxicological Prioritization Index (ToxPi) methodology to integrate and visualize data across the indicators and domains. We found that the highest vulnerability census tracts generally had multifactorial risk factors, with the most common drivers being flood risk, social vulnerability, and proximity to pollution sources. As a result of combining ToxPi with broadly collected geospatial information, HGBEnviroScreen is not only helping inform HGB-area communities and decision-makers of the physical locations of greatest vulnerability, but is also providing insights into which domains would most benefit from improved planning, policy, and action in order to reduce vulnerability in the future. *This work was supported by a grant from NIH/NIEHS (P42 ES027704) and a contract from Environmental Defense Fund.*

2245 Tox21 Approaches for Reduced Animal Testing: Alternative Approaches to Hazard Identification and Dose-Response for Agrichemicals

E. Freeman[1], P. Parsons[2], and R. Weidling[1]. *[1]Exponent, Washington, DC; and [2]Exponent, Harrogate, United Kingdom.*

With the US Environmental Protection Agency (EPA) directive to reduce animal testing, including reducing mammal study requests by 30% by 2025 and eliminating them by 2035, alternative approaches to hazard identification, dose-response and exposure assessments, and risk characterization are critical. For chemical uses regulated through the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), mammalian studies are critical to the hazard identification and dose-response evaluations of risk assessment. This project reviewed and evaluated points of departure (PODs) derived by regulatory agencies for conventional acute and chronic dietary and occupational risk assessments by pesticide type (insecticide, fungicide, or herbicide) and by chemical class. These PODs were compared with various crop-specific exposure estimates using tools such as commodity specific tolerance levels and dietary exposure models to determine margins of safety. The objectives of this project were to utilize the abundance of existing animal data to define POD ranges for use in risk assessment and to identify the key toxicity studies for various crop uses and chemical classes that are used to derive these PODs. This approach also supports the establishment of chemical class specific PODs as well as default worst case PODs for different use indications (insecticides for example). Utilization of existing data does allow prioritization of data generation such that only those studies critical for POD derivation will be conducted in future. Such an approach would significantly reduce and potentially replace the use of thousands of animals which is necessary to fulfill the data requirements providing a path forward to support the EPA's reduction of animal use directive.

2246 Streamlining Literature Capture: A Comparison of Automated Approaches to Identify and Categorize Literature for Review

J. R. Rochester[1], A. Varghese[1], J. Wignall[2], J. Trgovcich[1], and D. Burch[1]. *[1]ICF International Inc., Durham, NC; and [2]ICF International Inc., Burlington, VT.*

Systematic reviews that examine the risk of human exposure to environmental chemicals can be labor intensive, usually requiring human screening of thousands of publications for inclusion and categorization. Effective tools that facilitate grouping of literature to inform hazard identification, mechanisms of action, and toxicokinetics are needed to improve the planning and efficiency of systematic review efforts. We compared two approaches for collecting relevant mechanistic literature using the genotoxicity of chlorpyrifos as a test case: (1) using a set of specific keywords contained in CRAB 3, an online text mining tool that retrieves literature from PubMed using predefined but hidden keywords to identify and annotate cancer endpoint literature for user-designated chemicals; (2) using a broad set of keywords to retrieve a comprehensive set of literature from PubMed followed by machine learning to identify the relevant studies. For the latter approach, we used DoCTER, a text analytics tool that relies on supervised machine learning to identify and prioritize relevant studies, in two distinct ways: (i) using a previously annotated dataset to train the machine learning algorithm and (ii) using a customized active learning approach in which the DoCTER tool interacted with users during the algorithm training process and indicated when its predictive model had achieved the desired level of accuracy. DoCTER was also utilized to identify relevant studies from the CRAB-generated body of literature for inclusion. CRAB generated 177 records of which approximately 50% were determined to be relevant by expert review. In our second approach, DoCTER predicted 260 of 4,889 abstracts to be relevant. DoCTER predictions had a recall of 92% and a precision of 59% and resulted in a higher number of relevant studies retrieved than the CRAB approach. 96% of the studies identified by the CRAB approach were also identified in the second approach based on DoCTER. While CRAB is useful for initial scoping and mapping (especially for multiple chemicals and endpoints), it is limited by its use of hard-coded non-transparent keywords and high rate of capture of non-relevant literature. The PubMed-DoCTER approach resulted in a higher rate of capture of relevant documents but is less useful as a mapping tool. Thus, CRAB provides a rapid overview of literature categorization, while the PubMed-DoCTER approach is a more robust and transparent approach for in-depth assessments.

2247 Alice in Numberland: Mathematics of Variability and Uncertainty—Can Kinetics Help Us Understand Variability in Toxicity?

L. Lautz[1,2], K. Darney[1], E. Kasteel[2], N. Kramer[2], E. Testai[3], and J. Dorne[4]. *[1]ANSES, Paris, France; [2]Universiteit Utrecht, Utrecht, Netherlands; [3]ISS, Rome, Italy; and [4]European Food Safety Authority, Parma, Italy.*

In food safety assessment, risk characterisation requires the integration of external exposure (oral exposure), internal dose (kinetics), and toxicodynamic data. Here, a workflow allowing such integration is presented and is illustrated with examples from chemicals relevant for human health risk assessment. In 2015, EFSA funded collaborative research to characterise human variability in kinetics and toxicodynamics. Bayesian meta-analysis was used in order to derive pathway-specific uncertainty factors for several cytochrome P450 enzymes, such as CYP3A4, 2D6, 2C9, and 2C19, UGTs (UGT1A1, 1A3, 1A4, 1A6, 1A9, 2B7) and transporters (P-gp, BCRP, OATs), which can replace the relevant subfactors within the overall default uncertainty factor of 100. In addition, the estimated variability of the enzymes can be used to allocate distributions of kinetic parameters derived from quantitative *in vitro-in vivo* extrapolations. Based on *in vitro* intrinsic clearance assays with primary human hepatocytes it was possible to determine isoform specific metabolism and kinetics parameters for chemicals. Human variability distributions for metabolic pathways were assigned to estimate lognormal distribution for the chemical clearance. These distributions were used in a physiologically based kinetic (PBK) model with Markov-Chain Monte Carlo. Human physiological parameters were derived from Popgen, and partition coefficients were estimated using quantitative structure-activity relationship (QSAR). The PBK model was applied to data-rich and data-poor case study chemicals, including chlorpyrifos, phosmet, triflumeron, and resveratrol. Moreover, variability in toxicodynamic data was assessed for the main metabolites of chlorpyrifos and phosmet, chlorpyrifos-oxon and phosmet-oxon, using human donor blood. Inhibition of acetylcholinesterase was measured for different donors and variability in toxicodynamics was incorporated in the PBK model, resulting in a PBK-TD model, incorporating variability in both kinetics and dynamics. The PBK(-TD) model is available on an open source modelling platform TK plate.

2248 A Comparison of Threshold of Toxicological Concern (TTC) Values to Reference Dose (RfD) Toxicity Values

S. Borghoff[1], L. Pham[2], and C. Thompson[3]. *[1]ToxStrategies Inc., Cary, NC; [2]ToxStrategies Inc., Asheville, NC; and [3]ToxStrategies Inc., Katy, TX.*

There are thousands of chemicals for which limited, or no hazard data are available to characterize human risk. For such chemicals, threshold of toxicological concern (TTC) values constitute a science-based tool that helps prioritize potentially hazardous chemicals for further evaluation. Herein we gauge the level of conservatism of TTC values by comparing them to more rigorously derived reference dose (RfD) values for 288 chemicals identified in the US Environmental Protection Agency's (US EPA) Integrated Risk Information System (IRIS) database. Using both the Cramer decision tree and the Kroes tiered decision tree approach to determine TTC values for these chemicals, ~80% and 86% of these chemicals, respectively were determined to be more conservative than their corresponding RfD values. The median log ratio of RfD/TCC values was ~0.74 and ~1.5 for the Cramer and Kroes approach, respectively indicating that RfD values were, on average, 5.5 to 32 -fold higher than their corresponding TTC values. An investigation into log ratios that were 2 standard deviations below the median (i.e. RfD<<TTC) identified chemicals that may need a second evaluation. Overall, this analysis indicates that TTC values appear to be health protective and are more conservative than RfD values. Also, RfD values that are significantly lower than TTC values for a specific chemical suggest the need for reevaluation.

2249 Interpreting Occupational Exposure Limits: An Analysis of NIOSH Recommended Exposure Limits by Health Endpoint

C. Whittaker, and R. T. Niemeier. *NIOSH, Cincinnati, OH.*

Occupational exposure limits (OELs) are an essential tool for controlling worker exposures to toxic chemicals. OELs have been developed to protect workers from exposure to carcinogens, chemical irritants, sensitizers, neurotoxicants, and a variety of other toxicities. However, OELs are not all created equal. Many OELs are based on avoidance of chronic health effects, but others are based on acute health impacts. Health-based methods used to determine OEL values have ranged from a determined point of departure from an exposure-response relationship to quantitative risk assessment with extrapolation to a target risk level. In some cases, the OELs are not health-based, but are set based on the analytical limit of quantification or reliable quantitation limit. Still, the OEL (or a specified fraction of the OEL) is perceived as a "safe" level of exposure. In this presentation, thirty NIOSH Recommended Exposure Limits (RELs) are evaluated for the health endpoint basis of the REL, methods used for determining the OEL, target risk levels (where appropriate), and the analytical limit of quantification. The RELs are compared to the results that would be obtained from implementation of the NIOSH Occupational Exposure Banding eTool, and the EPA 8-hour time-weighted average (TWA) Acute Exposure Guideline Levels (AEGL). A description of the risk interpretations from the point of view of the risk assessor is compared with the point of view of the industrial hygienist. For example, the 8-hr TWA REL for ammonia is 25 ppm, with a STEL of 35 ppm. This is based on human observational studies showing respiratory irritation. Tier 1 occupational exposure banding would indicate that ammonia would be classified a band E chemical, corresponding to exposure concentrations of <0.1 ppm, and the AEGL-1 8-hour TWA value is 30 ppm (corresponding to acute health effects in the general population). Interpretation of the RELs, occupational exposure bands and AEGL values for ammonia and 29 other chemicals is discussed.

2250 Rapid Hazard Identification Using Human iPSC-Derived Cell-Based *In Vitro* Testing: A Case Study of a Hypothetical Spill of a Complex Substance

A. T. Roman-Hubers[1], Z. Chen[1], T. McDonald[1], K. Tuttle[2], I. Rusyn[1], and W. Chiu[1]. *[1]Texas A&M University, College Station, TX; and [2]CTEH, Little Rock, AR.*

Around a million tons of petroleum products are spilled worldwide annually as the result of accidents or negligent use. Assessment of the resulting human health and environmental hazards is challenging due to the chemical complexity of these substances. Crude oil consist of a multitude of naturally-occurring aliphatic and aromatic hydrocarbons, heteroatoms and other non-hydrocarbon molecules, while refined products may also contain proprietary additives. Here, we describe a case study involving the hypothetical spill of a real "oil blend" material whose composition is described only as "lubricant base oil (petroleum, various CAS numbers), >70%; and additives (proprietary), <30%". Due to this cryptic description of the product's composition, first responders and local authorities may require additional characterization of potential hazards in order to inform the choice of a cleanup standard. We hypothesized that *in vitro* bioactivity profiling in human iPSC-derived hepatocytes, neurons, and cardiomyocytes would be more informative than traditional chemical analytical data in performing rapid hazard identification. Our approach was to employ both traditional methods (EPA methods for trace metals, volatile and semi-volatile substances, as well as full-scan GC-MS) and bioactivity-based testing of the "oil blend" alongside two well-characterized petroleum refining products as well as a library of crude oils. Data were then presented to a group of professionals knowledgeable about oil spill response representing diverse stakeholders from industry and state agencies. Participants were asked to determine which type of information was most informative with respect to making decisions about the cleanup response of the "oil blend" in comparison to the other tested substances. The participants agreed that while rapid traditional chemical analysis was helpful to a limited degree, bioactivity testing data allowed for a more informed discussion of the potential hazards that may be present in the "oil blend," and provided a more confident basis for rapid decision-making in this hypothetical case study. *Funding for this research is by a grant from the National Academies of Sciences, Engineering, and Medicine's Gulf Research Program (GRP).*

2251 Deep Learning in Automated Text Classification: A Case Study Using Toxicological Abstracts

G. Agyeman-Badu, and A. Varghese. *ICF International Inc., Durham, NC.*
Sponsor: S. Snow

Machine learning technology has been widely adopted as a cost-saving document prioritization approach in systematic literature reviews related to human health risk assessments. It is typically applied using supervised machine learning approaches that use a training dataset composed of a relatively small set of documents with human-annotated labels indicating the topic of each document to build models that automatically predict the labels of a much larger set of unlabeled documents. Deep learning algorithms form a branch of machine learning that relies on complex neural network architectures to learn the features of the object to be classified. Although deep learning algorithms have until recently mainly been applied for image, video, and audio classification, they are increasingly being deployed on text classification problems. To explore the potential advantages and practicalities of

using deep learning algorithms in the document prioritization step of systematic literature reviews, we compare the performance of the most commonly used deep learning architectures (MLP, CNN, bi-LSTM, CNN-bi-LSTM, and bi-LSTM-CNN) to a traditional machine learning model (SVM) using a dataset of approximately 7,000 toxicological abstracts. We find that SVM baseline performs well (F1 accuracy score range of 0.80 to 0.85), MLP performs marginally better (F1 accuracy score range of 0.82 to 0.88), CNN performs similarly well (F1 accuracy score range of 0.81 to 0.85), bi-LSTM performs worse (F1 accuracy score range of 0.75 to 0.86), CNN-bi-LSTM performs worse (F1 accuracy score range of 0.76 to 0.86), and bi-LSTM-CNN performs better than SVM (F1 accuracy score range of 0.83 to 0.88). The results indicate that deep learning does not offer increased performance over SVM in all instances. In addition, we found that deep learning requires considerably higher levels of algorithm training, run time, computational power, and algorithm tuning compared to the baseline traditional machine learning algorithm (SVM). For these reasons, we conclude that deep learning algorithms may not be the best solution for text classification problems.

2252 Evaluation of the Reproducibility and Gender Effects of a Five-Day *In Vivo* Screening Approach Using High-Throughput Transcriptomics to Estimate Benchmark Doses of Apical Outcomes

W. M. Gwinn, S. Auerbach, F. Parham, M. Stout, G. Roberts, S. Waidyanatha, E. Mutlu, B. Collins, R. Paules, A. Merrick, S. Ferguson, S. Ramaiahgari, J. Bucher, and M. DeVito. *NIEHS, Research Triangle Park, NC.*

Risk assessors use data from long-term toxicity studies to estimate regulatory exposure levels that pose minimal human risk. These studies are often prohibitively expensive and time-consuming. The DNTP is currently evaluating alternative methods to provide estimates of chemical exposure levels that induce minimal risk. Recently, high-throughput transcriptomics (HTT) has been proposed as a timely and cost-effective screening approach that covers a vast array of biological space. We previously evaluated the use of HTT in a short-term 5-day *in vivo* assay in male rats with the objective to determine if benchmark doses (BMDs) for transcriptional changes in the liver and kidney were similar with BMDs for traditional toxicological (apical) endpoints. For most of the 20 chemicals tested, the 'most sensitive' transcriptional pathway BMDs from the 5-day assays were within a factor of 5 compared to the 'most sensitive' apical (histopathological) BMDs estimated from historical NTP chronic or sub-chronic toxicity studies. Thus, the 5-day assay can be effectively used to provide reasonable estimates of BMDs for apical endpoints. In the current study, we evaluated the reproducibility and gender effects of the 5-day assay using 4 of the 20 chemicals. Male or female HSD rats were exposed for 5 consecutive days by oral gavage to 8 or 10 dose levels of TBBPA, BDCA, PFOA, or furan. Liver and kidney were collected 24 hr after the final exposure for transcriptomic analysis using the rat S1500$^+$ platform. Uterus was also collected from female rats. HTT dose-response data were analyzed using BMD Express 2.2 to determine transcriptional pathway BMDs for liver, kidney, and uterus. Preliminary data have shown that, although the identities of the 'most sensitive' transcriptional pathways active in liver and kidney differed across independent experiments (n = 3 in males and 1 in females), the pathway BMDs were similar. This suggests that the 5-day assay with HTT is reproducible with regards to estimating the BMDs, but not the identities, of the 'most sensitive' transcriptional pathways in liver and kidney.

2253 Evaluation of Model Selection Criteria Including Model Averaging during the Application of Benchmark Dose Method to Quantal Response Data

K. Yoshii[1], H. Nishiura[1], K. Inoue[2], and A. Hirose[2]. *[1]Hokkaido University, Sapporo, Japan; and [2]National Institute of Health Sciences, Kawasaki, Japan.*

To employ the benchmark dose (BMD) method in toxicological risk assessment, it is critical to understand how the BMD lower bound (BMDL) for reference dose calculation is selected following statistical fitting procedures of multiple mathematical models. The purpose of this study was to compare the performance of various model selection criteria, model exclusion criteria and model averaging methods for developing the guidance of BMD method for quantal response data. Simulation-based evaluation of model exclusion and selection processes was conducted, comparing validity, reliability and other model performances. Three different empirical datasets were analyzed for exposition, each yielding different characteristics of the dose-response pattern (i.e. datasets with rich information in high or low response rate, and approximately linear dose response pattern). The best performing criteria of model exclusion and selection was different across differently characterized datasets. Nevertheless, a model averaging method over three models with the lowest three AIC values (MA-3) did not reveal the worst performance, and MA-3 without model exclusion offered the best results among model averaging methods. Model exclusion including the use of Kolmogorov-Smirnov test did not necessarily improve the validity and reliability. The present study indicates that using MA-3 would be a recommended option whenever applicable. *Acknowledgement: This study was commissioned under a grant for the 2018 Cabinet Office Research for Assessment of the Effect of Food on Human Health, Japan (ID: 1801, PI: Akihiko Hirose).*

2254 Development of the Tool Kit for the Individual-Based Aggregate Exposure Assessment of Biocides Using the Multi-Use Pattern of Consumer Products

J. Lee, J. Park, G. Yoo, J. Sohn, I. Park, H. Seol, D. Park, and S. Park. *EH R&C(EH Research & Consulting), Incheon, Korea, Republic of.* Sponsor: J. Choi

Current exposure assessment methods for consumer product were focused on the consumer-only exposure level to diagnose the safety level of consumer product. There remains, however, another question: where or not current exposure distribution in the general population by consumer product is safe. To answer this question, different type of approach needs to be applied to assess the aggregated exposure in the individual level using the multi-use pattern of consumer product. Different from the individual food consumption rate for each food group, there is no exposure factor matrix for the individual aggregate exposure assessment of consumer product, which include the individual exposure intensity for each consumer product which they use. Until now, most exposure factors for consumer product were calculated from consumer-only survey for each consumer product. So we could not estimate the individual aggregate exposure from consumer products. In this study, we derived the multi-use pattern of consumer products for the artificial reference population from the separately conducted two survey data: (1) the consumer-only survey for exposure intensity factor(use frequency, use amount, and use time) of more than 200 people and (2) the individual utilization survey for every types of consumer products for 3,000 people. To estimate the exposure intensity factor for 3,000 people from consumer-only survey data, a probabilistic machine learning algorithm, Variational Inference Auto-encoder (VIA), was applied. Finally, in this study, a new toolkit as a chemical-independent modeling framework for the aggregate exposure assessment for multi-use consumer products was developed. The individual aggregate exposure assessment method was compared with traditional methods using the representative value (mean or 95th percentile values) of exposure factor and the random variables by Monte Carlo simulation. This toolkit was firstly applied to screen the more risky biocide compounds in consumer products and to refine the exposure reduction measures such as product safety standard for biocide compounds such as surfactants commonly used both for cleaning compound and a preservative in many kinds of liquid type of chemical products.

2255 Application of a Systematic Evidence Map to Characterize Factors That Modify Chemical Exposure or Response

J. S. Lee[1], I. Druwe[1], M. Toledo[2], R. Jones[1], A. Cory[1], A. Davis[3], J. Gift[1], E. Yost[1], and P. Amanda[1]. *[1]US EPA, Research Triangle Park, NC; [2]Universidade de São Paulo, São Paulo, Brazil; and [3]US EPA, Washington, DC.*

Systematic evidence maps use systematic review methods to identify the amount and type of evidence available to address a particular topic. They are used for identifying and categorizing chemical-specific literature that may be potentially relevant to human health risk assessment, and employ the use of systematic review screening approaches such as a Population, Exposure, Comparator, Outcome (PECO) statement and software applications such as Distiller SR. This study explores the use and feasibility of the systematic evidence map approach to provide a clearer picture of the available literature on modifying factors that may impact the relationship between chemical exposure and outcome. Using inorganic arsenic as an example, studies that were previously identified via a literature search as potentially having susceptibility information were screened and tagged at the title and abstract screening level using Distiller SR. Each study was screened by two reviewers. The modifying factors for susceptibility that were included in the analysis were alcohol consumption, co-exposure to other environmental contaminants, environmental justice, gender, genetic polymorphism, lifestages, microbiome, nutritional deficiencies, pre-existing disease, and smoking status. Results of this screening process were compared with search string results and as expected, two-person screening at the title and abstract level was more precise with the level of effort still being manageable. Genetic polymorphisms and nutritional

deficiencies are the most studied modifying factors. Some modifying factors, such as genetic polymorphism or smoking, were easier to discern than others, like environmental justice. The resulting evidence map gives a better understanding of available literature on each of the modifying factors with specific focus on the chemical of interest. This case study moves the application of evidence maps beyond the chemical exposure and outcome dynamic and allows for a deeper insight into the available literature especially for data-rich chemicals. *Disclaimer: The views expressed are those of the authors and do not necessarily represent the views or policies of the US EPA.*

2256 Safer and Less Environmentally Harmful Alternative Electrokinetic Approach to Extraction of Living Plants for Cosmetic Ingredients

P. Recht[1], S. Micceri[1], L. Zhang[1], K. Winkowski[2], and S. Kim[3]. *[1]Ashland, Ossining, NY; [2]Ashland, Bridgewater, NJ; and [3]Ashland, Dublin, OH.*

Plant extracts are widely used in cosmetics, mainly as bioactive ingredients. There is a growing trend to highlight the use of natural ingredients in cosmetic end use products to differentiate them in the marketplace. The increased interest in employing bioactive ingredients propels the demand for evaluation of differentiated plant extracts. Traditional extraction processes usually require high energy consumption and/or the use of large amount of solvents, which could result in unfavorable safety and environmental profiles. To address these concerns, we have used a new approach that preserves the inherent osmotic pressure of the plant cell juice and uses it as a separation medium with targeted fractions being mechanically and gently separated based on their electrokinetic potential without the use of solvents for isolating plant fractions for cosmetic use. The process starts with the separation of a stable intracellular colloidal dispersion from live plants. The dispersion is separated into different fractions via targeted destabilization. This process can eliminate or drastically reduce the presence of certain toxins (e.g., parthenolide, pheophorbides, patulin, 5-methoxypsoralen, and heavy metals). A cradle-to-grave lifecycle analysis shows that this process has a lower environmental footprint compared to traditional technologies in several respects. This includes reduced global warming potential, ozone depletion potential, acidification potential, photochemical ozone potential, eutrophication potential, primary energy demand, abiotic resource use, and land use. The E-factor (ratio of mass of waste per mass of product) is very low (≤1) for fractions made via this process, and almost zero (≅0) is achievable. For comparison, E-factors for bulk chemicals, fine chemicals, and pharmaceuticals typically are in the ranges of 1-5, 5-50, and 25-100, respectively. In summary, this alternative process: (1) enables more effective utilization of the underexplored potential existing in living plants, (2) allows targeting of multiple biological pathways with a single ingredient, (3) provides superior efficacy, safety and reproducibility, (4) utilizes a solvent-free process for fractionation, and (5) utilizes a process that has a lower environmental impact and generates less waste.

2257 Development of the Modeling Framework for the Cohort-Based Risk Assessment Approaches Based on the Longitudinal Individual Aggregate Exposure and Biomarker: Case Study for Dioxins

J. Lee, G. Yoo, J. Park, J. Sohn, I. Park, and D. Hwang. *EH Research & Consulting, Incheon, Korea, Republic of.* Sponsor: J. Choi

New approaches for the risk assessment for the chemicals such as POPs with the long half-life in human body and has been developed because the traditional approach based on cross-sectional design have failed to assess the time trend of exposure level on the basis of the receptor. Cohort-based approach is an alternative for this type of chemicals, which can be applied to the life-long exposure assessment and the life-stage specific risk assessment. Critical parts in the part of exposure assessment of the cohort-based approach is the re-construcution of the past exposure and the projection of the future exposure, which can be derived by 'population kinetic model' depending on the emission trend and the half-life of the chemicals and confirmed by the longitudinal biomonitoring data. In this study, a systemic modeling framework was developed for the cohort-based risk assessment. The modeling framework is based on the individual level aggregate exposure assessment module including food consumption as a main exposure media for POPs such as PCBs and dioxins. Time trend of food concentration and individual food consumption rate on the basis of body weight and lipid content during the past 20 years were derived by nation-wide survey DB for about 10,000 Korean people every three years and applied to assess the individual external exposure distribution. The population kinetic model was used to predict the internal concentration of chemicals in the individuals with different body weight and lipid content along the ages from their cohort years from the external exposure amounts. Finally, the modeling framework will be used to compare the internal and external exposure in the individual level and applied to derive the kinetic parameters such as congener-specific half-life. The estimated kinetic parameter for each congener will be used to diagnose the current exposure levels and to project the future internal exposure level among Korean population. From this simulation can make it possible to assess retrospectively and prospectively the exposure distributions and to diagnose where or not current regulation measures is enough to reduce the exposure level below the safety guideline.

2258 Beauvericin and Zearalenone Metabolites Combinations Alter Viability and Oxidative Stress in Undifferentiated Neuroblastoma Cell Line

M. Ruiz, A. Juan-García, F. Agahi, and C. Juan. *Universitat de València, Burjassot, Spain.*

Beauvericin (BEA) is an emergent mycotoxin produced by many species of *Fusarium* and by *Beauveria bassiana;* while Zearalenone (ZEA) by several *Fusarium spp.* Metabolization of ZEA originates two main derivatives α-zearalenol (α-ZOL) and β-zearalenol (β-ZOL). BEA, α-ZOL and β-ZOL are present in stored grain and co-exposure through the diet is very common. Once ingested, it is possible to reach the brain and cause neuronal alterations. Combinations may cause increase of toxicity produced by these mycotoxins. In this *in vitro* study, it is presented the combined effects of all three mycotoxins in binary and triple mixtures on the viability and oxidative stress response of undifferentiated human neuroblastoma cell line (SH-SY5Y). Cell viability was assessed after 72 h using MTT assay and oxidative stress through reactive oxygen species (ROS) levels by malondyhaldehide (MDA) measurement during 120 min. Binary mixtures where α-ZOL was present revealed increase of ROS levels, while moderate levels where obtained in tertiary combinations. Our viability data showed that irrespective of the toxin combinations, the toxins have synergistic effect. BEA + β-ZOL and triple mixtures have induced a slight to high antagonistic response on ROS levels at low concentrations that have turned into strong synergism for high concentrations. This study clearly shows that co-contamination of food and feed with ZEA metabolites and BEA should be taken into consideration, as the co-exposure to mycotoxins might result in stronger adverse effect than resulted from the exposure to individual toxin. *Acknowledgments: This work was supported by the Spanish Ministry of Economy and Competitiveness (AGL2016-77610-R).*

2259 Effects of Nonnutritive Artificial Sweeteners on Lipid and Insulin Metabolism in the Model Organism *Caenorhabditis elegans*

M. Martin Mayor[1], N. Gilbert[1], A. Reynolds-Gray[1], R. Frye[1], L. K. Vaughan[1], and V. Fitsanakis[2]. *[1]King University, Bristol, TN; and [2]Northeast Ohio Medical University, Rootstown, OH.*

Obesity and type II diabetes (T2D) have reached epidemic proportions. Caloric reduction has been proposed as a primary intervention and treatment. The American Heart and Diabetes Associations have both endorsed the use of non-nutritive artificial sweeteners (nnAS) as a substitute for sugar. However, studies have suggested that the consumption of nnAS may disrupt both glucose and lipid metabolism. Based on this, we hypothesize that nnAS exposure would lead to increased lipid accumulation and disruption in insulin signaling. To this end we examined the effects of Sweet and Low® (SWL) or Splenda® exposure in the model organism *Caenorhabditis elegans.* Alteration in lipid accumulation was assayed in wild type N2 *C. elegans* with (SWL-10mM and 30mM), the active ingredient saccharin (SAC- 10mM) and glucose (GLU-10mM). Lipid deposition was assayed via the lipophilic dye Oil Red O' accumulation quantified through image analysis. Compared to control all SWL and SAC concentrations showed significantly more lipid accumulation, particularly around the digestive tract (p0.001). Insulin signaling disruption was evaluated using the TJ356 strain of *C. elegans*, which has a GFP tagged DAF-16 gene, a key component of the Insulin Like Signaling (ILS) pathway. DAF-16 (human ortholog FKHRL1) acts as a transcription factor that regulates the expression of genes related to fat metabolism, aging and stress resistance. Treatments consisted of control (CN), and 10mM or 30mM of Glucose (GLU), 10mM and 30mM of Splenda® (SP). Cellular localization of DAF-16 protein expression was evaluated using fluorescent microscopy imaging. Nuclear localization of DAF-16 expression was observed in all treatments when compared to control, indicating that DAF-16 is transported to the nucleus and therefore altering the regulation of fat, aging and stress response genes. SWL and SP exposure also increased lifespan when compared to glucose or control (27d CN, 25d SP, and 13d GLU), supporting the role of nnAS in ILS disruption. This was partially explained by the induction of dauer, a hibernation state, in SWL and

SAC worms which occurs in times of stress. These results indicate that nnAS are altering both glucose and lipid metabolism, although the mechanism and extent are still under investigation.

2260 Gap Analysis of Cannabidiol for Use as Novel Food in the European Union

D. M. Lozon, and J. Wan. *Intertek Group plc, Mississauga, ON, Canada.*

Cannabidiol (CBD) has been purported to aid in cognition and overall wellness; however, efforts to allow use of CBD in foods and dietary supplements has been met with resistance as many argue the science behind CBD has not caught up with these non-prescription uses. In early 2019, the European Commission decided that all extracts of hemp, and products including derived or synthetic CBD must undergo the Novel Food authorization procedure prior to being included in foods and dietary supplements. We have conducted an evaluation to determine if the existing data for CBD meets the criteria for use in Novel Foods as detailed in the European Food Safety Authority (EFSA) *Guidance on the preparation and presentation of an application for authorization of a novel food*. A common problem that arose was that many of the identified studies did not use purified CBD, and instead utilized hemp oil, CBD oil, or hemp extracts, all of which had different compositions and extraction processes. The studies evaluated included oral repeat-dose toxicity studies in at least 4 species (up to 3 months of dosing), reproductive and developmental toxicity (DART) studies, genetic toxicity studies, and sensitization. Three standardized genotoxicity assays using hemp extract were identified, in addition to 2 non-standard genotoxicity studies in human-derived cell lines. Additionally, while an *in vitro* (Ames) assay, *in vivo* (Comet and bone marrow micronucleus) assay, a 26-week toxicology study, and two DART studies were identified in the United States (US) Food and Drug Administration (FDA) Drug Review for Epidiolex (CBD), the full study reports are not publicly available and, thus, cannot be used to support a petition in the EU. As such, Tier 1 genotoxicity (bacterial reverse mutation assay [OECD TG 471] and *in vitro* mammalian cell micronucleus test [OECD TG 487]) and 90-day subchronic toxicology [OECD TG 408] studies with purified CBD should be conducted prior to submitting a novel food application. Depending on the results of the genotoxicity and 90-day studies, additional ADME studies, DART studies, chronic toxicity, and human studies may be required. Additional studies on the CBD metabolites would likely also be required due to observed interspecies differences in the metabolism of CBD.

2261 Modulation of the Pesticide Paraquat-Affected Molecular Pathways by Anthocyanins in *Caenorhabditis elegans*

Y. Ye[1,2], J. Ji[2], X. Sun[2], J. Wang[1], and L. Tang[1]. [1]*University of Georgia, Athens, GA; and* [2]*Jiangnan University, Wuxi, China.*

Anthocyanins are a group of C15 aromatic flavonoid compounds naturally existing in many food types, especially in fruits and vegetables. These phytochemicals have been shown to have multifaceted beneficial functions in the maintenance of human and animal health, with the most recognized being their free radical scavenging and antioxidant functions. However, we still lack a detailed understanding of how the metabolism of these compounds relates to their various functions. In this study, we conducted a metabolomic analysis to evaluate the modulation of metabolic profiling of anthocyanins in the nematode *Caenorhabditis elegans* treated with the pesticide paraquat (PQ) (0.1 mM to 0.9 mM). Briefly, N2 wide-type *C. elegans* were independently pretreated for 12 h with three anthocyanins (cyanidin, malvidin, and peonidin) at concentrations ranging from 10-100 μM, followed by treatment with PQ for another 12 h. After quenching with liquid nitrogen, a 3:3:2 v/v/v mixture of methanol/isopropanol/water was used to extract metabolites of worms at cryogenic temperatures. The extracts were freeze-dried via vacuum and then derivatized using the two-step methoximation/silylation protocol prior to analysis. The metabolites were detected by gas chromatography-time-of-fly/mass spectrum (GC-TOF/MS) and processed using multivariate statistical analysis. The metabolite sets were screened for further pathway analysis using rules of t-test (P) value < 0.05, and similarity value > 500. Our results suggested that PQ treatment primarily affected the metabolism of amino acids, energy, and lipids in *C. elegans*, and pretreatment with anthocyanins reversed PQ-impacted metabolic pathways. As compared to the metabolic profiling in PQ-treated and control worms, anthocyanins mainly protected two dominant metabolic pathways: amino acid metabolism and glycometabolism. Our findings demonstrate that metabolomic pathway analysis can provide a new perspective to better understand the protective effects of anthocyanins. Importantly, this could represent an effective method to elucidate the mechanism by which anthocyanins protect against chemical toxicant-induced adverse health effects.

2262 Quality Appraisal of Methodology for *In Vitro*, Nonclinical, and Clinical Studies Evaluating the Impact of Sucralose on the Gut Microbiota

A. Mak, and A. R. Lobach. *Intertek Group plc, Mississauga, ON, Canada.*

Sucralose is a non-nutritive sweetener approved by the US FDA for use in human food, with an acceptable daily intake (ADI) of 15 mg/kg body weight. However, there is recent debated evidence demonstrating that sucralose consumption may alter the composition of the gut microbiota. Therefore, in this study, a quality appraisal of methodology for published scientific literature was conducted to investigate whether the available data would support this claim. In total, 105 studies were identified; based on a defined set of inclusion criteria, 10 full articles and 6 conference abstracts were determined to be relevant (3 clinical, 10 non-clinical, and 3 *in vitro* studies). The design of each study (*e.g.,* dose, exposure route, duration, controls) and the reported outcomes related to the gut microbiome were critically evaluated. The 3 *in vitro* studies were determined to be of limited relevance to human exposure. Most of the non-clinical studies (9/10) were flagged with issues, such as exposures in excess of the ADI and/or lack of proper control groups, therefore limiting the significance of the reported changes on the gut microbiota. For the clinical studies, 2 conference abstracts reported that sucralose consumption can alter the gut microbiota; however, there was not enough detail in the abstracts to fully assess the studies. The 1 peer-reviewed full article reported that ingestion of sucralose (9.3 to 12.8 mg/kg body weight/day) for 7 days does not alter the gut microbiota in healthy adult male subjects. In conclusion, based on the quality of evidence, the available data do not provide a clear conclusion that sucralose modulates the gut microbiota at exposures relevant to human use in food.

2263 A Reassessment of Regulatory Reference Values and Background Exposure Levels for Heavy Metals in the Human Diet

C. Wong[1,2], and I. Saab[2]. [1]*University of Rochester Medical Center, Rochester, NY; and* [2]*International Life Sciences Institute North America, Washington, DC.*

Heavy metals, such as arsenic, lead, cadmium, mercury, and chromium, are of concern in the food supply as oral exposures to these metals can cause adverse health effects such as organ damage, cancer, and neurodevelopmental effects. It is not possible to eliminate risks associated with exposure to heavy metals since they occur naturally in the environment and can also originate from anthropogenic activities that contaminate water, soil, and air. Therefore, it is important to periodically assess exposures from food and water and relate them to updated safe reference values on a national level. The objectives of this study were to 1) identify current regulatory reference values for heavy metals, 2) evaluate changes in reference values over time, 3) compare reference values set by different agencies, and 4) review total background level exposure from food and water to better understand the overall state of human exposure to heavy metals from consumption. Key scientific studies and endpoints used to derive current reference values were also compared across agencies. In general, heavy metal exposures to arsenic, cadmium, and mercury were below current regulatory reference values. Oral exposures to chromium were determined not to be a significant public health concern. However, total background level exposures to lead exceeded the new Interim Reference Level set by the FDA, especially for young children. Reference values and background-level exposure values presented here were also integrated into the International Life Sciences Institute (ILSI) North America Heavy Metal Screening Tool hosted by the Joint Institute for Food Safety and Applied Nutrition (JIFSAN). This tool allows users to utilize these values in an accessible website interface to conduct a screening-level risk assessment of heavy metal risks in foods and food ingredients. *This work was funded by the International Life Sciences Institute North America Summer Fellowship Program.*

2264 Mitigation of Mycotoxins in Fruit Juices by Pulsed Electric Fields (PEF)

N. Pallarés, H. Berrada, M. Fernández-Franzón, M. Ruiz, and E. Ferrer. *Universitat de València, Valencia, Spain.* Sponsor: A. Juan-García

The population has increased the demand and consumption of foods with fresh-like. The emerging technologies, like pulsed electric fields (PEF) are effective at mild temperatures and use short treatment times, resulting in minimally processed food with less change of sensory and nutritional properties (1). Mycotoxigenic moulds may infect fruits during crop growth, harvest and/or storage. Mycotoxins produce toxic effects; aflatoxins (AFs) are

carcinogenic compounds and emerging mycotoxins [enniatins and beauvericin (ENNs and BEA)] are cytotoxic compounds (2). One industrial application of PEF is the treatment during fruits and vegetables processing. Two studies are available in bibliography about the reduction effect of PEF on AFs contents (3-4). The aim of the present work is to study the mitigation effect of PEF on AFB2, AFG2, ENNs and BEA contents in fruit juices containing seeds and vegetable roots. The samples were treated by PEF under field strength of 3 Kv /cm and specific energy of 500 KJ/kg. Then, the mycotoxins were extracted by dispersive liquid-liquid microextraction method (DLLME) and determined by HPLC-MS / MS-IT. After the PEF treatment, mycotoxins reductions around 40 and 60% were observed for ENNs and BEA and up to 70% for AFB2 and AFG2. Subsequently, degradation products formed during PEF treatment have been identified by HPLC-Q-TOF-MS. Acknowledgments: This research was supported by Conselleria de Educación, Investigación, Cultura y Deporte (AICO/2018/199) and the Ministry of Economy and Competitiveness (AGL2016-77610-R). *References: (1) Picart-Palmade, L., Cunault, C., Chevalier-Lucia, D., Belleville, M. 2265 Subchronic Exposure to Cellulose Nanofibrils Modulates Gut Microbiome and Associated Metabolic Pathways

H. S. Xu, Y. Chen, and T. Guo. *University of Georgia, Athens, GA.*

It has been reported that cellulose nanofibrils (CNF) can decrease fat absorption and glucose release, suggesting their potential application as food additives or supplements in diets containing high contents of fat and sugars. However, the long-term effects of CNF uptake remained unknown. The purpose of this study was to determine the effects of subchronic CNF consumption at a physiologically relevant dose (30 mg/kg) by gavage on gut microbiome and associated metabolic pathways in Western diets (WD)-fed male C57BL/6 mice. The 16S rRNA sequencing analysis of fecal samples indicated that the gut microbiome communities were well separated on the unweighted Unifrac, an index of β diversity indicating presence/absence. However, after taking the difference in abundance into account, no clear patterns of separation on the weighted Unifrac among the groups were observed. Both the PD whole tree and chao1, indexes of α diversity that reflected the genetic diversity of the communities under study, were not significantly different among the groups. Further taxonomy profiling using LEfSe suggested that CNF treatment induced substantial shifts in gut microbiome when compared to either the vehicle or cellulose at the same dose. The *Clostridiaceae*, which was increased by CNF when compared to either the vehicle or cellulose, negatively correlated with the colon length and %body lean. The PICRUSt analysis of functional metagenomics identified multiple pathways (more than 50) that are either increased or decreased following CNF ingestion when compared to either the vehicle or cellulose treatment. Collectively, our study provides key findings regarding the safety of long-term CNF consumption associated with the ecology of gut microbiome and energy metabolism. *Supported by the USDA National Institute of Food and Agriculture [grant no. 2016-67021-24994/project accession no. 1009090], and in part by NIH [grant no. R41AT009523 and R41DK121553].*

2266 Absence of *In Vivo* Genotoxicity of a Purified *Aloe vera* Whole Leaf Juice Concentrate When Tested in Rats Using the Comet Assay

J. Hu[1], C. Hobbs[2], M. A. Streicker[2], K. Burke[2], Q. Gao[1], and V. Frankos[1]. *[1]Herbalife Nutrition, Torrance, CA; and [2]Integrated Laboratory Systems Inc., Morrisville, NC.*

Hydroxyanthracene derivatives (HADs) are a class of compounds naturally present in edible plants, including *Aloe vera*. HAD compounds such as aloin A, B and aloe-emodin found in the latex layer of *Aloe vera* leaf have been shown to be genotoxic in bacteria and mammalian cell assays, possibly attributing to colonic carcinogenicity observed in a 2-year rodent cancer bioassay of an orally administered *Aloe vera* whole leaf extract. In commerce, HADs in *Aloe vera* leaf are typically removed through an activated charcoal filtration process, also known as decolorization, during the production process of *Aloe vera* ingredients for use in foods and supplements. However, limited evidence is available regarding the *in vivo* genotoxicity potential of highly purified decolorized *Aloe vera* ingredients. The present study evaluated the *in vivo* genotoxicity potential of an orally administered purified *Aloe vera* whole leaf juice concentrate containing negligible levels of HADs (as test article [TA], < 0.3 ppm of aloins and non-detectable aloe emodin [LOQ = 0.02 ppm]). A GLP-compliant *in vivo* comet assay (OECD 489) was performed to test DNA damage in the colon and kidney following oral gavage administration of TA at 500, 1,000 and 2,000 mg/kg bw/day in male F344 rats for 2 consecutive days. Vehicle control (purified water), and ethyl methanesulfonate (EMS) were used as negative and positive controls, respectively. Rats administered TA exhibited no significant differences in final body weight compared to concurrent control animals. No other abnormal clinical observations associated with TA exposure were observed. For both kidney and colon, no dose level exhibited a statistically significant increase in DNA damage compared to the concurrent vehicle control group, and there was not a dose-related response. The positive control, EMS, resulted in statistically significant increases in DNA damage in the kidney and colon of the animals. The comet assay revealed that the purified *Aloe vera* whole leaf juice concentrate with *de minimis* HADs did not induce DNA damage in colon and kidney tissues under the experimental conditions described.

2267 Effects of Acrylamide on Isolated Rat Aorta and Mouse Phrenic-Nerve Diaphragm Toxicity

Y. Chen, S. Hsiao, and J. Liao. *National Chung Hsing University, Taichung, Taiwan.* Sponsor: D. Hung

Acrylamide (AA) can be formed during high-temperature frying or baking in the presence of both free asparagine and reducing sugars. AA could cause genotoxicity, carcinogenicity, neurotoxicity and reproductive toxicity. The mechanisms acrylamide induced vasotoxicity and neuromuscular toxicity are still unclear. This study is to investigate the possible mechanism of vasotoxicity and neuro-muscular toxicity of acrylamide. Vascular toxicity was studied by using an isolated rat aortic ring model, the aortic ring was divided into different doses group with or without endothelium, nitric oxide synthase (NOS) inhibition group (L-NAME), acetylcholine receptor (AChR) inhibition group (atropine and mecamylamine) and extracellular calcium inhibition. The changes in tension are to be an indicator of vasotoxicity. The nerve-muscle toxicity using a phrenic nerve-diaphragm model for testing, and experiments were performed AChR inhibition group and extracellular calcium inhibition group. The muscle stimulation changes are to be indicators of neuro-muscular toxicity and muscle contracture. The aortic ring results revealed that acrylamide caused relaxation in a dose-dependent when incubated with phenylephrine (PE) pre-induced endothelium-intact and -denuded aortic rings. Meanwhile, the half effective concentration (EC_{50}) values of acrylamide in endothelium-intact and -denuded aortic rings were 57.5 mM and 85.3 mM. The acrylamide-induced relaxation could be significantly attenuated by NOS inhibitor and AChR inhibitor (mecamylamine), and the other groups showed no significant inhibition. The phrenic nerve-diaphragm results revealed that acrylamide caused reducing stimulation and muscle contracture. There was no significant difference in the AChR inhibition group; the removal of extracellular calcium did not inhibit muscle contracture. These results indicate that vasodilatation induced by acrylamide is regulated by nitric oxide synthase via aortic endothelium. The regulation of muscle stimulation and contracture is caused by the nicotinic acetylcholine receptor.

2268 Multi-'omics Analysis to Understand the Mechanism Involved in Patulin-Induced Cell Transformation

K. M. Ansari, and N. Singh. *CSIR-Indian Institute of Toxicology Research, Lucknow, India.*

Patulin is a mycotoxin that naturally contaminates fruits and their products. Our unpublished results demonstrated that low dose chronic exposure of patulin leads to neoplastic changes in normal intestinal cells, thus, indicating the tumorigenic property of patulin. However, the mechanism(s) lying behind patulin's tumorigenic ability has not been fully understood. Therefore, in the current study, using a multi-omics approach, we identified the molecular and biochemical alterations accompanying patulin-induced tumorigenicity. Here, we performed RNA seq, high-resolution mass spectrometry and high-resolution magic angle spinning NMR technique for transcriptomics, proteomics and metabolomics. The differential analysis identified 163 transcripts, 297 proteins and 15 metabolites that were significantly altered in patulin transformed cells compared to passage-matched control cells. We observed that out of totals, 135 transcripts, 136 proteins, and all metabolites were significantly up-regulated, while 28 transcripts and 161 proteins were significantly down-regulated. Furthermore, analysis of gene expression data revealed that genes such as VCAN, SPP1, TNC, KCNN4, MUC5B, ETV4 have the potential to serve as prognosis biomarkers for the identification of early intestinal cancer patients. Moreover, the metabolomic study suggests that glutamine, taurine, leucine, valine, and alanine are the major altered metabolites. Among these, high levels of glutamine are very well reported in cancer cells. Similarly, leu-

cine, valine, and alanine found to be associated with cell proliferation and level of taurine could be used to predict the malignant transformation of certain tumors. In addition, serine and acetate act as a precursor for the synthesis of many other macromolecules. Furthermore, joint pathway analysis of proteomics and metabolomics indicated that (i) aminoacyl tRNA biosynthesis, (ii) glycosaminoglycan degradation, (iii) valine, leucine, isoleucine biosynthesis and (iv) glycosphingolipid biosynthesis pathways were deregulated in patulin transformed intestinal cells. Collectively, our findings provide insight into the biological reprogramming accompanying patulin-induced transformation in intestinal cells.

PS 2269 Boosting Levels of NAD+/NADH through NAD+ Precursor Promotes Mitochondrial Dysfunction

M. Sonavane, F. Hayat, M. Makarov, M. E. Migaud, and N. R. Gassman.
University of South Alabama College of Medicine, Mobile, AL.

Nicotinamide adenine dinucleotide (NAD^+) is both an essential co-factor and substrate derived from vitamin B3 and is intimately implicated in all essential bioenergetics. A decrease in intracellular NAD^+ levels is known to cause multiple metabolic complications and age-related disorders. Interest in pharmacological agents capable of increasing intracellular NAD^+ levels has driven attention to the use of dietary supplementation with NAD^+ precursors. One such NAD^+ precursor is dihydronicotinamide riboside (NRH), which increases NAD^+ levels more potently in both cultured cells and mice than current supplementation strategies with nicotinamide riboside (NR). However, the consequences of extreme boosts in NAD^+ levels are not fully understood. Here, we demonstrate the potential downside of acute NRH exposure in mammalian cells. Hepatocellular carcinoma (HepG3) cells treated with 100 μM of NRH showed slight but significant increase in cytotoxicity. NRH at 4 h exposure increased levels of oxidative stress by significantly increasing cellular reactive oxygen species (ROS). NRH substantially affected mitochondria health by altering mitochondrial membrane potential, increasing mitochondria superoxide formation and inducing mitochondrial DNA damage. As expected, NRH also causes metabolic dysfunction, altering mitochondrial respiration. Altogether, we demonstrated the adverse effects of acute NRH exposure in HepG3 cells. Extreme boosts in NAD^+/NADH likely have detrimental consequences in the liver cell model and further warrants to study these effects in other systemic models.

PS 2270 Estragole: DNA Adduct Formation in Primary Rat Hepatocytes and Genotoxic Potential in HepG2-CYP1A2 Cells

R. Schulte-Hubbert[1], J. Küpper[2], and D. Schrenk[1]. *[1]Technische Universität Kaiserslautern, Kaiserslautern, Germany; and [2]Brandenburgische Technische Universität, Senftenberg, Germany.*

Estragole is a natural constituent in herbs and spices and their essential oils. After CYP450-catalyzed hydroxylation and subsequent sulfation, estragole acts as a genotoxic hepatocarcinogen in rodents. Because of the genotoxic mode of action and the wide-spread occurrence in food and phytomedicines a refined risk assessment for estragole is needed. We analyzed the time- and concentration-dependent levels of the adducts N^2-(isoestragole-3′-yl)-2′-deoxyguanosine (E3′N^2dG) and N^6-(isoestragole-3′-yl)-desoxyadenosine (E3′N^6dA) in primary rat hepatocytes (pRH) in culture after incubation with estragole. We also investigated the genotoxicity in native and CYP1A2-overexpressing (HepG2-CYP1A2) HepG2 cells. pRH were incubated with estragole for different times. After cell harvest and lysis, DNA was extracted and enzymatically hydrolysed. The levels of the DNA adducts E3′N^2dG and E3′N^6dA were measured via HPLC-ESI-MS/MS using stable isotope dilution analysis. Genotoxicity was tested in the micronucleus assay incubating HepG2 cells or HepG2-CYP1A2 cells for 24 h with estragole und further 72 h without. Both adducts were formed in pRH and could be quantified after an incubation time of 1 h (E3′N^2dG: 1 μM; E3′N^6dA: 10 μM estragole). E3′N^2dG was the main adduct at all incubation times and all concentrations. E3′N^2dG could be detected after incubation at estragole concentrations as low as 0.1 μM after 24 h and 0.5 μM after 48 h. At all incubation times DNA adduct formation increased with increasing test concentrations, the concentration-response relationship showing indications for hypolinearity ('practical threshold'). DNA adduct levels were highest after an incubation time of 6 h and showed a downward trend at later time-points, possibly due to DNA repair. In the micronucleus assay no mutagenic potential of estragole was found in HepG2 whereas in HepG2-CYP1A2 cells 1 μM estragole led to a 3.2 fold and 300 μM to a 7.1 fold increase in micronuclei counts. In summary we could show, that DNA adduct formation from estragole is concentration- and time-dependent in pRH with E3′N^2dG as the main adduct. Both adducts could be quantified already after an incubation time of 1 h, E3′N^2dG being detectable already at 0.1 μM estragole after 24 h. The micronucleus assay confirmed the mutagenic potential of estragole.

PS 2271 Protective Effect of *Marinobacter hydrocarbonoclasticus* Culture Extracts against an Induced Oxidative Stress in Caco-2 Cells

M. Martínez-Larrañaga[1], I. Ares[1], B. Lopez-Torres[1], J. Maximiliano[1], M. Martínez[1], A. Anadon[1], M. Cueto[2], J. De la Rosa[3], and M. Martínez[1].
[1]Universidad Complutense de Madrid, Madrid, Spain; [2]Instituto de Productos Naturales y Agrobiología, CSIC, La Laguna, Spain; and [3]Universidad de La Laguna, La Laguna, Spain.

There is growing interest in the use of natural products to aid in the maintenance of human health. *Marinobacter hydrocarbonoclasticus* (strain CB08035) culture extracts CB08035-SCA (cultivated with yeast extract, soybean peptone and starch in artificial seawater) and CB08035-SYP (cultivated with casein and starch in artificial seawater) were found to show activity against *E. coli*, *E. faecalis,* and *P. aeruginosa*. Identified constituents by NMR spectrometry and MS from the extracts include phenylacetic acid, 4-hydoxyphenylacetic acid, 3-chloro-4-hydoxyphenyl acetic acid and a mixture of diketopiperazines. The study objective was to evaluate the cytotoxicity and the antioxidant response of Caco-2 cells to extracts CB08035-SCA and CB08035-SYP. Cytotoxicity induced by the extracts (10, 50, 100, 250 and 500 μg/mL), for 24 h incubation period, was assessed determining cell viability by lactate dehydrogenase (LDH) leakage and (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl-tetrazolium bromide) MTT assays. Extract antioxidant activities by directly scavenging intracellular reactive oxygen species (ROS) and extract effects against a cellular oxidative stress induced by *tert*-butil hydroperoxide (*t*-BOOH) were also evaluated. Treatment of Caco-2 cells with extracts evoked no changes in cell viability, indicating that the concentrations selected did not damage cell integrity during the incubation period. Treatment of Caco-2 cells with extracts (100, 250, 500 and μg/mL) evoked a significant dose-dependent reduction in cellular ROS generation. The dramatic increase in ROS generation induced in Caco-2 cells by 200 μM *t*-BOOH was significantly reduced by half when the cells were pretreated with the extracts (250 and 500 μg/mL). The remarkable decrease in ROS levels and consequently in the oxidative stress condition leads to a decline of Caco-2 cell death. These findings support the use of these extracts for potential nutraceuticals purposes. *Work supported by Project Ref. RTA2015-00010-C03-03 from Ministerio de Economía, Industria y Competitividad, Spain.*

PS 2272 Toxicological Risk Assessment of Pyrrolizidine Alkaloids: Investigations of the Hepatotoxic and Genotoxic Potential

L. Rutz[1], L. Gao[1], J. Küpper[2], and D. Schrenk[1]. *[1]Technische Universität Kaiserslautern, Kaiserslautern, Germany; and [2]Brandenburgische Technische Universität, Cottbus-Senftenberg, Germany.*

Pyrrolizidine alkaloids (PAs) probably represent one of the most significant groups of natural phytotoxins. To date, approximately 600 different PAs are known[1]. PAs can be found as contaminants in foods like teas, herbs and honey[2]. They are generally considered acutely and chronically hepatotoxic, genotoxic and carcinogenic[3]. For this reason, we generate data concerning *in vitro* cytotoxicity and genotoxicity of some food-relevant individual PAs. We want to provide data for a better risk assessment and further investigate the influence of PA structures on their toxicity as previously suggested by introducing interim Relative Potency Factors (iREPs)[4]. Genotoxicity of these selected PA congeners was determined in HepG2-CYP3A4 clone 9 cells[5] using the micronucleus test: monocrotaline, echimidine, europine, heliotrine, indicine, lasiocarpine, lycopsamine, retrorsine, riddelliine, senecionine and seneciphylline. Concentration-dependent increases in micronuclei counts were observed with most of the PAs. Cytotoxicity of PAs was tested in incubations with primary rat hepatocytes, HepG2 cells and HepG2-CYP3A4 clone 9 cells. They were tested at concentrations ranging from 1 to 300 μM. The cell viability was measured using the Alamar blue assay after 24 h and 48 h of incubation. In primary rat hepatocytes lasiocarpine (open-chained di-ester, 7S-structure) was the most cytotoxic congener, followed by the di-esters echimidine, retrorsine, riddelliine, seneciphylline and senecionine. The mono-esters heliotrine, indicine, europine and lycopsamine and the di-ester monocrotaline were much less cytotoxic. Similar cytotoxic effects were observed in HepG2-CYP3A4 clone 9 cells. In HepG2 cells, lacking CYP3A4, none of the selected PAs showed cytotoxicity in the concentration range tested. Genotoxic potencies of the congeners in the micronucleus assay were in good agreement with the cytotoxicity data although some PA-specific differ-

ences were found. *References: [1] CONTAM (2011) EFSA Journal 9(11):2406; [2] Allemang et al. (2018) Food Chem. Toxicol. 121, 72-81; [3] Fu (2017) Chem. Res. Toxicol. 30, 81-93; [4] Merz and Schrenk (2016) Toxicol. Lett. 263, 44-57; [5] Herzog et al. (2015) J. Cell. Biotech. 1, 15-26.*

2273 Effect of Magnesium and Silicon Oxides Nanoparticles on Immunological Alterations Induced by Mycotoxins in Rats

S. S. Essa[1], E. M. El-Saied[2], O. S. El-Tawil[2], M. B. Mahmoud[1], and S. S. Abd El-Rahman[2]. *[1]Animal Reproduction Research Institute, Giza, Egypt; and [2]Cairo University, Giza, Egypt.*

Mycotoxins specially Aflatoxin B1 (AFB1) is considered one of the major hazardous secondary metabolites. AFB1 is well-known as a feed borne-hepatotoxic and immunosuppressive mycotoxin. This study was conducted to evaluate the efficacy of nanocomposite magnesium oxide and silicon oxide (MgO-SiO2) in reducing the toxic effects of AFB1 on the immunity of adult male Sprague Dawley rats. Animals were divided into a control (Gp1) and three experimental groups (Gps); Gp2 received feed contained 200 ppb AFB1, Gp3 received feed contained 200 ppb AFB1 and 0.5 g/kg MgO-SiO2 nanocomposite. While, rats of Gp4 received feed contained 0.5 g/kg MgO-SiO2 nanocomposite. Cellular and humoral immune responses, as well as caspase-3 expression in liver, spleen, and intestine, were all evaluated. Residual concentration of AFB1 was determined in serum, liver and fecal samples. The obtained data were statistically analyzed. AFB1 markedly reduced body weight gain and food and water consumption. Cellular immune response (total and differential leukocytes count, neutrophils phagocytic activity, lymphocyte transformation, macrophage activity and serum lysozyme activity), serum total protein, and humoral immune response (fractions of protein as estimated by SDS- PAGE electrophoresis) were all severely reduced by AFB1. These findings suggested that the nanocomposite MgO-SiO2 has high affinity to adsorb AFB1 and can effectively modulate its toxicity in rats. Therefore, Nanocomposite MgO-SiO2 may offer a novel effective and cheap approach for the preventive management of aflatoxicosis in animal.

2274 Are Dried Soybean (*Glycine max*) Seeds a Dietary Source of Metals (Al, Cd, Pb, Ni)?

M. Rubio-Armendáriz, G. Giannantonio, S. Paz, D. González-Weller, Á. J. Gutiérrez, and A. Hardisson. *Universidad de La Laguna, San Cristóbal de La Laguna, Spain.*

The soybean (*Glycine max*) is a legume with high nutritional value with a world production of 320 million tons. Many soy-based products (soy milk, soya cheese, soy sauce, fermented derivatives (tofu, miso), protein powder, lecithins, oil, dried beans, sprouts) are commercialized. Some nutritional aspects of dried soybeans have been studied but the toxicological evaluation of its metal content has not been assessed. Metals such as Al, Cd, Pb and Ni are toxicologically relevant as there are fixed TWI (tolerable weekly intake): 1 mg Al kg bw/week, 2.5 µg Cd/kg bw/week, 4.41 µg Pb/kg bw/week (nephrotoxicity), 19.6 µg Ni/kg bw/week. Objectives (i) to determine the content of Al, Cd, Pb and Ni in dried soybean seeds marketed for direct dietary consumption; (ii) to evaluate the exposure to Al, Cd, Pb and Ni derived from the consumption of soybeans in different consumption scenarios (25 g/day and 50 g/day). The content of Al, Cd, Pb and Ni has been determined in 39 samples of soybeans using ICP OES (inductively coupled plasma - optical emission spectrometry). For the estimation of intakes and their contributions to TWI, a body weight of 81.1 kg in men and 66.9 kg in women and various consumption scenarios have been used. Considering the mean concentrations detected, Al (6.31±2.6 mg/kg), Cd (0.03±0.01 mg/kg), Pb (0.06±0.01 mg/kg) and Ni (1.88±1.4 mg/kg), a consumption daily of 25 g/day would mean intakes of 158 µg Al/day (% TWI: 1.36% men, 1.65% women), 0.75 µg Cd/day (% TWI: 2.60% men, 3.14% women), 1.5 µg Pb day (% TWI: 2.94% men, 3.56% women) and 47 µg Ni/day (% TWI: 20.6% men, 25.1% women). The consumption of 50 g/day of soybean seeds would mean an intake of 316 µg Al/day (% TWI: 2.73% men, 3.31% women), 1.5 µg Cd/day (% TWI: 5.20% men, 6.30% women), 3.0 µg Pb/day (% TWI: 5.90% men, 7.12% women) and 94 µg Ni/day (% TWI: 41.2% men, 50.2% women). Men would reach 100% of the TWI of Ni with a consumption of 121 g/day and women would reach 100% of the TWI of Ni with a consumption of 99.6 g/day. Soybean seeds are a dietary source of metals, especially Ni. Soybased products should be considered as an additional food group in studies estimating total dietary intakes of metals and other nutritional compounds. Monitoring the contamination of soybeans with toxic metals should be implemented and limits for these metals in all soybean's products should be established.

2275 High-Voltage Atmospheric Cold Plasma (HVACP) Efficacy to Degrade Aflatoxin B1, B2, G1, and G2 and Safety of Aflatoxin Degradation Products

K. Nishimwe. *Iowa State University, Ames, IA.*

Mycotoxins, particularly aflatoxins (AFs), are of public health importance because they cause a number of negative human and animal health impacts. They are secondary metabolites produced by fungi, i.e., *Aspergillus flavus* and *A. parasiticus* and are four different types of AFs, B1, B2, G1, and G2. Aflatoxins are very toxic to humans and animals; they cause liver cancer, associated with immunosuppression, stunting, and at high doses will lead to death. Human exposure to aflatoxins is the result of ingestion of contaminated foods, such as cereal grains or milk (M1 toxin) produced by animals previously exposed to aflatoxins in feeds. Cold plasma is a physical, novel non-thermal method, which is currently used in food industry. Cold plasma can refer to "gas-derived mix of atoms in their quasi-neutral ionized forms mainly composed of photons, ions, and free electrons as well as atoms in their fundamental or excited state with a net neutral charge". The plasma is generated using only atmospheric air and electricity. In this study, plasma was generated using High Voltage Atmospheric Cold Plasma (HVACP) operated at 85 kV and 60 Hz and generated 180 W. Pure aflatoxin (B1,B2, G1, and G2) was dissolved into chloroform, and an equivalent of 200 µM poured onto watch glasses until complete dry. Watch glasses containing aflatoxin were placed into boxes (27.31 cm x 17.78 cm) with 4.44 cm of gap distance, sealed into hermetic plastic bag, and directly treated in duplicate for 2, 5, 10, and 20 min with HVACP system described above. After the treatment, boxes were left over night to allow generated reactive species recovering their fundamental state into air. Aflatoxin residuals were extracted with chloroform and analyzed with LC-MS/MS. Preliminary results showed that aflatoxin B1 and G1 ("1") were sensitive to HVACP system; the aflatoxin B1 showed a reduction 90% after 2 min of HVACP treatment and aflatoxin G1 74% decrease after 2 min. After 10 min, the aflatoxin G1 residuals were below the limit of detection. Aflatoxin B2 and G2 ("2") were reduced for 38% and 79%, respectively after 20 min HVACP treatment. The large variability seen with B2 and G2 reduction likely results from the primary difference between the "1" and "2" toxins, which is the presence of a double bond at C8-C9 position, and readily degraded by reactive gas species. This double bond is absence in B2 and G2. The reduction of this C8-C9 double bond significantly lowers the aflatoxin toxicity. Chemical analyses are on-going to confirm these hypotheses. Future studies will correlate the aflatoxin degradation to toxicity. Toxicity assessment will be performed using *in vitro* methods using HepG2 cell and test for cytotoxicity, DNA fragmentation, and apoptosis.

2276 Analysis of Gallic Acid in *Hyperacanthus amoenus* and *Carissa bispinosa* Foliages

K. G. Kgosana. *Agricultural Research Council, Pretoria, South Africa.*
Sponsor: M. Davis

Overproduction and accumulation of reactive oxygen species (ROS) and free radicals in living organisms are associated with adverse physiological effects such as ageing, cancer, cardiovascular and inflammatory diseases. Naturally occurring polyphenols including gallic acid (GA), have emerged as strong anti-oxidants and radical scavengers, and are thus potentially beneficial to organisms. The abundance of GA in feed has anti-nutritive and toxic effects. It affects bioavailability of micronutrients by forming insoluble complexes, induces apoptosis and interferes with signalling pathways. Hence, the objective of this study was to carry out aqueous extraction of commercial feeds, *Hyperacanthus amoenus* (HA) and *Carissa bispinosa* (CB) foliages. The extracts were subjected to quantitative analysis of GA levels as putative anti-nutritive and toxic factors using HPLC-DAD and HPLC-VWD. The quantification method was validated for linearity, accuracy, precision (repeatability, reproducibility, intra- and inter-day variability), limits of detection (LOD) and quantitation (LOQ). Furthermore, GA recoveries (n=6) in feed were 111 (% RSD=1.36), 94 (% RSD=1.04) and 92% (% RSD=2.10) at 2 ppm, 4 ppm and 6 ppm fortification levels, respectively, whereas in CB they were 103 (% RSD=2.42), 97 (% RSD=1.71) and 90 % (% RSD=2.38), and in HA, 114 (% RSD=1.51), 91 (% RSD=1.76) and 107% (% RSD=2.51). The determined LOQ in feed, CB and HA were 0.25, 2.39 and 0.032 ppm, respectively, whereas LOD were 0.083, 0.79 and 0.011 ppm, respectively. Repeatability (n=9) of CB and HA resulted in 1.17 and 2.33 % RSD, respectively, and reproducibility (n=9) of 1.72 and 0.46 %RSD. The GA contents of 2.00±0.04, 10.9±1.22 and 14.1±1.36 mg/g DW were obtained in feeds, CB and HA, respectively. These results were significantly different ($p<0.05$). These methods indicate that GA contents in selected plants may have adverse health and growth performance effects on livestock and can provide a valuable basis for quality determination of GA in plants.

2277 Evaluation of Immunological Effects of Dietary E171, a Food Grade TiO_2

A. P. Bach[1], L. K. Blevins[1], R. B. Crawford[1], M. D. Rizzo[1], J. Zhou[1], J. E. Henriquez[1], I. Khan[1], S. Sermet[1], L. L. Arnold[2], K. L. Pennington[2], N. P. Souza[2], S. M. Cohen[2], and N. E. Kaminski[1]. *[1]Michigan State University, East Lansing, MI; and [2]University of Nebraska Medical Center, Omaha, NE.*

E171, food grade titanium dioxide (TiO_2), is a common additive in many foods. A recent study reported that exposure of rats to E171 in drinking water, after pretreatment with 1,2-dimethylhydrazine (DMH) (a gastrointestinal carcinogen and inflammagen) induced inflammation in the gastrointestinal tract, increased the percentage of dendritic cells (DC), and decreased $T_{regulatory}$ (T_{reg}) cells in Peyer's patches. Here, rats received food *ad libitum* containing increasing doses of E171 (0, 40, 400, or 5,000 ppm) for a total of 100 days and were evaluated for tissue specific and systemic changes in immune parameters. Food consumption was similar over the 100-day period between groups with maximum total exposure to E171 being 29,400 mg/kg in 100 days. No significant differences were observed in any E171 dose groups in the percentage of DC, $CD4^+$ T or T_{reg} cells within Peyer's patches or the periphery, compared to control diet fed animals. No E171 associated changes were observed in the profile of cytokine production in plasma, sections of jejunum, and colon in E171 alone fed rats. Significant differences were observed for IL-17A in colon (400 ppm E171+DMH) and IL-12p70 plasma (40 ppm E171+DMH). Thus, there is minimal to no effect of E171 administration in diet for 100-days on the immune system. *This work was supported by Michigan State University Center for Research on Ingredient Safety, the Grocery Manufacturers Association, the Titanium Dioxide Manufacturers Association, the International Association of Color Manufacturers, and the Fred and Pamela Buffett Cancer Center Tissue Sciences Facility Shared Resource, supported by the National Cancer Institute under award number P30 CA036727.*

2278 Differential Tissue, Cellular, and Molecular Sensitivity between Metabolic Syndrome Models Induced by Fructose and High-Fat Diets

Y. Chen, D. Arneson, S. Majid, I. Ann, Z. Kurt, G. Diamante, G. Zhang, W. Liu, P. Allard, and X. Yang. *University of California Los Angeles, Los Angeles, CA.*

Metabolic syndrome (MetS) is a complex metabolic disorder with multidimensional etiology that encompasses diverse symptoms such as hyperlipidemia, abdominal obesity, insulin resistance, and hypertension. Both high fat diet (HFD) and high fructose diet have been associated with the increased prevalence of MetS worldwide and research at the bulk tissue level have shown involvement of different tissues in its pathogenesis. However, cell-specific mechanistic research has been limited by the previous lack of high throughput single cell techniques. Thus, the paucity of systemic investigation across different tissues and cell types has prevented a holistic understanding of MetS pathogenesis. Here we used single cell RNA sequencing to examine thousands of individual cells from hypothalamus and peripheral metabolic tissues (liver, adipose, and small intestine) from both HFD- and fructose-induced MetS models and chow-diet fed control mice. t-Distributed Stochastic Neighbor Embedding (tSNE) analysis showed altered cell expression profile in different dietary exposure and tissues. To further quantify these differences, we applied Euclidean distance-based measurement to quantify transcriptome change under dietary exposure. Differential cellular sensitivity was found in both dietary exposure models, such as stronger alterations in the transcriptome of hypothalamic neurons in fructose-induced MetS and more prominent changes in adipose cell types in HFD-induced MetS. We further used co-expression network modeling to characterize cell-cell interactions across tissues and revealed altered cellular communication circuits in each MetS model. For example, the tight interactions between hypothalamic cell types and adipose mesenchymal stem cells appeared to be weakened in MetS models, and a stronger immune component was observed in high HFD induced MetS. Finally, humanin (*mt-Rnr2*), a mitochondrial gene linked with metabolic homeostasis, was found to be differentially regulated between the two MetS models. Our results indicate that HFD and fructose diets promote MetS by engaging different cell types, modulating cell type specific molecular pathways, and rewiring within-cell and between-cell gene networks across endocrine and metabolic tissues. The identification of major cell types and regulators of different subtypes of diet-induced MetS will facilitate precision medicine for MetS.

2279 Inactivation of Encysted Muscle Larvae of *Trichinella spiralis* in Pigs after Mebendazole Drug Treatment

J. Fredericks, D. E. Hill, D. S. Zarlenga, V. M. Fournet, D. S. Hawkins-Cooper, and J. F. Urban Jr. *US Department of Agriculture, Beltsville, MD.*

The production of safe and healthy food products represents one of the main objectives of the food industry. The presence of microorganisms in meat and products containing meat can result in a range of human health problems, as well as economic losses to producers of these products. However, contaminated meat products continue to initiate serious and large-scale outbreaks of disease in consumers. *Trichinella spiralis (T. spiralis),* which is the cause of trichinellosis (also known as trichinosis), is a parasitic nematode found in many warm-blooded carnivores and omnivores, including pigs. *Trichinella spiralis* has a long-standing association with pork products, not only in the US but around the world. Infections occur worldwide, but are most prevalent in regions where pork or wild game is consumed raw or undercooked. Therefore, it is necessary to evaluate new therapeutic and/or chemoprophylactic strategies to treat or prevent infection in animals maintained in management systems that do not preclude infection. We evaluated the effect of 4 anthelmintic treatments on the viability of *T. spiralis* encysted muscle larvae (ML) in pigs. Pigs were infected at 8 weeks of age with *T. spiralis* (ISS 44) first stage muscle larvae (ML) obtained by artificial digestion of infected rat muscle. At 55 days post-infection (PI), pigs were randomly assigned into 5 groups: control (sterile saline), levamisole, mebendazole, doramectin, or moxidectin. Pigs were humanely euthanized on day 66 PI. Muscle larvae were then isolated from pig tissues by artificial digestion, collected, and counted to determine worm burdens in muscles of treated pigs versus control animals. These ML were then inoculated into mice for 30 days isolated larvae mice to assess viability. Mice were then euthanized and ML were then isolated from mouse tissues by artificial digestion, collected, and counted to determine worm burdens in muscles of treated mice versus control animals. Results indicated that only mebendazole treatment had toxic effects on *T. spiralis* ML in pigs and ML viability in mice. In conclusion, this experiment provides a way to eliminate *T. spiralis* and its potential to cause illness from infected pork.

2280 Application of Machine Learning on Food Safety Data Analysis

W. Zou[1], W. Zhao[1,2], H. Hong[1], and W. Tong[1]. *[1]US FDA/NCTR, Jefferson, AR; and [2]Central China Normal University, Wuhan, China.*

With the development of new technologies such as next-generation sequencing (NGS) in pathogen detection and surveillance, the size of data in clinical and public health laboratory is increasing dramatically, including meta data. The major challenges currently exist on the interpretation and analysis of large size of data. In previous studies, we have developed a framework to pursue data mining on NGS datasets by topic modeling, which is an active research field in machine learning and has been mainly used as an analytical tool to structure large textual corpora for data mining. In this study, we continued the research on applying machine learning algorithms on the functional genomic analysis of NGS data. An NGS data set of 323 *Salmonella* isolates was retrieved from National Center for Biotechnology Information (NCBI) database, and SNPs were generated using our previously developed framework. Random Forest (RF) and Supporting Vector Machine (SVM) algorithms were then applied on both the SNPs dataset the SNPs corpus to predict the serotypes of *Salmonella*. High prediction accuracy and specificity were obtained in both datasets, with even better performance in the SNPs corpus. The implementation of topic modeling and other machine learning algorithms provides a new way in food safety data analysis. The machine learning algorithms can be applied on various datasets of different sizes to elucidate genetic information and potential biomarker identification, which is especially useful in big data era.

2281 The Analytical Method for the Determination of Polycyclic Aromatic Hydrocarbons from Milk Product Samples in the South Korea Market

H. Kim[1], J. Choi[1], B. Moon[2], and K. Lee[1]. *[1]Korea University, Seoul, Korea, Republic of; and [2]Chung-Ang University, Ansung, Korea, Republic of.*

Polycyclic aromatic hydrocarbons (PAHs) are substances composed of two or more aromatic rings. The International Agency for Research on Cancer (IARC) determined that benzo[a]anthracene (BaA), chrysene (CRY), and benzo[b]fluoranthene (BbF) are possibly carcinogenic to humans (group 2B), and benzo[a]pyrene (BaP) is carcinogenic to humans (group 1). Additionally, the

European Food Safety Authority (EFSA) suggested that PAH8 (BaA, CRY, BaP, BbF, benzo[k]fluoranthene (BkF), indeno[1,2,3-c,d]pyrene (IcdP), dibenzo[a,h] anthracene (DahA), and benzo[g,h,i]perylene (BghiP)) are suitable indicator for carcinogenic PAHs in foods. In our study, we validated PAH8 using the method of ultrasonication and gas chromatography with mass spectrometry (GC-MS) in milk. Benzo[a]pyrene-d12 and chrysene-d12 were used as internal standards. In the present study, we obtained 35 milk product samples from national supermarket chains in 10 cities with a population of more than 1 million people in South Korea. In order to represent the analyzed products, we composited samples in one. The results indicate that the recovery of PAH8 from milk product samples ranged from 80% to 110%, precisions (RSD, %) were within 20%, and the all of R^2 was above 0.99. The limit of detection and limit of quantification of PAH8 were ranged from 0.037 to 0.097 μg/kg and 0.114 to 0.295 μg/kg, respectively. The result revealed that in 35 milk product samples, B(a)P and PAH8 content were significantly higher in stir-fried butter (0.210 μg/kg and 1.780μg/kg, respectively) and PAH4 (BaA, CRY, BaP, BbF) contents were significantly higher in infant formula milk powder (0.637 μg/kg).

2282 Total Arsenic and Arsenic Speciation Concentration of Rice-Based Food in South Korea

C. Noh, S. Choi, M. Kim, and K. Lee. *Korea University, Seoul, Korea, Republic of.*

Arsenic is a type of toxic metalloid occurring in the environment that can be absorbed into various organisms, especially rice plants. Rice is the major route of arsenic intake through food and was usually consumed as steamed rice. However, nowadays, there are many processed foods made of rice such as cake and cracker. The average daily consumption of rice in South Korea is up to 200 g per day, including the intake of rice-based food. In 2016, South Korea's Ministry of Food and Drug Safety (MFDS) established the regulation on the concentration of inorganic arsenic in rice less than 200 ng/g. Nevertheless, there is a lack of research on the concentration of arsenic species in rice-based food. In this study, total arsenic (tAs) and four arsenic species (arsenite (As (III)), arsenate (As (V)), monomethylarsonic acid (MMA), dimethylarsinic acid (DMA)) were analyzed in steamed rice (n = 22), rice bread (n = 14), rice cracker (n = 15), rice wafer (n = 4), rice liquor (n = 16), and rice drink (n = 7) samples. All of the samples were purchased in 2019. For the present study, inductively coupled plasma-mass spectrometry (ICP-MS) was used to analyze tAs and high-performance liquid chromatography coupled with inductively coupled plasma-mass spectrometry (HPLC/ICP-MS) was used to analyze 4 species of arsenic. The result revealed that no As was detected in rice liquor and rice drink. Also, tAs concentration in all samples was under 200 ng/g, and inorganic arsenic concentration in all samples was under 100 ng/g. Such findings have shown that in South Korean markets rice-based food has low risk issues based on the level for inorganic rice arsenic standard from the MFDS.

2283 Total and Arsenic Speciation Analysis in Rice-Based Products for Infants in South Korea

S. Kim, C. Noh, and K. Lee. *Korea University, Seoul, Korea, Republic of.*

Rice-based products can be a major source of arsenic since rice easily absorb arsenic from soil and water compared with other grains. Rice is widely used for infant food in which infants are more sensitive and have a low resistance to the toxicity of heavy metals. The toxicity level of arsenic depends on chemical form and inorganic arsenic (iAs) is more toxic than organic arsenic. The objective of this study was to investigate the total arsenic (tAs) and four arsenic species (arsenite (As (III)), arsenate (As (V)), monomethylarsonic acid (MMA), dimethylarsinic acid (DMA)) in dry form of baby food (n = 9), paste form of baby food (n = 15), rice snack (n = 13), rice drink (n = 6) and others (n = 5) samples. For the present study, tAs was analyzed using inductively coupled plasma-mass spectrometry (ICP-MS) and separation of 4 species of arsenic was analyzed by high-performance liquid chromatography coupled with inductively coupled plasma-mass spectrometry (HPLC-ICP-MS). In our study, the predominant arsenic species were As (III) and DMA. In paste form of baby food and rice drink, As (V) or MMA were not detected. Total and inorganic arsenic content was found to have a similar tendency except others. Total and inorganic As content was found to be the highest in dry form of baby food, followed by rice snack, rice drink, paste form of baby food. The result of this study can provide a basis data for assessing the risk of exposure to As from ingestion of rice-based products.

2284 Analytical Method Validation for Polycyclic Aromatic Hydrocarbons in Edible Oil Using GC-MS and Content Change by Cooking Methods

K. Lee. *Korea University, Seoul, Korea, Republic of.*

Polycyclic aromatic hydrocarbons (PAHs) in edible oil are known to be affected by the environmental contamination, manufacturing process or the nature of oil. The content of PAHs in edible oils is affected by cooking methods. We selected eight edible oils including soybean oil, rice bran oil, grape seed oil, rapeseed oil, sunflower seed oil, olive oil, corn oil, and perilla oil that are consumed with high frequency in the South Korean markets. The oil samples obtained from the representative stores distributed in South Korea were pooled, homogenized, and cooked by five methods including raw, stir-frying, pan-frying, boiling, grilling, and deep-frying. In this study, a liquid-liquid extraction method was applied to determine 8 different compounds of PAHs (PAH8) (benzo[a]pyrene, benzo[a]anthracene, chrysene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[g,h,i]perylen, dibenz[a,h]anthracene, and indeno[1,2,3-cd]pyrene). Gas chromatography with mass spectrometry (GC-MS) was used for qualification and quantification. The accuracy varied between 90 and 110%, and the precision was within 20%. The linearity (r^2) was greater than 0.999. The limit of detection was 0.084 μg/kg, and the limit of quantification was 0.255 μg/kg. The values of PAH8 decreased by 0.2 to 1.8 μg/kg with boiling, while increased by 0.1 to 0.5 μg/kg with deep-frying. Also, stir-fried perilla oil had the highest value of PAH8 (5.5 μg/kg).

2285 Prenatal Nutrition Measured by *My Nutrition Index* Is Associated with Birth Weight and Cognitive Function in Children at Seven Years

C. Gennings[1], A. Wolk[2], N. Hakansson[2], and C. Bornehag[3]. *[1]Icahn School of Medicine at Mount Sinai, New York, NY; [2]Karolinska Institutet, Stockholm, Sweden; and [3]Karlstads Universitet, Karlstad, Sweden.*

Nutrition is a multi-faceted, complex construct, where good nutrition should be associated with improved health outcomes. This is particularly true during pregnancy when prenatal maternal nutrition may impact the child's development. Most research papers on nutrition focus on individual nutrients and health outcomes. In contrast, our focus is on a holistic measure of nutrition. *My Nutrition Index* (MNI) is an index that measures the nutrient quality (i.e., "nutritiousness") of a specified daily diet and is calculated based on quantification of dozens of macro- and micronutrients that are specific to an individual's nutritional needs (as defined by published recommended guidelines for individual nutrient target ranges) by incorporating dietary restrictions, subject characteristics, activity level, and health behaviors. Other nutrition indices are based on scored food groups consumed and may not adequately adjust for micronutrient inadequacies during pregnancy. The Swedish Environmental, Longitudinal, Mother and child, Asthma and allergy (SELMA) study is a pregnancy cohort in Värmland, Sweden, with prenatal endocrine disrupting chemicals (EDC) exposure and dietary data available, making it possible to test for the potential mitigating effect of good nutrition on health effects from EDCs. Using prenatal nutrients from food frequency questionnaire (FFQ) data to construct an individual's MNI, the index is significantly and positively associated with important metabolic (as measured by birth weight) and cognitive function at age 7 years (as measured by IQ-WISC) in children when adjusted for co-variates. Regression models included both prenatal concentrations of an EDC (bisphenol F, PFOA) and MNI demonstrating the adverse association with EDCs and the positive association of a nutritious diet during pregnancy. Thus, MNI is evidently a metric of the general nutritiousness of daily diets and is useful in environmental health studies in representing the impact of good nutrition. *We gratefully acknowledge support from NIEHS: #R01ES028811.*

2286 Investigation of the Effect of Cold Plasma on *Aspergillus flavus* and *Aspergillus parasiticus* Inoculated on Raw and Processed Pistachio During Storage

M. Mahdavi-Yekta[1,2], and A. Malekirad[3,4]. *[1]Shahriyar Technical University, Tehran, Iran, Islamic Republic of; [2]Islamic Azad University, Tehran, Iran, Islamic Republic of; [3]Tehran University of Medical Sciences, Tehran, Iran, Islamic Republic of; and [4]Markazi Province of Payame Noor University, Arak, Iran, Islamic Republic of.*

Pistachio is one of the most important horticultural products in the Iran which is very important in export and economy of Iran. One of the serious issues that endanger the export of this crop today is aflatoxin poisoning in pistachio production. Aflatoxin is a secondary metabolite of molds such as *Aspergillus fla-*

vus and *A. parasiticus* that poses many risks to human health. Plasma technology is one of the non-thermal methods to reduce the microbial burden and toxins produced on the surface of fresh and processed foods. In this study, 84 pistachios (42 crude and 42 processed) were obtained from Kerman province. And pistachio levels were disinfected by 0.3% sodium hypochlorite and the initial aflatoxins of the samples were measured by HPLC. *Aspergillus flavus* and *Aspergillus parasiticus* which were lyophilized and were prepared from Tehran University of Veterinary Medicine It was cultured in culture medium (SDA) and incubated at 25 ° C for 7 days. Then mold spores were removed from the plate was sprayed on pistachios and kept in 25 degree incubation for days 3, 7, 5, 10 and 21. The samples were divided into two groups and were exposed to plasma radiation for 10 minutes on the third and fifth days, on the seventh day for 15 minutes and on the 21st day for 20 minutes and at 30 KV. Then chemical tests including determination of fatty acid profile and peroxide number as well as determination of aflatoxins (B1, B2, G1, G2) were done three times in completely randomized block design using SPSS16 software. The results showed that plasma had no significant effect on chemical parameters (plasma penetration power is low) but it had a significant effect on pistachio aflatoxins and plasma radiation of helium origin had a more effective effect than plasma radiation of oxygen- origin. Therefore, it can be concluded that cold plasma can be used as a non-thermal method to reduce pistachio toxins.

PS 2287 A 90d Subchronic Toxicity Evaluation of Blueberry Polyphenols in Ovariectomized Sprague Dawley Rats

D. P. Cladis[1], S. Li[1], L. Reddavari[1], A. Cox[1], M. G. Ferruzzi[2], and C. M. Weaver[1]. *[1]Purdue University, West Lafayette, IN; and [2]Plants for Human Health Institute, Kannapolis, NC.* Sponsor: J. Cannon

Fruit and vegetable derived polyphenols are associated with numerous health benefits when consumed regularly. Because of this, consumers are increasingly turning to dietary supplements, which contain concentrated extracts of polyphenol-rich fruits and vegetables, to increase their consumption of these compounds. However, the safety of this consumption modality has not been adequately vetted. To address this, the safety of purified blueberry polyphenols was investigated over 90d in female, ovariectomized (OVX) Sprague-Dawley rats, following OECD 408 guidelines. Animals were dosed via oral gavage at 0, 50, 250, or 1000 mg total polyphenols/kg bw/d, and monitored daily. No differences in behavior, body weight, or food consumption were observed. Upon study completion, a complete necropsy was performed, with tissues harvested for histopathology and blood and urine collected for hematology, serum biochemistry, and urinalysis. No tumors or other macroscopic changes were observed at necropsy. Histopathological analysis did not show differences among treatment groups. A few statistically significant differences were observed in blood (total cholesterol and chloride ion concentration) and urine (color, pH, and bacterial counts) analyses, though these parameters were within normal ranges for the animals and not considered biologically significant. Intestinal permeability was tested using the FITC-dextran method. Increased gut permeability was observed in the high dose group, though no morphological differences were observed histopathologically in any section of the GI tract. Given the lack of changes noted elsewhere, the importance of the difference in intestinal permeability is likely of minimal physiological importance. These results indicate that the NOAEL for blueberry polyphenols in OVX-SD rats is ≥1000 mg total phenolics/kg bw/d. This translates to consuming ~10 g polyphenols in a 70 kg human, which is higher than the amounts present in commercially available dietary supplements.

PS 2288 Evaluation of Drug Interactions Using Primary Turkey Hepatocyte Cultures

S. Lyster, G. Kirby, S. Enouri, Y. Gu, T. Saleh, and R. Johnson. *University of Guelph, Guelph, ON, Canada.* Sponsor: T. Saleh, American Physiological Society

Accurate prediction of drug clearance in food-producing animals is critical for human food safety through prevention of violative drug residues. Although common in the commercial turkey industry, concurrent use of two or more drugs in the same feed can result in drug-drug interactions (DDIs) that may impact drug metabolism and clearance. Primary hepatocyte cultures have been used successfully for the development of models to assess drug metabolism in various species, however, data on hepatocyte cultures in poultry are extremely limited. The objective of this study was to establish and validate primary turkey hepatocyte monolayer cultures for use as a high-throughput *in vitro* model to screen for DDIs between drugs used in combination in poultry feed. Hepatocytes were isolated from the livers of adult male turkeys under general anesthesia using collagenase perfusion followed by culture in monolayer. The functional activity of cultured hepatocytes was assessed by monitoring albumin concentrations in culture media by ELISA and by evaluating gene expression of cytochrome P450 (CYP450) enzymes predominantly involved in poultry drug metabolism. Albumin levels peaked on the third day of a five-day period, with a maximum concentration of 232.72 ng/ml. RT-qPCR analysis of CYP1A4/5, CYP2C23, CYP2C45, and CYP3A37 revealed that CYP3A37 is the most abundant isoform expressed. The inducibility of the key CYP450 enzymes was assessed following treatment with known CYP450 inducers: rifampicin, phenobarbital, or 3-methocholanthrene. Treatment with phenobarbital resulted in a 50-fold and a 15-fold increase in CYP2C23 and CYP2C45, respectively. Drug depletion experiments have begun, with hepatocyte cultures being treated with either fenbendazole (anthelmintic), monensin (ionophore antibiotic), or fenbendazole+monensin at an initial concentration of 1µM for each drug, in quadruplicate. Tissue culture media samples were collected at 0, 0.5, 1, 2, 4, and 24 hours and analyzed by validated mass spectrometry. Linear regression analysis will be used to evaluate differences in the depletion rate for the drugs alone versus the drugs in combination, suggesting a DDI. Preliminary results of the first drug combination experiment show substantial depletion of both drugs within 24 hours. In order to achieve adequate statistical power, the experiment will be repeated in more birds. Additional combinations of drugs will be tested as part of the project.

PS 2289 Assessing the Effect of Gastrointestinal Digestion on the Pro-Inflammatory Potential of Dietary Advanced Glycation End Products Using an *In Vitro* Model of the Gastrointestinal Tract (TIM-1)

T. van der Lugt[1], K. Venema[2], S. van Leeuwen[3], M. F. Vrolijk[2], A. Opperhuizen[4,1], and A. Bast[1]. *[1]Maastricht University, Maastricht, Netherlands; [2]Maastricht University, Venlo, Netherlands; [3]Wageningen University and Research, Wageningen, Netherlands; and [4]Netherlands Food and Consumer Product Safety Authority, Utrecht, Netherlands.*

Protein- and sugar-rich food products processed at high temperatures contain large amounts of dietary advanced glycation endproducts (dAGEs). Our earlier studies have shown that specifically protein-bound dAGEs induce a pro-inflammatory reaction in human macrophage-like cells. To what extent these protein-bound dAGEs survive the human gastrointestinal (GI) tract is still unclear. In this study we analysed gastric and small intestinal (SI) digestion of dAGEs using a validated, standardised *in vitro* digestion model: the TNO gastroIntestinal Model (TIM-1) is a dynamic *in vitro* model that is able to mimic much of the human GI tract. This model takes multiple parameters into account, such as: dynamic pH curves, peristaltic mixing, addition of pancreatic digestive enzymes, and passive absorption. Samples of different digested food products were collected after (i) only gastric digestion and (ii) after both gastric plus SI digestion at different time points. Samples were analysed using UPLC-MS/MS for Nε-carboxymethyllysine (CML), methylglyoxal-derived hydroimidazolone-1 (MG-H1), and glyoxal-derived hydroimidazolone-1 (G-H1). All AGEs were quantified in their protein-bound and free form. After gastric digestion, only protein-bound AGEs were detected and no free AGEs. After 2 hours of SI digestion, approximately 10% of the protein bound AGEs were hydrolysed, the other fraction still remained bound to proteins. The results of this *in vitro* study give a strong indication that protein-bound dAGEs survive gastrointestinal digestion. This also indicates that dAGEs enter the human GI tract with potential pro-inflammatory characteristics. These findings might have severe health implications for the general population and even more for susceptible patient groups. These results are part of a larger study on the health risk of dAGEs in processed food.

PS 2290 Burden of Disease of Neurodevelopment Impairment Associated with Cassava Cyanide in the Democratic Republic of the Congo (DRC)

C. Chen, M. J. Boivin, and F. Wu. *Michigan State University, East Lansing, MI.*

Cassava is an important dietary staple in many tropical nations worldwide, mostly in sub-Saharan Africa. It contains naturally occurring cyanogenic glycosides that can cause both acute and chronic diseases in humans. It is especially risky in child populations suffering conditions of famine and conflict, as cassava is more likely to be consumed without proper processing to remove the cyanogenic glycosides. The World Health Organization (WHO) recently estimated the global burden of diseases caused by cassava cyanide associated with konzo, an irreversible spastic paraparesis of sudden onset. But recent studies have shown that exposures to cassava cyanide can also impair neurocognitive health among human children who do not develop konzo. Additionally, children with konzo not only suffer from the paralysis, but also from neurocognitive and motor deficits. This will increase the over-

all burden of disease of cassava cyanide. The aim of the present study is to calculate a more comprehensive estimate of burden of disease caused by cassava cyanide exposure in the Democratic Republic of the Congo (DRC). We describe the concentration-response relationship for cyanide in cassava flour and children's Intelligence Quotient (IQ), the occurrence of cyanide from cassava flour, the integration of concentration--response and exposure into estimates of incidence of intellectual disability (ID), and the translation of incidence estimates into DALYs. The average IQ decrements was 0.38 attributable to dietary exposure of cyanide among children in DRC. The median incidence of mild (65<IQ<69), moderate (60<IQ<64), severe (50<IQ<59), and profound (IQ<50) ID was 5.43×10^4, 2.48×10^4, 1.78×10^4, and 2.15×10^3 respectively. On the basis of the potential years of life lost due to intellectual disability and life expectancies, the estimated DALYs were calculated as the cases in each ID category and the total cases using age 2 as the time of onset for the disease, which resulted in the loss of DALYs at 1.37×10^6 in DRC. We recommend educational efforts of interventions are recommended to reduce the presence of cyanide in the diet of at-risk populations in DRC and other sub-Saharan African countries.

2291 Surveillance of Aflatoxin Contamination Levels in Household Maize for Human Consumption in Kenya, East Africa

R. N. Wangia[1], J. Ombaka[2], L. Tang[1], K. Xue[1], and J. S. Wang[1]. *[1]University of Georgia, Athens, GA; and [2]Maseno University School of Public Health and Community Development, Maseno, Kenya.*

Aflatoxins [AFs] are a group of naturally occurring mycotoxins produced by *Aspergillus flavus*, *Aspergillus parasiticus* and other related *Aspergillus* fungi. Staple food items including maize and maize products, peanut, sorghum, tree nuts, and spices are highly susceptible to AFs contamination. There are four groups of AFs in order of toxicity namely AFB_1>AFG_1>AFB_2>AFG_2. AFB_1 is a group I human carcinogen, an immunosuppressant, an anti-nutritional agent, and most recently, have been implicated to contribute to growth impairments in children. In this study, we determine the occurrence and level of AFs contamination in freshly harvested maize for human consumption in rural Kenya to establish the current database for exposure assessment. Up to 338 maize kernels and freshly milled flour samples were collected from households in Siaya and Makueni counties of Kenya. Samples were analysed for AFB_1, AFB_2, AFG_1 and AFG_2 using Ultra High-Pressure Liquid Chromatography with Fluorescence detection. AFs were detected in 100% of the samples with the range of 2.14 - 411 µg/kg. The geometric mean of total AFs in all samples from Makueni County is 62.5µg/kg with 95% CI: 53.7, 71.4 while in Siaya County is 52.8 µg/kg with 95% CI: 44.0, 61.7. More than 90% of samples exceeded the maximum limit of 10 µg/kg. Makueni County is a hotspot for AFs contamination with numerous reported outbreaks of aflatoxicosis which is poisoning and deaths attributed to consumption of AF contaminated maize. Before this study, little to no surveillance data was available for AFs contamination in food supplies produced and consumed in Siaya County. This study showed that AFs contamination is prevalent in maize based foods in both counties and efforts should be undertaken to prevent adverse health outcomes in human populations.

2292 Safety Assessment for 5 mg/day Zinc in Dietary Supplement Products without Co-Supplementation of Copper in the 50+ Populations

B. Sun[1], D. Ramsey[2], L. Okeeffe[3], and C. Mahony[3]. *[1]New Chapter Inc./ Procter & Gamble, Brattleboro, VT; [2]Procter & Gamble, Mason, OH; and [3]Procter & Gamble, Egham, United Kingdom.*

The Tolerable Upper Intake Levels (UL) for zinc, established by authoritative or scientific review groups, are designed to ensure absence of adverse effects on relevant indicators of copper status, with the value of 25 mg/day set by EFSA being the most conservative UL. The current assessment aimed to model the impact of 5 mg/day (low dose) supplemental zinc (without supplemental copper) on the zinc/copper ratio in older adults, aged 50 +. An analysis of the most recent National Health and Nutrition Examination Survey (NHANES) data (2013-2014) found that the typical ratio of zinc/copper intake, defined as the median was 8.6 in 50 + men (5^{th} to 95^{th} percentile ranging from 4.83 to 18.88) and 7.9 in 50 + women (5^{th} to 95^{th} percentile ranging from 4.25 to 16.78). Modelling of the data using 5 mg/day supplemental zinc (w/o copper) showed that the median ratio increased to 13.2 and 13.5 in 50 + men and women respectively, bringing 26.2 % of the males and 22.6 % of the females into a more favorable range (8.5 : 1 - 12.5 : 1) of zinc/copper intake ratio from nutritional perspective. Meanwhile, 16 % population of 50 + men and 29 % population of 50 + women had their zinc/copper intake ratio increased beyond the typical ranges of zinc/copper ratio (>95^{th} percentile) coming from diet only. However, these individuals have a relatively low baseline dietary intake for both copper and zinc. The exposure to the total zinc (even after 5 mg/day zinc) in the majority of these individuals remained below the most conservative EFSA UL of 25 mg/day for Zinc, meaning that such exposures are deemed to not adversely impact copper status. It is further interesting to note that zinc deficiency is more detrimental to copper status when copper intakes are low than when they are sufficient, thus the impact of zinc supplementation in these individuals may arguably be of greater nutritional benefit. In conclusion, for the US adults aged 50+ years, a low dose of supplemental zinc (w/o copper) does not adversely impact on human health and the overall level of risk is assessed as low when considering the established safe levels of zinc and the benefit this supplementation may bring.

2293 Can the Effects of Green Tea on Gut Microbiota Be Sustained?

F. Alqudrah, A. Liu, and C. S. Yang. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Studies have shown that green tea polyphenols can influence gut microbiota associated with a decrease of obesity and diabetes in mice fed a high-fat diet. This present study aimed to determine whether the effects of green tea polyphenols on gut microbiota (after 5 weeks of treatment of mice fed a low-fat diet) can be sustained after termination of the treatment in mice challenged with a high-fat diet. C57BL/6J (6-week old) male mice were fed a low-fat diet for 5 weeks. All 4 experimental groups, with 8 or 7 mice per group, were given drinking fluid containing 0.1% citric acid to stabilize the polyphenols and mask the bitter taste of tea preparations. During the 5 week period, one treatment group was given 0.6% green tea extract (GTE) and the other 0.2% epigallocatechin-3-gallate (EGCG) in drinking water. This time period is critical as most of the gut microbiome changes occur. Body weight, and diet and water/treatment consumptions were measured 3 times a week. The body weights for all groups increased steadily. The diet and water consumptions for all groups were approximately constant throughout the 5 week period. However, liquid consumption in the EGCG group was lower than other groups. After 5 weeks of treatment, all groups were switched to a high-fat diet (except one control group) with drinking water (no tea preparation) for 2 weeks. Body weight increased significantly for all 4 groups. The water consumption increased greatly at week 6, and then slightly declined by week 7. Diet consumption slightly decreased and remained constant throughout two week period. Fresh fecal samples were collected at week 0, 5, 6, and 7. Fasting blood glucose levels were measured at week 6 and 7 after treatment was removed. The control group with HFD was higher compared to other groups, but was not significant. In conclusion, no sustained effects (reduction in body weight and blood glucose levels) were observed due to the treatment.

2294 Characterizing the *In Vitro* Immunomodulatory Effects of *Echinacea purpurea* Products as a Strategy for Test Article Selection

K. Ryan[1], T. Gulledge[2], D. Germolec[1], E. Mutlu[1], S. Waidyanatha[1], J. Pierfelice[3], T. Cristy[3], and V. Johnson[2]. *[1]NIEHS, Research Triangle Park, NC; [2]Burleson Research Technologies, Morrisville, NC; and [3]Battelle Memorial Institute, Columbus, OH.*

Echinacea is continually one of the best-selling supplements in the mainstream market for use as an immune stimulant to lessen the symptoms of the common cold or infections. *Echinacea purpurea* (EP) is one of the most popular species used by consumers even though there is very little safety data for use in children, pregnant women, immune-compromised individuals, or those taking EP products while on other medications. Similar to other botanical products, EP is a complex mixture with little known about its bioactive constituents, and additional concerns regarding product quality (i.e. contamination or adulteration). The National Toxicology Program (NTP) procured a variety of EP products to screen for immune effects *in vitro* and assist in the selection of a representative test article for future *in vivo* toxicity testing. Twenty-nine EP products (bulk material or finished), 6 reference materials, and 6 *Echinacea*-specific constituents were evaluated for immunomodulatory activity using a whole blood assay system. Cells were cultured in the presence of EP with and without stimulation with LPS or anti-CD3 antibody and anti-CD28 antibody and the secretion of proinflammatory cytokines (IFN-γ, IL-10, IL-12p70, IL-13, IL-1β, IL-2, IL-4, IL-6, IL-8, and TNF-α) was measured using a multiplex immunoassay. EP preparations were also evaluated for endotoxin levels to address potential impact on cytokine secretion. Endotoxin contamination was detected in 16 EP samples, 3 samples could not be evaluated due to assay interference, and 10 samples had no detectable endotoxin (<5 EU/mL). Three of the 10 endotoxin-free samples (EP-22 > EP-35 > EP-13) led to strong increases in constitutive cytokine levels. However, cytokine levels after

EP costimulation with LPS or α-CD3/CD28 were increased the most by treatment with EP-35. Additionally, EP-22 suppressed LPS-stimulated production of several cytokines. These results were integrated with phytochemical profiles of each sample (generated by nontargeted chemical analysis) to better describe the relationship between biological activity and chemical profile of EP products. Combining biological and chemical data, EP-35 was selected as the NTP test article for further *in vivo* testing.

2295 Pharmacological Evaluation of *Brugmansia sauveolens* Leaf Extracts and Its Fractions for Anti-Asthmatic Properties

A. Attri, K. Sharma, R. Goyal, and G. Kaur. *Shoolini University, Solan, India.*

Asthma is one of the most common chronic diseases in developing countries with high air pollution especially in India. It causes respiratory problems with moderate to severe episodes. In present study, we evaluated one of the common herbs, currently available in local Himalayan region, *Brugmansia suaveolens*, also known as 'White Angel trumpet' for its anti-asthmatic properties. The leaf extract and fractions of the leaves were prepared and phytoconstituents, alkaloids, flavonoids, steroids and phenolic were characterized using TLC ad HPTLC. In preliminary *in vivo* study on Guinea pigs showed significant increase in cough latency time, decrease in cough frequency and increased antioxidant level. Further mechanistic evaluation for efficacy for receptor, beta-2, M3 (for bronchodilator) and H1 (for hypersensitivity) using molecular docking study was done. *In vitro* testing for involvement of leukotrienes (LTs), interleukins (ILs), transforming growth factor (TGF)-B, and prostaglandins (PGs) inhibition were also performed using human lung epithelial cells. The efficacy and toxicity testing displayed similar protective effect on the lung cells. These results suggest that the phytoconstituents of *Brugmansia sauveolens* have a potential to be used therapeutically for treatment of asthma.

2296 Nuclear Receptors and Transcriptional Regulation of Drug-Nutrient Interactions

J. Vanden Heuvel[1,2], M. Granda[1], and B. Sherf[2]. *[1]Pennsylvania State University, University Park, PA; and [2]Indigo Biosciences Inc, State College, PA.*

Drug-nutrient interactions are defined as physical, chemical or physiologic relationships between a drug and a nutrient. This association can result in altered absorption, distribution, metabolism, function, catabolism and excretion of either the drug or the nutrient upon co-administration or -exposure. Drug metabolism enzymes (DMEs) are transcriptionally controlled by xenobiotic-sensing nuclear receptors and transcription factors including pregnane-X-receptor (PXR), constitutive androstane receptor (CAR2 and 3), farnesoid-x-receptor (FXR), vitamin-D-receptor (VDR), arylhydrocarbon receptor (AhR) and Nuclear factor erythroid 2-related factor 2 (NRF2). In addition to many drugs and man-made chemicals, these proteins have naturally-occurring bioactive molecules, such as plant-based polyphenols, that act are modulators of their activity. Thus, nuclear and xenobiotic receptors are important mediators of drug-nutrient interaction by affecting the expression and hence activity of DMEs. We developed a work-flow to examine the potential of botanical extracts to cause drug-nutrient interaction through modulation of DME transcription, in a rapid and efficient manner. Botanical extracts are first examined in a mixture of optimized cell-based reporter assays, called the Drug-Nutrient Interaction (DNI) panel, consisting of assays for PXR, CAR2, CAR3, FXR, VDR, AhR and Nrf2. Any extract that results in a significant increase in reporter gene activity in the DNI panel is subsequently examined for relative contribution of each member of the panel to determine mechanism of action. The alteration of transcript levels for DMEs are examined upon treatment of the human hepatocyte cell-line upcyte. Several extracts used as dietary supplements increased activity in the DNI panel, most commonly through affecting AhR, PXR or Nrf2. Upon treatment of upcyte cells with these extracts, several clinically-relevant cytochrome P450s mRNA levels were modulated. Thus, this approach is a simple, mechanism-based way to examine the potential of botanical extracts and dietary supplements to cause drug-nutrient interactions.

2297 The Effect of Betulinic Acid on eNOS Expression via ERK5/HDAC5-Mediated KLF2 Pathway in Human Endothelial Cells

J. Park, G. Lee, T. Pham, and H. Jeong. *Chungnam National University, Daejeon, Korea, Republic of.*

Betulinic acid (BA) is a pentacyclic triterpene of the lupine-type that attenuates vascular diseases and atherosclerosis, but the mechanism by which it stimulates endothelial nitric oxide synthase (eNOS) is unclear. In previous studies, we demonstrated that beneficial cardiovascular effects such as increased NO production through enhancement of eNOS activity for this compound. Krüppel-like factors (KLFs) are a subclass of the zinc finger family of DNA-binding transcription factors, and are expressed in endothelial cells (ECs). Fluid shear stress induces KLF2 expression, which in turn regulates many flow-responsive genes, including endothelial eNOS. Furthermore, KLF2 and eNOS were found to regulate leukocyte adhesion to the endothelium by down-regulating expression of adhesion molecules that recruit leukocytes. Therefore, KLF2 and eNOS serve as genes that are important in the integration of multiple endothelial functions. The aim of this study is to investigate the molecular mechanisms of eNOS transcriptional activation by BA. In human EA.hy926 endothelial cells, BA increased the expression of eNOS and Krüppel-like Factor 2 (KLF2), which is a transcription factor for eNOS. In addition, BA induced both signaling pathways of CaMKIIα/AMPK/HDAC5 and ERK5/MEF2, which are involved in KLF2 expression and its transcriptional activity. Furthermore, treatment with a selective CaMKIIα inhibitor KN-62, a selective AMPK inhibitor Compound C and a selective inhibitor of ERK5 XMD8-92 suppressed BA-induced eNOS and KLF2 expression. Taken together, these results indicate that BA increase eNOS and KLF2 expression via the CaMKIIα/AMPK/HDAC5 and ERK5/MEF2 pathways. These findings provide further insight into the eNOS signaling pathways involved in the anti-atherosclerosis effects of BA.

2298 The Analgesic, Anti-Inflammatory, and Antipyretic Activities of the Bulb Extract of *Crinum jagus* (Amaryllidaceae)

I. A. Asadu, J. O. Ode, F. C. Nwinyi, J. N. Omeje, and M. M. Onakpa. *University of Abuja, Abuja, Nigeria.*

Pain, inflammation and sometimes fever are experienced in diverse pathologies and disease syndromes. Most of the medications used for treating these clinical entities including opioids, steroidal and non-steroidal anti-inflammatory agents do not only elicit adverse drug events due to toxicity but they are also expensive and not readily available especially in the rural settings of developing countries. Plants are known sources of bioactive compounds; there is indication to evaluate *Crinum jagus* bulb for highly acclaimed folkloric analgesic, anti-inflammatory and antipyretic effects. The extract was prepared by cold maceration in 80% methanol and concentrated in a vacuum rotary evaporator. Oral acute toxicity studies showed that methanol extract of *Crinum jagus* bulb (MECJB) was safe at 5000 mg/kg, hence did not cause mortality of experimental mice. The extract demonstrated a dose dependent inhibition of formalin-induced pain sensitivity in mice at 100, 200 and 400 mg/kg respectively. The lower test doses (100 and 200 mg/kg) of the extract exhibited a comparable anti-inflammatory effect to 50 mg/kg aspirin at 120 and 180 min in egg albumin-induced rat pedal edema. MECJB (100 mg/kg) exerted an almost equal potency with paracetamol (50 mg/kg) in suppressing yeast-induced hyperthermia. The extract reduced the mice rectal temperature by 79.5% relative to 83% with paracetamol. Two fractions (F_1 and F_2) with Rf values of 0.5 and 0.68 in hexane-ethyl acetate-chloroform (3:2:1) solvent system appeared to be the major analgesic components of the extract with ability to inhibit 90.2% and 80.9% acetic acid-induced pain sensitivity in mice respectively. Both fractions (F_1 and F_2) from the extract proved to have increased analgesic potency (85.8% pain inhibition) compared to piroxicam (50 mg/kg). *Crinum jagus* bulb could be a source for isolation of active compounds against pain, inflammation and fever.

2299 Effects of a 28-Day Oral Exposure to the Dietary Supplements Nattokinase and Lumbrokinase and of their Combined Exposure with Aspirin in Sprague Dawley Rats

L. Camacho[1], C. S. Silva[1], M. M. Vanlandingham[1], R. E. Patton[2], G. R. Olson[2], R. P. Felton[1], S. A. Ferguson[1], C. D. Law[1], J. F. Bowyer[1], S. Swift[3], A. Abdel-Rahman[3], and S. C. Fitzpatrick[3]. *[1]US FDA/NCTR, Jefferson, AR; [2]TPA Inc., Jefferson, AR; and [3]US FDA/CFSAN, College Park, MD.*

The dietary supplements nattokinase (produced by *Bacillus* subtilis var. *natto*) and lumbrokinase (powdered *Lumbricus rubellus* or *Eisenia fetida* earthworms) are promoted as beneficial for cardiovascular and circulation health. Both compounds have fibrinolytic activity and have been reported to degrade blood clots both *in vitro* and *in vivo*. We assessed whether an oral exposure to these compounds leads to an increased risk of bleeding, either when administered alone or in combination with aspirin. Adult male and female Sprague-Dawley rats were dosed orally for 28 consecutive days by gavage with the vehicle or 1,000 mg/kg body weight (bw)/day of nattokinase or lumbrokinase. Additional animals were exposed to these compounds in combination with aspirin (10 or 100 mg/kg bw/day). No treatment-related changes were observed in body weight, grip strength or motor coordination behavior assessments, bleeding time, or clinical pathology. As expected, both doses of aspirin inhibited the arachidonic acid-induced platelet aggregation. This effect was observed also when aspirin was co-administered with nattokinase or lumbrokinase, with the exception of the low aspirin plus lumbrokinase combination group, in which the platelet aggregation was similar to that in the vehicle group. Statistically significant effects were observed also in males treated with the high dose of aspirin for a few parameters measured by thromboelastography. The magnitude of these effects was more pronounced in the high aspirin plus nattokinase combination group; however, the main driver of the effect was aspirin. The only treatment-related histopathological lesions were an increase in the incidence of mucosal erosion and regenerative epithelial cell hyperplasia in the glandular stomach of the high aspirin groups, individually or in combination with lumbrokinase or nattokinase. The results suggest a lack of significant toxicity of nattokinase and lumbrokinase upon oral exposure. *This work was sponsored under an interagency agreement between the FDA/NCTR and the NIEHS/NTP (FDA IAG # 224-12-0003/NIEHS IAG # AES12013).*

2300 CBD Particle Size Dynamics: A Characterization of Cannabidiol E-liquids

M. Katsigeorgis[1,2], J. Adragna[1], and T. Gordon[1]. *[1]NYU School of Medicine, New York, NY; and [2]New York University, New York, NY.*

Despite the widespread use of electronic cigarettes and e-cigarette alternatives, knowledge of possible acute and long term health effects remain limited. This is particularly true in regards to a popular vape alternative, cannibidiol, or CBD. Several studies have characterized nicotine based e-liquids, yet to our knowledge no data have been published characterizing e-cigarette alternatives such as CBD. As e-liquids are transformed in the process of aerosolization, and subsequently inhalation, there is a need to characterize the size and composition of particles in these products. Particle size characterization can be a useful predictor to determine where CBD aerosols deposit and potentially react within the respiratory system. In this study, particle size characterizations were obtained and analyzed for 5 different aerosolized CBD e-liquids using a 7 stage In-Tox cascade impactor. CBD e-liquids were chosen based on ingredient list in order to give a good representation of products currently available on the market. Among products chosen were a high VG/PG blend, a pure CBD distillate, an MCT oil blend, a CBD and VG/PG blend, and a JUUL competitor blend. Products were aerosolized using a 3 port Electronic Cigarette Aerosolization Generator (ECAG). Our study found that particle size of aerosolized CBD vape liquids differed significantly from product to product. Of note, 60% of the mass for aerosolized liquid in the high VG/PG blend was over 2.85 µm, while pure CBD distillate showed over 90% of the mass to be less than 1.72 µm. CBD concentrations in the e-liquid and the airborne aerosols were also evaluated and differed by CBD product type. These results show that aerosol deposition may vary between products, and further analysis is needed to determine chemical compositions of unregulated CBD e-liquids. Thus, the observed product-dependent variability in exposure parameters must be taken into account in animal and *in vitro* assessments of the toxicity of CBD products.

2301 Virgin Coconut Oil Mitigates Oxidative Stress Induced by Sodium Fluoride *In Vitro* and *In Vivo*

S. P. Illam[1], A. Narayanankutty[1], S. P. Kandiyil[1], R. M. Uppu[2], and A. C. Raghavamenon[1]. *[1]Amala Cancer Research Center, Amala Nagar, India; and [2]Southern University and A&M College, Baton Rouge, LA.*

Sodium fluoride is a well-known environmental pollutant with pro-oxidant potential. Fluorosis due to fluoride intoxication through drinking water is a serious health concern globally. The fluoride-induced oxidative stress model in rodents has been widely used in pre-clinical experiments aimed at evaluating the antioxidant potential of natural products and pharmaceutical formulations both *in vitro* and *in vivo*. Virgin coconut oil (VCO) extracted from coconut kernel without subjecting to any mechanical means is an emerging functional food with reported pharmacological properties and health benefits. Herein VCO, its polyphenolic (VCO-PF) and VCO-PF minus Oil fractions (VCO-OF) were individually tested against the fluoride-exposed normal intestinal cells (IEC-6) as well as in mice to address their contribution in the documented antioxidant potential. Pre-treatment of VCO-PF (40 µg/mL) was found to be effective in bringing down the fluoride-induced cell death when compared to VCO (100 µg/mL) and VCO-OF fraction (60 µg/mL) as analyzed by the tetrazoliun (MTT) reduction assay. Further, sodium fluoride (3 mM) exposure increased the intracellular ROS in IEC-6 cells as measured by the uptake and intracellular hydrolysis of 2′,7′-dichlorodihydrofluorescin diacetate (H_2DCFDA) and subsequent oxidation of the product H_2DCF to DCF (collectively referred to as the DCF fluorescence method). VCO-PF significantly reduced the fluoride-induced ROS generation assessed based on the DCF fluorescence. VCO-PF, however, did not alter the ROS levels in normal cells, indicating its specific action towards the fluoride ions in the cellular milieu. In mice intoxicated with sodium fluoride in drinking water, oral administration of VCO (2 ml/Kg bw) as such reversed the drop in the hepatic catalase, glutathione-s-transferase, glutathione reductase and superoxide dismutase activities and maintained redox status to near normal levels. Concomitantly, hepatic lipid peroxidative changes as inferred by the thiobarburic acid-reactive substances were minimal in these animals. On the other hand, VCO-PF and VCO-OF fractions were found to be less effective in lowering the sodium fluoride induced increases in the hepatic oxidative stress markers. It is thus reasoned that oil components in VCO complement the natural antioxidant components for their better bioavailability.

2302 The Acute Toxicity of Water Hemlock (*Cicuta douglasii)* in a Goat Model

K. Welch, C. Stonecipher, S. Lee, and D. Cook. *USDA-ARS Poisonous Plant Research, Logan, UT.*

Water hemlock (*Cicuta douglasii*) is one of the most toxic plants in North America. It has been reported to cause numerous poisonings in livestock species, as well as humans. Humans eat water hemlock because they mistake the tuber of water hemlock to be wild carrots or wild parsnips. Clinical signs in humans poisoned by water hemlock include nausea, sweating, salivation, vomiting, severe seizures and death. The toxins in water hemlock are C_{17} polyacetylenes, with cicutoxin being the most studied. The proposed mechanism of action of these toxins is due to their action as noncompetitive gamma aminobutyric acid ($GABA_A$) receptor antagonists in the central nervous system. Little information is known regarding the amount of tuber required for death to occur. Therefore, the objective of this study was to determine a lethal dose of water hemlock in a goat model. Tubers and above ground parts were dosed separately to goats via oral gavage of freeze-dried ground plant material. All goats dosed with tubers at 2.0, 0.5 and 0.25 g/kg developed severe seizures and were dead/euthanized by 30-120 min after dosing, with a clear dose-dependent response as to the severity and time of onset of the seizures. None of the goats dosed with tubers at 0.1 g/kg developed any clinical signs of poisoning. Similarly, none of the goats dosed with above ground parts of the plant at 2.0 g/kg showed any clinical signs. When goats were dosed with above ground parts at 10.0 g/kg, one goat developed seizures 2 hours post dosing and was euthanized. Two other goats showed minor signs of poisoning, while the fourth goat exhibited no adverse effects. The results from this study confirm anecdotal observations that the above ground parts of water hemlock are much less toxic than the tubers. The results from this study indicate that cicutoxin is the most toxic of the C_{17} polyactylenes, as the concentration of cicutoxin is much greater in the tubers compared to the above ground parts of the plant. These results also suggest that the NOEL for tubers in goats is 0.1 g/kg. This would correspond to 1-2 small fresh tubers.

2303 The Antimycobacterial, Cytotoxicity, and Selectivity Index of Some Menispermaceae Species

R. T. Akande[1,2], I. M. Famuyide[1], S. Nkadimeng[1], A. Aro[3], T. Hlokwe[4], and L. McGaw[1]. *[1]University of Pretoria, Pretoria, Gauteng, South Africa; [2]Nigeria Atomic Energy Commission, Abuja, Nigeria; [3]University of South Africa, Florida, South Africa; and [4]Agricultural Research Council - Onderstepoort Veterinary Institute, Pretoria, Gauteng, South Africa.*

Tuberculosis is a disease of worldwide occurrence that affects millions of people annually. One of the top 10 causes of death and the leading cause from a single infectious agent. Resistance is developing against current antituberculosis drugs, which also have toxicity concerns. Some plants from the Menispermaceae family have been used traditionally to treat tuberculosis and cough related symptoms. In this study, the antimycobacterial effect of *Cissampelos owariensis*, *Cissampelos mucronata* and *Tinospora fragosa* from the Menispermaceae family were investigated. Acetone, methanol:water (4:1), hot water and dichloromethane:methanol (1:1) extracts of *Cissampelos owariensis* whole plant, *Cissampelos mucronata* leaves, and stem, *Tinospora fragosa* aerial part were tested against non-pathogenic and pathogenic mycobacterial strains (*M. smegmatis*, *M. fortuitum*, *M. aurum,* and *M. bovis*) using a two-fold serial microdilution assay and thiazolyl blue tetrazolium bromide (MTT) as the growth indicator. Cytotoxicity of the active extracts was determined using a tetrazolium based colorimetric assay against Vero monkey kidney cells. The selectivity index of the active extracts was also evaluated. The acetone extracts were most active with minimum inhibitory concentration (MIC) values between 30 - 940 µg/ml. *Cissampelos mucronata* (leaves and stem) and *Cissampelos owariensis* were toxic to Vero cells with LC50 values of 20, 30, 40 µg/ml respectively while *Tinospora fragosa* was safer with LC50 of 3180 µg/ml. *Tinospora fragosa* also had the highest selectivity index of 39.75. Further studies are on-going on the isolation of the bioactive compounds of the extracts.

2304 Development of a Method to Survey Hemp-Derived Ingredients in Cosmetic Products

Z. Wang[1], S. Pourzal[1], C. Avonto[2], S. Khan[2], A. G. Chittiboyina[2], I. Khan[2], L. Katz[1], and N. Sadrieh[1]. *[1]US FDA, College Park, MD; and [2]University of Mississippi, Oxford, MS.*

As a result of the Agriculture Improvement Act of 2018 (the 2018 Farm Bill), which removed hemp from the Controlled Substances Act, the FDA observed an increase in the number of cosmetic products being marketed in the United States containing hemp-derived ingredients, including cannabidiol (CBD). In order to better understand the presence of these ingredients in cosmetic products, we initiated a project to develop an assay which would allow a survey of marketed products. We selected the products to be surveyed from a publicly available database (Mintel Global New Products Database or GNPD). Our search of the GNDP between 2017 to the present showed that, in addition to cosmetic products marketed in the United States, there appears to be an increase in cosmetic products claiming to contain hemp-derived ingredients internationally. The overall objective of this project was to develop a robust analytical method to assess the quality and quantity of hemp-derived ingredients used in marketed hemp-containing cosmetics. A total of 69 hemp and/or CBD containing cosmetic products in the GNPD were selected based on product labels stating what they contained. The presence of CBD, Δ9-tetrahydrocannabinol (Δ9-THC), and eight other marker cannabinoids found in *Cannabis sativa* were determined using a newly developed LC/MS method. Twenty-four out of 69 (34.8%) products were found to contain CBD. Of these, 19 products contained only CBD; whereas five also contained THC or THC plus other cannabinoids. All CBD positive products except for one had label information related to CBD, hemp extract, *Cannabis sativa* cell culture extract, phytocannabinoids, hemp or industrial hemp. Hemp seeds do not naturally contain significant amounts of THC or CBD. However, one product that claims to contain *Cannabis sativa* seed oil was also positive for CBD and THC. The remaining 45 (65.2%) cosmetic products did not contain CBD or any other cannabinoids evaluated in the assay. The products that tested negative for cannabinoids all claimed to contain *Cannabis sativa* seed oil (34/45) or hemp oil (9/45) in their list of ingredients.

2305 Creating a Literature Database for Cannabidiol (CBD): Systematic Evidence Mapping

R. G. Henderson[1], A. Franzen[2], K. Franke[3], L. Payne[3], D. Schmitt[4], and D. Wikoff[3]. *[1]ToxStrategies Inc., Wilmington, NC; [2]ToxStrategies Inc., Monroe, LA; [3]ToxStrategies Inc., Asheville, NC; and [4]ToxStrategies Inc., Naperville, IL.*

As part of the US FDA's evaluation of potential regulatory frameworks for cannabidiol (CBD) and other cannabis-derived products, the agency has consistently raised concerns about the limited scientific information on CBD and need for further study. To assist in identifying knowledge gaps and inform future decision making, systematic mapping of the safety-related literature for CBD was performed. The systematic evidence map approach uses a structured process to describe the state of knowledge for a topic and provides a comprehensive synthesis of available data that can be queried for specific information. The systematic map for CBD was prepared using evidence-based methods, following an *a priori* protocol and the PECO (population, exposure, comparator, outcome) approach to develop research objectives. A broad and transparent systematic literature search was conducted in PubMed and Embase. Titles and abstracts were assessed and categorized in DistillerSR, and evidence tables and other visualizations prepared. The literature search yielded a total of >3,100 unique returns; of these, >2,200 articles (most published since 2010) were deemed relevant and included in the systemic map. Studies evaluating the beneficial properties and mechanistic pathways of CBD accounted for ~40% and ~20%, respectively. Regarding safety, the frequency of endpoints of interest assessed was as follows: pharmacokinetics > drug interactions > developmental and reproductive toxicity (DART) = general toxicity > immunomuodulatory effects > mutagenicity/genotoxicity = hepatotoxicity. Additional categorical information was assessed, including test material, test system, route of exposure, and adverse/beneficial findings. For example, studies reporting DART outcomes were conducted primarily in laboratory animals; few were conducted *in vitro* or in humans. While many studies reported adverse reproductive effects associated with CBD, the lack of a published guideline compliant reproductive toxicity study was identified as a data gap. This assessment provides a reliable summary of the state of the evidence for evaluating health risks following exposure to CBD. The mapping results will help identify knowledge gaps and future research needs, as well as support future systematic reviews and other safety assessments of human exposure to CBD.

2306 Protective Effect of Extract of *Arrabidaea chica* Verlot (Bignoniaceae) on SH-SY5Y Cells Treated with Zearalenone Metabolites Mycotoxin

A. Juan Garcia[1], N. Alvarez-Ortega[2], F. Agahi[1], C. Juan Garcia[1], K. Caballero-Gallardo[3], and J. Olivero-Verbel[2]. *[1]Universitat de València, Valencia, Spain; [2]Universidad de Cartagena, Cartagena, Colombia; and [3]Universidad de Cartagena, Turbaco, Colombia.*

Arrabidaea chica is a medicinal plant with numerous health benefits such as wound healing, immune system stimulation, and antioxidant properties, among others. Zearalenone metabolites (α-ZOL and β-ZOL) are mycotoxins with estrogenic capacity produced by some species of *Fusarium* that occur as contaminants, mainly in cereals. The aim of this study was to evaluate the protective effect of the ethanolic extract of *A. chica* leaves against the cytotoxicity of α-ZOL and β-ZOL in an undifferentiated neuroblastoma cell line, SH-SY5Y. Cells were cultured in 96-well plates for 24 h followed by 24 and 48 h treatment with the extract (4-1000 ppm). The cytotoxicity of β-ZOL and α-ZOL was measured in 9 concentrations in a range from 2 to 100 µM. The cytoprotective effect was evaluated using a mixture of concentrations below the IC50 of β-ZOL and α-ZOL, with concentrations of 16 and 32 ppm of the plant extract, respectively. Cell viability was evaluated by the MTT assay. Cells treated with the plant extract had viability greater than 50% at 63 ppm in the 24 and 48 h tests. Cells treated with α-ZOL remained viable during the first 24 h. However, at 48 h concentrations of 25, 50 and 100 µM of α-ZOL had viability below 50%. In addition, β-ZOL at 24 h showed cytotoxicity below 50% only at 100 µM while at 48 h viability decreased below 25% for 12.5, 25, 50 and 100 µM. A Mixture of *A. chica* extract at 32 ppm and α-ZOL showed a significant increase in cell viability at 25 and 50 µM ($p<0.05$). Mixtures of the plant extract and β-ZOL improve significantly cell viability at 48 h for 12.5, 25, 50 and 100 µM of β-ZOL ($p<0.001$). In short, extract from this plant isolated from the flora of the Colombian Caribbean is promising to counteract the toxic effects of mycotoxins that affect cereals. *Colciencias-UniCartagena (Grant FP 44842-212-2018, Scholarships 567-2012 and 727-2015), and Spanish Ministry of Education and Competitiveness (AGL2016-77610-R).*

2307 Evaluation of Levels of Select Toxic Metals in Commonly Used Herbal Medicines in Benin City, South-South Nigeria

H. B. Osadolor[1], O. G. Igharo[2], J. O. Osakue[2], J. O. Osakue[2], and E. A. Onuyoh-Adaitire[2]. *[1]University of Benin and Igbinedion University, Benin City, Nigeria; and [2]University of Benin, Benin City, Nigeria.*

Herbal medicine has been gaining growing attention as medicinal plants are now the major remedy to diseases in some places, especially in Africa. Some herbal preparations are made without standard manufacturing and safety standards, a practice that makes the products susceptible to contaminants which may include toxic metals. Even at low concentrations or levels of exposure, toxic metals have also been reported to pose health risks to man. The study aimed to evaluate the levels of toxic metals in herbal medicines commonly prepared and used in Benin City, Edo state, Nigeria. Herbal medicines (n=8) were purchased from on-the-street vendors and evaluated for levels of five toxic metals (lead, nickel, mercury, cadmium and arsenic). Analysis of toxic metals was carried out in the analytical services laboratory of the International Institute of Tropical Agriculture (IITA) Ibadan using Inductively Coupled Plasma Mass Spectrometry. The results obtained should that lead (mg/L) respectively detected in the eight sampled herbal preparations were 0.025, 0.022, 0.092, 0.088, 0.052, 0.074, 0.051 and 0.092; while nickel levels (mg/L) were 0.075, 0.066, 0.277, 0.265, 0.153, 0.158, 0.029, and 0.052; and levels of cadmium in mg/L detected were 0.014, 0.013, 0.052, 0.50, 0.029, 0.029, 0.153 and 0.277. In addition, Levels of mercury (mg/L) observed in the respective herbal samples were 0.035, 0.031, 0.129, 0.124, 0.071, 0.072, 0.071 and 0.129; and arsenic (mg/L) levels as observed were 0.002, 0.002, 0.007, 0.006, 0.004, 0.004, 0.004 and 0.007. Data obtained from this study indicate that the herbal preparations studied contain detectable amounts of toxic metals and by implication, the frequent and unorthodox use of these herbal preparations may increase the body burden of these metals which have been reported to be toxic at any level of exposure.

2309 Paraquat Inhalation, a Translational Route of Exposure, Results in Sex-Specific Alterations in Locomotor and Olfactory Behavior

T. Anderson, M. Sobolewski, E. Marvin, K. Conrad, R. Gelein, G. Oberdorster, and D. Cory-Slechta. *University of Rochester, Rochester, NY.*

Many widely used pesticides, including paraquat (PQ), exhibit neurotoxic effects. Historically, oral, dermal or injection (s.c., i.p.) exposure to pesticides have been used to evaluate toxicity. However, increasing evidence suggests that pesticide inhalation - the realistic mode of human exposure - is an emerging air pollution concern. Epidemiological research indicates that agricultural environments are associated with Parkinson's disease (PD), a phenotypically heterogeneous disease that is hallmarked by bradykinesia as a result of loss of nigrostriatal dopaminergic neurons. Such motor symptoms are preceded by a myriad of prodromal symptoms including anxiety, loss of balance and hyposmia, which may serve as outcome measures for the early stages of PD. Previous research indicates that exposure to PQ via injection results in PQ accumulation in brain, dopaminergic cell loss, motor function alterations, and olfactory deficits in rodent models. Here, we utilized an environmentally-relevant whole-body inhalation paradigm to determine if similar PQ accumulation and neurobehavioral effects consistent with the trajectory of PD were observed. We exposed juvenile (PND40) male and female C57bl/6J mice to either filtered air or PQ aerosols generated using an ultrasonic nebulizer (200 µg/L for 4 hours per day) for 1 day only or for 7 days. An additional group of adult mice (PND120) was exposed to same concentration for 20 days. In all exposures, whole body inhalation resulted in PQ accumulation in olfactory bulb and cerebellum of exposed animals as determined by Q Exactive Plus mass spectrometry, but we did not observe any adverse pulmonary effects or weight loss in exposed mice. Females exposed to PQ for 7 days made significantly more errors in an odor discrimination test, which suggests that repeated exposure to inhaled PQ may adversely affect olfaction. Adult males exposed to PQ for 20 days exhibited significantly lower ambulatory episodes and stereotypic counts, suggesting prolonged PQ inhalation exposure results in locomotor deficits. These data indicate that low level whole body inhalation resulted in PQ accumulation in the brain and alterations to locomotor and olfactory behavior. These behavioral effects are sex-specific, and future research is needed to identify mechanisms of sex-differentiated toxicity. *Supported by ES001247 and ES025541.*

2310 An Inter-Species Comparison of Renal Transport of MCPA *In Vitro*

A. Gledhill[1], R. Bowen[1], C. Grant[2], C. Brown[3], G. Chung[3], A. Bond[4], and H. Berry[5]. *[1]ERM Regulatory Services Ltd., Harrogate, United Kingdom; [2]Regulatory Science Associates, Inverkip, United Kingdom; [3]NewCells Biotech Limited, Newcastle, United Kingdom; [4]ALBReg Services Ltd., Chelmsford, United Kingdom; and [5]Nufarm UK Ltd., Bradford, United Kingdom.* Sponsor: C. Brown, International Society for the Study of Xenobiotics

4-Chloro-2-methylphenoxyacetic acid (MCPA) is a phenoxyacetic acid herbicide, a class of chemicals that shows species differences in toxicity, with dog being particularly sensitive compared to other species. Toxicokinetic measurements show prolonged systemic exposure in dog compared to other species. The widely accepted proposed mode of action is that dog has an intrinsically lower capacity to secrete some phenoxyacetic acids *via* the kidney, resulting in the observed higher and more prolonged systemic exposure. The aim of this study was to test this hypothesis using an established *in vitro* proximal tubule cell model, to compare the movement of [^{14}C]MCPA across kidney cell membranes in rat, dog and human. Primary dog, rat and human proximal tubule cells, cultured to form monolayers, were used to investigate the renal handling of MCPA in these species. The activity of the organic anion transporters OAT1 and OAT3 in the model was determined using the standard substrate, para-aminohippurate (PAH). Probenecid, a specific OAT1/3 inhibitor, was co-administered with MCPA or PAH to confirm the involvement of these transporter proteins. Secretory flux in all species was shown to be greater than absorptive flux, consistent with OAT1/3 transporters being a mechanism of excretion for MCPA. There were clear species differences in the renal transport of MCPA, with rat and human showing similar secretory flux, which was markedly lower in dog. Data from this assay therefore confirm that the secretory flux of MCPA is mediated by an organic anion transporter, with OAT1 and/or OAT3 identified as the predominant transporters, implying that MCPA has lower affinity for dog isoforms, than for rat and human. The data provides mechanistic evidence for the observed differences in renal handling of MCPA, demonstrating similarity between rats and humans, whilst highlighting the poorer excretory efficiency in dog. These findings explain the significantly slower clearance of MCPA measured in dog compared to rats and humans, and provide a mechanistic explanation for the greater sensitivity of dogs to MCPA toxicity, supporting the position that dog is not an appropriate species to be used for human risk assessment.

2311 High-Throughput Screening Data for the Conazoles Do Not Support a Human-Relevant Common Mechanism Group for Cumulative Risk Assessment

D. A. Dreier. *Syngenta Crop Protection, LLC, Greensboro, NC.*

Cumulative risk assessments (CRAs) require the establishment of a common mechanism group (CMG), which consist of a group of pesticides that share a common mechanism of toxicity. To this end, adverse outcome pathways (AOPs) can be used to examine whether a CMG exists in humans. The conazole fungicides have recently been considered for a CRA based on liver effects, but multiple lines of evidence indicate the known liver AOP for the conazoles is only operant in mice and rats, and not in humans. However, high-throughput screening data offer additional mechanistic information, and it is important to consider this information in the overall weight of evidence analysis. Thus, the primary objective of this work was to determine whether high-throughput screening data in ToxCast/Tox21 support the current AOP for the conazoles. ToxCast/Tox21 data for the conazoles were analyzed following published methods to: (1) Examine potential constitutive androstane receptor (CAR) bioactivity (i.e., molecular initiating event in AOP), (2) Explore other potential bioactivities, (3) Determine whether quantitative structure-activity relationships exist between specific conazole ToxPrint chemotypes and assay bioactivity. It was found that the conazoles were not active in ToxCast/Tox21 CAR assays (i.e., ATG_CAR_TRANS_up, TOX21_CAR_Agonist) after controlling for cytotoxicity and quality control flags. When additional ToxCast/Tox21 assays were considered, the conazoles had distinct bioactivity profiles, and there was more bioactivity in assays with rat targets than those with human targets. Finally, binary correlations (Phi coefficients) were calculated between conazole ToxPrints (i.e., ring:hetero_[5]_N_triazole_(1_2_4-), ring:hetero_[5]_N_triazole_(1_3_4-), ring:hetero_[5]_Z_1_2_4_1_3_4-Z) and ToxCast/Tox21 assays, and it was found that these ToxPrints were strongly associated with rat CYP inhibition, but not with human CYP inhibition. Thus, high-throughput screening data did not identify a human-relevant CMG for the conazoles, and therefore a CRA is not appropriate.

2312 Localization of Accumulation of Glyphosate Herbicide within the Body of *Drosophila melanogaster*, a Nontarget Animal

K. Herrera, B. Talyn, and E. Melchiorre. *California State University San Bernardino, San Bernardino, CA.*

The widespread use of glyphosate-containing herbicides like Roundup in food and crop production has raised questions about whether their presence in foods and the environment can negatively impact public health. Glyphosate-containing herbicides, designed to destroy agricultural weeds, are extremely toxic to living organisms at high concentrations. Although Roundup manufacturers claim the herbicide formulations are non-toxic, growing evidence indicates that animals and humans exposed to high concentrations suffer a variety of health consequences, including development issues, reduced fertility, and disease. Our preliminary data suggest that Roundup increases mortality, affects ovary size, and can accumulate to high concentrations in *Drosophila melanogaster.* This study aims to determine where glyphosate is accumulated within *Drosophila* to begin to explore its mechanism of action in the physiological systems of non-target organisms. In this study, we exposed *Drosophila melanogaster* to medium containing Roundup Super Concentrate with a glyphosate concentration of 10g/L to localize glyphosate accumulation within the organism. A total of 20 flies chronically exposed to the treatment for 7 days as adults were dissected to isolate their heads, thoraxes and abdomens. Separately, both ovaries or both testes were removed from 10 females and 10 males and tested for glyphosate accumulation. The samples were analyzed by HRI Labs by liquid chromatography-mass spectrometry to determine their glyphosate concentration. The ovary and testes samples contained the least amount of glyphosate, displaying concentrations of 614.2 µg/g and 211.6 µg/g. The highest amount of glyphosate was accumulated within the abdomen with a concentration of 4572.1 µg/g, followed by the thorax at 1577.5 µg/g and the head displayed a final glyphosate concentration of 1100.8 µg/g. That lower levels of glyphosate were accumulated in gonad samples suggests that the reproductive effects of glyphosate exposure are not a result of glyphosate affecting the reproductive organs, but rather an indirect mechanism. An overall high concentration of glyphosate within the abdomen may indicate undigested food remained within the digestive tract of the flies. Accumulation of glyphosate within the head may be linked to growth, developmental and reproductive effects as the neuroendocrine system in the brain regulates the production of hormones and other biological processes. Along with ongoing experiments, this sheds light on how glyphosate-containing herbicides affect the health of those exposed to these herbicides throughout their lifetime.

2313 Safety Assessment Case Study of an Herbicide Groundwater Metabolite Using Realistic Exposure Route and Dose Setting Approach

Z. Liu, B. Sharma, and K. Bentley. *FMC Corporation, Newark, DE.*

Carfentrazone-ethyl is a protoporphyrinogen oxidase (PPO) inhibitor herbicide undergoing EU renewal. Carfentrazone-ethyl is not classified for acute, genotoxicity, reproductive/developmental toxicity or carcinogenicity. M9 is a soil metabolite which was not identified in the rat metabolism studies. The predicted potential exposure concentration in groundwater (PECgw) of M9 exceeded 0.75 µg/L in a couple EU scenarios with the highest PECgw of 0.885 µg/L. According to the Sanco/221/2000 groundwater metabolite guidance document (rev. 10, 2003), a non-relevance assessment is triggered including herbicidal activity, acute oral, genotoxicity, repeated dose toxicity studies and consumer risk assessment. The studies demonstrated that M9 is less than 50% herbicidally active compared with the parent; not acutely toxic (oral LD_{50}>5000 mg/kg); not genotoxic in a battery of *in vitro* and *in vivo* genotoxicity studies. In the 28-day oral toxicity study in rats, M9 was administered *ad libitum* via drinking water (a more realistic method of exposure for consumers) at concentrations of 1, 10, and 100 ppm (near the M9 solubility limit). The NOAEL was determined to be 100 ppm, equivalent to 10 and 13 mg/kg/day for males and females, respectively. An acceptable daily intake (ADI) of 0.01 mg/kg/day was derived using this NOAEL of 10 mg/kg/day and a safety factor of 1000x. A consumer risk assessment showed that maximum theoretical consumption of M9 via drinking water contributed 0.30%, 0.89%, and 1.32% of the ADI for adults, toddlers and bottle-fed infants, respectively. Based on a conservative 10% allocation of the total daily intake to drinking water, consumption of M9 via drinking water will not represent an unacceptable risk to consumers. This case study exemplifies a suitable safety assessment approach for ground water metabolites based on toxicology studies that use a realistic human exposure approach (i.e., drinking water tested up to the limit of solubility in contrast to oral feeding of solid test materials at extremely high dose levels).

2314 Monitoring of Agricultural Workers Exposed to Cholinesterase-Inhibiting Pesticides

S. Hung, and O. Laribi. *Office of Environmental Health Hazard Assessment, Oakland, CA.*

The California Medical Supervision program is intended to protect workers who regularly mix, load, or apply Category I and II organophosphate (OP) and N-methyl carbamate (CB) pesticides. Exposure to OPs or CBs lower the level of cholinesterase (ChE), a critical enzyme that regulates neurotransmitter signaling. The Program uses ChE levels in blood as a biomarker to detect excessive exposure to these pesticides prior to the onset of illness. Since 2011, the six clinical laboratories performing ChE analysis under this Program have been required to report test results electronically to the California Department of Pesticide Regulation and the California Office of Environmental Health Hazard Assessment (OEHHA), allowing for statewide evaluation of the Program. Analysis on data collected from 2011 through 2013 revealed that poor data quality and missing information significantly hampered data analysis. This led to regulatory changes, effective January 2017, requiring employers of workers subject to the Program's requirements to exclusively contract with medical supervisors (physicians) who are registered with OEHHA. In the last three years, 120 physicians have registered with OEHHA. Preliminary analysis of data from 2017 - 2018 found a total of 16,719 unique records, of which 12,739 (76.19 %) were reported by registered physicians. Overall, registered physicians were more likely to order 14-day baseline tests (44.64% vs. 12.00%) and follow-up with their patients over time (21.81% vs. 3.51%). All test results of significant ChE depression (<80% baseline) were from individuals followed by registered physicians (19 of 327 individuals with identifiable baseline estimates had at least one reported event of significant ChE depression), which may have been due to the higher frequency of follow-up tests conducted by registered physicians. In conclusion, we observed an improvement in data quality with the registration of physicians, which enhanced data analysis, helped to increase the accuracy of our Program evaluation, and most likely improved the effectiveness of the Program to protect pesticide handlers from over-exposure to OPs and CBs.

2315 Occupational Organophosphate Pesticides Exposure and Reproductive Effects in Women Farmers

M. Xotlanihua-Gervacio[1], E. Garcia-Montalvo[2], C. Trujillo-Carretero[2], M. Ramos-Cortés[2], M. Bulás-Mendoza[2], A. Hernández-Zavala[3], and O. Valenzuela[2]. *[1]Universidad Veracruzana, Xalapa, Mexico; [2]Universidad Veracruzana, Orizaba, Mexico; and [3]Instituto Politécnico Nacional, Mexico City, Mexico.*

Since chayote sowing is perennial, in Veracruz (as in the whole country), many people are chronically exposed to pesticides. Most pesticides act as endocrine disruptors, thus compromising reproductive function in humans. Luteinizing hormone (LH) is a gonadotropic hormone, responsible for regulating reproductive function in mammals, as well as exerting primary actions on gonads and its blood concentration is considered an infertility marker. The aim of the study was to determine the relationship between serum luteinizing hormone and occupational exposure to organophosphate pesticides in Veracruz farmers. This case-control study was conducted on farmers and residents of Cuautlapan, Veracruz, Mexico. Information related to pesticides exposure and clinical symptoms were collected from a questionnaire. Serum LH levels were determined by the ELISA method. All analyses were conducted in the statistical package STATA v.15.0., using a significance of $p<0.05$ value. In total of 64 subjects were included in the study, with an average age of 34 years. 51.5% of the population was exposed to pesticides (14 women and 19 men), mainly to chlorpyrifos (25.6%) and methamidophos (16.3%), of which 33% do not use protective equipment. Headaches, blurred vision, nausea, insomnia and pruritus were the most prevalent symptoms of intoxication. In woman LH levels were found outside the reference values according ovulation phase and menopause ($p<0.05$) in exposed group. Occupationally exposed men had higher levels of LH compared to those not exposed ($p<0.05$). It is concluded that chronic exposure to organophosphorus pesticides affects the fertility of men and women. However, women have more health problems due because luteinizing hormone modulates their reproductive phase and menopause.

2316 Residential Proximity to Agricultural Crops and Acetylcholinesterase Activity, a Pesticide Exposure Biomarker, Assessed from Childhood through Adolescence

J. R. Suarez-Lopez[1], N. Nadhim[2], H. Checkoway[1], G. Kayser[1], and J. Suarez-Torres[3]. *[1]University of California San Diego, La Jolla, CA; [2]Loma Linda University, Loma Linda, CA; and [3]Fundación Cimas del Ecuador, Quito, Ecuador.* Sponsor: J. Martino

Off-target drift of pesticides from farms increases the risk of pesticide exposure of people living nearby. Commonly used insecticides in agriculture are cholinesterase inhibitors (i.e. organophosphates and carbamates), which inhibit the enzymatic activity of acetylcholinesterase (AChE). AChE is a known regulator of the neurotransmitter acetylcholine. In this study we characterized the associations between residential proximity to greenhouse agriculture where pesticides are used and AChE activity in children (lower values indicate greater cholinesterase inhibitor exposures). This study included 1145 observations from 3 exams (2008, Apr 2016 and Jul-Oct 2016) of 622 children aged 4-to-17 years living near agriculture in Ecuador (ESPINA study). AChE and hemoglobin were measured from fingerstick blood samples. Geographic positioning of greenhouses (primarily floricultural) and homes were obtained using GPS receivers and satellite imagery. We calculated the distances between homes and the nearest greenhouse edge and areas of greenhouse crops within various buffer zones around homes ranging from 150m to 500m. Repeated-measures regression models adjusted for hemoglobin and demographic, socio-economic and anthropometric variables. The pooled mean (SD) of AChE activity was 3.58 U/mL (0.60). The median (25^{th}-75^{th} %tile) of residential distance to homes was 334 m (123, 648) and of crop areas within 500 m of homes was 18,482 m^2 (7115, 61841, among those with non-zero values). Areas of crops near homes was negatively related to AChE activity. This association was strongest among children living within 150m of crops (AChE difference per 10,000 m^2 [95% CI] = -0.07 U/mL [-012, -0.01]), and weaker, but also significant, associations were observed among those living within 151-500m of crops. Overall, residential proximity to the nearest crop was not associated with AChE activity (AChE difference per 100m of *proximity*= 0.000 U/mL[-0.003, 0.005]); however, this association was significant among children who had at least 811m^2 (5^{th} percentile, N_{obs}=522) of crops within 300m of their homes (-0.051 U/mL [-0.098, -0.004]). Our findings suggest that residential proximity to greenhouse crops where pesticides are used, and greater areas of such crops near homes result in sufficient pesticide exposures to decrease AChE activity of children living within 500m (and especially 150m), despite the relative confinement of greenhouse agriculture. Added precautions to reduce the off-target drift of pesticides from crops, or more stringent requirements separating residential from agricultural zoning are recommended.

2317 Immune Effects of Carboxylesterase Inactivation in the Neonatal Murine Lung

B. N. Szafran, A. Borazjani, R. Carr, M. K. Ross, and B. L. Kaplan. *Mississippi State University, Starkville, MS.*

Carboxylesterases (Ces) are enzymes that metabolize xenobiotics and anti-inflammatory lipid mediators. Chlorpyrifos (CPF) is an organophosphate pesticide (OP) that inhibits Ces activity at doses that do not inhibit acetylcholinesterase, the canonical toxic mechanism of action. Our lab's recent data showed that chronic low-dose CPF inhibited lung Ces1c and Ces1d in neonatal mice. We hypothesized that pretreatment of neonatal mice with CPF would attenuate LPS-induced lung inflammation because of the diminished catabolism of anti-inflammatory lipids. Neonatal mice were treated with CPF (2.5 mg/kg, p.o.) or corn oil for 7 days from post-natal days 10 to 16, followed by LPS (1.25 mg/kg, i.p.) or saline. Tissues were harvested 6 hours after the LPS treatment. Lung *IL-6*, *TNF-α*, and *IL-1β* mRNA levels in response to LPS were unaltered by CPF exposure. CPF also did not alter the innate and adaptive immunophenotype of lung tissue in response to LPS. On the other hand, CPF decreased lung 2-arachidonoylglycerol (2-AG) levels independent of LPS treatment, but it did not alter the levels of other lipid mediators including prostaglandins. Contrary to our hypothesis, Ces inhibition by CPF did not modulate LPS-induced lung inflammation, and 2-AG levels were decreased rather than increased. These results suggest that Ces1c and 1d are bio-scavenging enzymes that have a protective role against CPF exposure in neonatal lung. *Supported by NIH R15 GM128206.*

2318 Effect of Calcium and Pyrethroids on Adipogenesis and Lipid Accumulation in Murine Adipocytes

V. G. Robinson, S. E. Cevik, and S. E. Fenton. *NIEHS, Research Triangle Park, NC.*

Pyrethroids are a chemical class of insecticides that are used by pest management professionals. They are structurally derived (manmade) from naturally occurring insecticides called Pyrethrins. Pyrethrins are a mix of six chemicals used to control mosquitoes, fleas, ants and, other pests. Two pyrethroids were indicated as possible obesogens in a blinded study of 70 chemicals in mouse 3T3-L1 cells, therefore an investigation of the several pyrethroids on the market and their two common metabolites was initiated. This study was developed to determine the mode of action(s) for pyrethroids in 3T3-L1 cells across a dose range and in two different calcium concentrations. In 96 well plates, 3T3-L1 cells were treated with two different concentrations (1.8mM and 10mM) of Calcium, three different concentrations (1μM, 5μM, and 10μM) of 10 separate pyrethroids, vehicle (0.05% DMSO) and rosiglitazone (1μM) as a positive control, in differentiation media, for 6 days in 96 well plates. On Day 6, the cells were fixed with 4% Paraformaldehyde and stained no more than 24 hours prior to ImageXpress® Micro (IXM) analysis with Nile Red and Hoechst 33342. The experiments were repeated in three biological replicates. Data were analyzed using linear mixed-effects models to account for multiple images obtained per well, and technical replicate wells within a plate. Biological replicates were defined as the same experimental conditions tested on a different multi-well plate on separate days. For each pyrethroid, cell count (to indicate cytotoxicity), number of adipocytes, and the mean lipid droplet area (MLDA) (μm^2) per adipocyte were evaluated using this mixed effect model approach. There was no significant decrease in cell count for Cypermethrin, Bifenthrin, Allethrin, or Tetramethrin, and no interaction with calcium for cell count. There was no change in number of adipocytes or MDLA per adipocyte for any concentration of Bifenthrin, Allethrin, or Tetramethrin, and no interaction by calcium concentration. However, there was a significant increase in number of adipocytes and MDLA per adipocyte after exposure to 10μM Cypermethrin. 10μM Cypermethrin increased the number of adipocytes by 9% and increased the MLDA per adipocyte by 17.5%. These data suggest that Cypermethrin had an effect on adipogenesis and lipid accumulation, regardless of calcium concentration.

2319 Assessment of Human Health Risks from Potential Exposure to the Pesticide Chlorthal-Dimethyl and Its Degradates in California Groundwater

K. Sutherland-Ashley, R. Woods, B. Eya, L. Lim, D. Ting, and L. Zeise. *Office of Environmental Health Hazard Assessment, Sacramento, CA.*

The Office of Environmental Health Hazard Assessment (OEHHA) conducted a risk assessment for the pesticide active ingredient chlorthal-dimethyl (DCPA; dimethyl tetrachloroterephthalate; dacthal) and its environmental degradates, monomethyl tetrachloro-terephthalic acid (MTP) and tetrachloroterephthalic acid (TPA). DCPA is a pre-emergent herbicide used for the control of annual grasses and certain broadleaved weeds. TPA and MTP were detected in multiple water wells in three California counties by the Department of Pesticide Regulation's (DPR) groundwater monitoring program. The highest detections were 159 ppb for TPA and 0.13 ppb for MTP. OEHHA reviewed the available toxicity database to (1) evaluate DCPA, MTP, and TPA for toxicity endpoints related to carcinogenicity, mutagenicity, teratogenicity, and neurotoxicity, (2) develop public health concentrations (PHCs) in the drinking water for DCPA and TPA, and (3) use the PHCs to determine the human health risks from potential exposures in the drinking water. PHC is the concentration of a chemical in drinking water that is not expected to pose a significant risk to human health when consumed over a lifetime. The toxicological database was complete for DCPA, limited for TPA, and insufficient for MTP. OEHHA determined that the two degradates are more water soluble with much lower toxicities than their parent compound. Thus, separate PHCs for DCPA and for TPA were derived. A PHC could not be calculated for MTP due to lack of data. The lowest PHC was 2 ppb for DCPA, based on hepatocellular adenomas and carcinomas in mice following chronic dietary exposure. The PHC for TPA was 2500 ppb, based on no observable adverse effects in a subchronic rat dietary study, soft stools and hematologic effects in a rat subchronic gavage study, and applicable uncertainty factors. Because MTP is an intermediate degradate of DCPA, the PHC for TPA was applied to the sum of the highest detected levels of TPA and MTP for the assessment. OEHHA determined that neither degradate is likely to cause adverse health effects if found in the groundwater at the levels detected, and consumed in drinking water over a lifetime. The highest detected levels of MTP and TPA were more than 15-fold lower than the calculated PHC, indicating an adequate margin of safety.

2320 Oral Exposure to Mancozeb Alters Serum and Feces Essential Metal Levels and Glutathione in Sprague Dawley Liver and Kidney

B. R. Kistinger, and D. Hardej. *St. John's University, Queens, NY.*

Mancozeb (MZ), a member of the ethylene bisdithiocarbamate (EBDC) class of fungicides, is widely used commercially. MZ is complexed to Mn and Zn. The presence of metals in MZ, as well as the transchelation ability of EBDCs, raises the concern that MZ exposure produces metal overload-induced oxidative stress. Nabam (NB; sodium salt of EBDC) or a mixture of $MnCl_2$ and $ZnCl_2$ (MnZn) treatments distinguish MZ effects mediated by the EBDC backbone or metals. Our previous work found that MZ and NB caused significant accumulation of Cu in kidney of treated rats, but MZ caused a significant decrease in Cu in the rat liver. In both liver and kidney, Mn levels were increased in MnZn and MZ treated rats, but NB treated rats had decreased Mn levels. The aim of the present study is to use inductively coupled plasma-optical emission spectroscopy (ICP-OES) to measure Mn, Zn, Cu, and Fe levels in serum, blood clot, urine, and fecal samples from MZ , NB, and MnZn treated rats, as well as assess oxidative stress parameters (TBARS and total glutathione) in rat liver and kidney due to altered metal levels. Sprague-Dawley rats were treated orally with MZ, NB, MnZn, or vehicle control (25% (v/v) PEG400 : H_2O) every day for 28 days. After the last dose, rats were individually housed and fasted overnight with water *ad libitum* in metabolism cages. Urine and feces were collected and stored until further use. Rats were anesthetized and blood was collected via cardiac puncture. Coagulated blood was centrifuged to separate serum from the blood clot, and each were stored until analysis. Organs were harvested and stored in liquid N_2 until biochemical analyses. In urine and blood clot samples, there were no significant differences in the levels of metals tested in the treatment groups. Serum iron levels were significantly higher in NB (22.20 ppm/g) treated rats than in PEG (18.12 ppm/g) or MnZn (17.69 ppm/g) groups. MnZn and MZ treated rats had higher fecal Mn (140.4 and 134.7 ppm/g) and Zn (13.74 and 15.26 ppm/g) levels compared to PEG (Mn: 51.04, Zn: 10.75 ppm/g), but only MZ treated rats had decreased fecal Fe levels (78.64 ppm/g) compared to PEG (133.4 ppm/g). For all treatments, liver and kidney indicated no significant differences in TBARS levels, but total glutathione levels for NB and MZ treated rats were increased compared to PEG rat liver and kidney. Results demonstrate metal alterations in all treatment groups and shift in antioxidant balance in liver and kidney of NB and MZ treated rats.

2321 Mancozeb Exposure Results in Apoptosis and Disruption of Mitochondrial Complex IV and V Activity in Transformed Human Colon Cells

A. Dhaneshwar, and D. Hardej. *St. John's University, Queens, NY.*

Ethylene bisdithiocarbamate pesticides (EBDC), such as Mancozeb (MZ), are mainly used in agriculture as fungicides on a variety of crops. Structurally, this class of pesticide has an ethylene bisdithiocarbamate organic backbone complexed to metal moieties. Mancozeb is complexed to the metals manganese and zinc. Common routes of Mancozeb exposure are ingestion of food containing pesticide residue and occupational exposure. Previous work in our laboratory has demonstrated that Mancozeb exposure to both transformed human colon cancer cells and non-transformed human colon cells causes increased lipid peroxidation, decreased ratio of reduced glutathione to glutathione disulfide, and increased caspase 3/7, 8, and 9 activities. It was determined that both the ethylene bisdithiocarbamate backbone and metal moieties contribute to the toxicity of Mancozeb (Hoffman and Hardej, 2012; Hoffman et al., 2016). This study investigated the effect of Mancozeb on the induction of apoptosis and mitochondrial activity of HT-29 colon cancer cells. Previous experiments have shown cytotoxicity, induction of both apoptosis and oncosis, and decreases in both Complex I and Complex II enzyme activities. Current experiments utilized kinetic assays to evaluate and compare the effect of Mancozeb on the activity of mitochondrial enzymes, Complex IV and Complex V. Cells were dosed for 24 hours with MZ concentrations of 60 µM, 100 µM, and 140 µM. Mitochondria were isolated using a commercially available kit. Complex IV enzyme showed a significant decrease in activity at 60 µM, 100 µM, and 140 µM Mancozeb. Activity of Complex V enzyme showed a significant decrease at 60 µM Mancozeb. Scanning electron micrographs of cells exposed to Mancozeb (60-160 µM) for 24 hours showed a disruption of the plasma membrane, particularly blebbing. The current data indicates that HT-29 colon cancer cells exposed to Mancozeb results in decreased activity of mitochondrial Complex IV and Complex V.

2322 Epigenetic Modification by Mancozeb in Astrocytes and PC12 Cells

J. Alejanzales[1], B. Galante[1], A. Kaplan[1], J. Mannan[1], R. Mieses Jr.[1], S. Pettie[1], V. Zhang[2], and S. Cheng[1]. *[1]John Jay College of Criminal Justice, New York, NY; and [2]Watchung Hills Regional High School, Warren, NJ.*

Chronic exposure to manganese is associated with various neurological disorders such as Parkinson's disease. Mancozeb which contains manganese can potentiate parkinsonian toxicant MPP^+ toxicity and also activate NFκB in PC12 cells. Studies show that epigenetic related proteins JMJD3 and HDAC1 can regulate NFκB signaling pathway. Epigenetic modification in manganese neurotoxicity is not fully unveiled. This study was to elucidate the effects of mancozeb (MZ) and manganese chloride ($MnCl_2$) on epigenetic modification in astrocytes and PC12 cells. Epigenetic related protein DNMT1, JMJD3 and HDAC1 were the main focuses of this study. Cells were treated with MZ or $MnCl_2$ at 5 µM, 25 µM, and 50 µM for 24 hours. Nuclear proteins were extracted after chemical treatments. Protein concentrations were determined by Bio-Rad DC assay. Epigenetic related proteins (DNMT1, JMJD3 and HDAC1) and NFκB proteins were detected by using immunoassay kits from EpiGentek and Abcam, respectively. The results showed the levels of DNMT1 and HDAC1 were increased after MZ treatments in a dose-dependent manner in PC12 cells, but no change in the expression of JMJD3. In PC12 cells treated with $MnCl_2$, the levels of DNMT1, HDAC1 and JMJD3 were not significantly altered as compared with control. In astrocytes, only the levels of HDAC1 were increased in response to MZ and $MnCl_2$ in a dose-dependent manner. There were no changes in the levels of DNMT1 and JMJD3 of astrocytes after chemical treatments. Interestingly, MZ at 5 µM enhanced the expression of NFκB in PC12 cells, but inhibited the expression of NFκB at higher MZ doses. $MnCl_2$ has no effect on the NFκB expression in PC12 cells. For the expression of NFκB in astrocytes, MZ and $MnCl_2$ both decreased the expression of NFκB in a dose-dependent manner. And MZ has stronger effect on the expression of NFκB in astrocytes as compared with astrocytes treated with $MnCl_2$. Further studies are needed to uncover the relationship between the expression of epigenetic related proteins and NFκB in both cell lines in response to MZ and $MnCl_2$.

2323 Methylation of the Dithiocarbamate Fungicide Maneb Reveals Potential Toxic Mechanisms in Neuroblastoma

C. C. Anderson, and J. Roede. *University of Colorado Denver, Aurora, CO.*

The dithiocarbamate fungicide maneb (MB) has received research interest due to the increasing concern of the negative health effects of pesticides, as well as its association with Parkinson's disease (PD). However, few studies focus on the molecular mechanisms of MB in human cells, with identified toxicities including mitochondrial dysfunction, proteostasis disruption, and apoptosis of dopaminergic neurons. Our laboratory has previously reported distinct phenotypic changes of neuroblastoma cells exposed to acute, subtoxic levels of MB including decreased mitochondrial respiration, altered lactate dynamics, and metabolic stress. In this study, we aimed to define specific molecular mechanisms of MB through the comparison of several thiol-containing compounds and their effects on energy metabolism and antioxidant defense. The Seahorse XFe96 extracellular flux analyzer was employed to evaluate alterations in energy metabolism of SK-N-AS human neuroblastoma cells after acute exposure of an array of chemicals including dithiocarbamates (maneb, nabam, zineb) and other thiol containing small molecules (glutathione, N-acetylcysteine). These studies revealed MB and its methylated form (MeDTC) as unique toxicants, with significant alterations to mitochondrial respiration, proliferation, and glycolysis. Next, we investigated glutathione and thioredoxin/peroxiredoxin redox homeostasis, finding decreased glutathione and altered thiol oxidation status of peroxiredoxin 3 (Prx3, mitochondrial) after acute MB exposure. We then used redox Western blotting to pinpoint a potential MB-specific modification of cellular and recombinant Prx3, which we subsequently confirmed by Mass Spectrometry (MS) techniques. Finally, an ELISA for S-adenosylmethionine (SAM) revealed a MB-mediated decrease cellular SAM after a 2 hour exposure, confirmed by MS. The data presented strengthens the argument that MB can preferentially target mitochondrial enzymes containing thiol or iron-sulfur moieties, giving further credence to the MB model of PD in which many disease associated proteins contain these functional groups (Ubiquinol-cytochrome c reductase, aconitase, ALDH2, etc.). Additionally, our data supports a novel cellular "detoxification" mechanism via enzymatic methylation, potentially contributing to the complex toxicity profile of MB.

2324 Reduction of Pesticide Bioavailability with Charcoal and Clay-Based Sorbents

S. E. Hearon, M. Wang, and T. D. Phillips. *Texas A&M University, College Station, TX.*

Widespread use of pesticides has resulted in the accumulation of pesticide residues in the environment due to their persistence and stability. To reduce potential exposures, we have developed broad-acting clay-based materials that can be used to reduce the bioavailability and toxicity of diverse chemicals. In this study, activated charcoal (AC), calcium montmorillonite clay (CM) and acid-processed calcium montmorillonite clay (APM) were used to determine their potential as sorbents of dieldrin, an organochlorine insecticide, and glyphosate, an organophosphorous herbicide. We used adsorption isotherms, thermodynamics, and dosimetry studies to determine the capacities and affinities of the clays, enthalpies of the binding reactions, and potential doses of sorbent that could protect against high exposures. Cultures of *Hydra vulgaris* were used to determine the ability of sorbents to protect a living organism from pesticide toxicity. Additionally, soil and plant models were used to determine sorbent ability to reduce pesticide bioavailability in soil and to reduce plant uptake of pesticides from soil. Adsorption isotherms for all sorbents of dieldrin fit a Langmuir model. Isotherm results for APM showed high enthalpy (suggesting chemisorption) and high capacity (Q_{max} = 0.45 mol kg^{-1}), indicating tight binding of dieldrin. Inclusion of CM and APM resulted in the highest reduction of dieldrin toxicity (60 and 70%, respectively) in the hydra. Further work indicated that AC, CM and APM can significantly reduce the bioavailability of dieldrin from soil ($p \leq 0.01$). Inclusion of 1% AC and CM significantly reduced residues of a toxic glyphosate metabolite (AMPA) in corn sprouts (60%), confirming that these sorbents can reduce uptake of glyphosate from soil and water. These results suggest that the tested charcoal and clays can be effective sorbents of dieldrin and glyphosate and may be included in the diet and/or garden soil to protect against environmental exposures. These sorbents and combinations of sorbents can be further developed to bind other environmentally relevant chemicals and chemical mixtures. *Supported by NIEHS SRP P42 ES0277704.*

2325 A Tiered Approach to Prioritizing Registered Pesticides for Potential Cancer Hazard Evaluations: Implications for Decision Making

P. Schwingl[1], S. Mehta[2], S. Atwood[1], and R. Lunn[2]. *[1]Integrated Laboratory Systems Inc., Morrisville, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

The US has >800 pesticides (including insecticides, rodenticides, and herbicides) registered for use. Some historical pesticides (e.g., lindane, DDT) have been identified as human carcinogens and subsequently severely restricted or banned. A growing body of animal and human studies raise concern that some replacements may also be carcinogenic, including some high-volume pesticides with a potential for ubiquitous US exposure. The US Environmental Protection Agency (EPA) conducts cancer hazard evaluations of these chemicals, mostly during the pesticide registration process. These evaluations often rely on proprietary studies and can sometimes be outdated. We aim to examine the scope of registered pesticides in the US to identify gaps and to determine which non-banned pesticides would be potential candidates for a cancer hazard evaluation. A systematic, tiered review approach was used to prioritize pesticides currently listed in EPA's public database. Initial criteria for consideration include: (a) EPA's human carcinogenicity classifications; (b) high volume use in US agricultural, commercial, or residential sectors; (c) no recent carcinogenicity evaluation; and (d) pesticides not listed by the International Agency for Research on Cancer (IARC) or the US Report on Carcinogens (RoC). Subsequently, evidence maps for each pesticide were created from searchable libraries of peer-reviewed literature compiled since the last EPA carcinogenicity evaluation. Database searches focused on identifying epidemiological studies that investigated the relationship between human exposure to pesticides and cancer. Preliminary results identified 16 pesticides classified as possible or probable carcinogens by EPA, used in high volumes, not listed by IARC or RoC, and having no recent carcinogenicity evaluation by EPA, some for as many as 35 years. For six pesticides, including mancozeb, carbaryl, and metolachlor, multiple population-based cancer epidemiology studies with reports on at least three cancer-specific sites have been published since EPA's last review. These results warrant further scoping to determine if a re-evaluation is needed. We recommend prioritizing and updating hazard evaluations for these pesticides to ultimately inform regulatory and public health decision-making.

2326 Imidacloprid Containing Mesoporous ZnO/SiO_2 Nanopesticide as an Environmentally Friendly Controlled Release Formulation: An Approach Toward Sustainable Agriculture

A. Singh, A. K. Kar, D. Singh, N. Dhiman, M. P. Purohit, D. Ghosh, and S. Patnaik. *CSIR-Indian Institute of Toxicology Research, Lucknow, India.* Sponsor: K. Ansari

Poor utilization efficiency of pesticide formulations is one of the significant problems conjoined with conventional agronomic practices which have resulted in overuse of pesticides, leading to higher costs and ecological hazard not only to non-targeted organisms but also to humans. Pesticides related risks have also impacted adversely to flora and fauna as well as our aquatic systems. Recent innovations in nanotechnologies and consequently, its applications in agriculture towards nanopesticide formulations hold promise to address this challenge by improving the utilization efficiency of pesticides with a much lesser pesticide load. In the present study, a slew of unique nanopesticide controlled release systems (CRS) were designed by entrapping Imidacloprid, a neonicotinoid systemic insecticide, in mesoporous ZnO/SiO_2core-shell nanoparticles. These systems were characterized using microscopy, spectroscopy, and thermal techniques. Additionally, to further minimize the pesticide burden, a biopesticide tomatine was loaded in the CRS eliciting a synergistic effect in terms of insecticidal efficiency towards *Aphis craccivora*, a model target pest. Preliminary data purport photostability and controlled release behavior. Risk exposure study using human dermal fibroblast (HDF) cell line and *Vigna radiata* as a model plant delineated its safer toxicity profile when compared to the bulk pesticide. Future work will encompass ecotoxicology study evaluated as per OECD guidelines, on zebrafish, one of the non-target organisms, to assess any risk involved. The present work embodies the concept of better pest control and crop management using sustainable eco-farming approach.

2327 Chlorpyrifos-Induced Cell Proliferation in Human Breast Cancer Cell Lines Differentially Mediated by Estrogen and Aryl Hydrocarbon Receptors and KIAA1363 Enzyme After 24-Hour and 14-Days Exposure

P. Moyano, J. Garcia, A. Pelayo, P. Muñoz-Calero, M. T. Frejo, M. J. Anadon, J. M. Garcia, M. Lobo, and J. Del Pino. *Universidad Complutense de Madrid, Madrid, Spain.*

Organophosphate biocide chlorpyrifos (CPF) is involved with breast cancer. However, the mechanisms remain unknown. CPF increases cell division in MCF-7 cells, by estrogen receptor alpha (ERα) activation, although it is a weak ERα agonist, suggesting other mechanisms should be involved. Aromatic hydrocarbon receptor (AhR) activation increases cell division in human breast cancer cells, and CPF strongly activates it. Finally, the KIAA1363 enzyme, which is regulated by CPF, is overexpressed in cancer cells. Accordingly, we hypothesized that CPF or its metabolite chlorpyrifos-oxon (CPFO) could induce cell viability promotion in MCF-7 and MDA-MB-231 cell lines, through mechanisms related to ERα, AhR, and KIAA1363, after 24 h and 14 days treatment. Results show that, after acute and long-term treatment, CPF and CPFO alter differently KIAA1363, AhR, ER and CYP1A1 expression. In addition, they induced cell proliferation through ERα activation after 24 h exposure in MCF-7 cells and through KIAA1363 overexpression and AhR activation in MCF-7 and MDA-MB-231 cells after acute and long-term treatment. The results obtained in this work provide new information relative to the mechanisms involved in the CPF toxic effects that could lead to breast cancer disease.

2328 Development of a Strategy to Bridge Agrochemical Formulations Based on Historical Acute Toxicity Data and Formulation Composition

M. Trevisan Inforzato[1], G. Duck[2], L. Galiano[1], C. Elliott[2], and A. Hofstra[3]. *[1]Syngenta Crop Protection LLC, Greensboro, NC; [2]Syngenta Ltd., Jealott's Hill, United Kingdom; and [3]Syngenta Canada Inc., Guelph, ON, Canada.*

To reduce the use of vertebrate testing, alternative approaches including bridging arguments can be submitted in lieu of studies. Historically, as part of an application package for a new agrocultural pesticide formulation, a defined battery of acute toxicity studies known as the "6-pack" was required. While the opportunity to bridge a new pesticide formulation from previously assessed formulations is attractive, the criteria that factor into a reliable bridging argument is not well defined. We assessed historical acute toxicity data to develop a step-wise approach in order to confidently and effectively bridge

across similar formulations. As a starting point we focused on acute oral toxicity data from formulations for which two or more versions of a formulation have been tested. We compared the oral LD_{50}, the EPA and GHS classifications, and the formulation composition of greater than 250 variants. Composition, study design and reported LD_{50s} were investigated to help establish reasons for similarities and differences. This gave us a broad overview of considerations for bridging rationales. The ultimate goal is to understand what composition changes do and do not lead to a change in the acute toxicological profile of agricultural pesticide formulations and provide confidence in bridging assessments.

2329 Environmental Impact of Underwater Released Exhaust Gas from Ships and Its Potential as Antifouling Strategy

Y. Wei[1], Y. Xu[1], L. M. van der Loos[1], A. J. Murk[1], and E. M. Foekema[1,2]. *[1]Wageningen University, Wageningen, Netherlands; and [2]Wageningen Marine Research, Den Helder, Netherlands.*

In an effort to reduce harmful emissions and increase energy efficiency, the application of Liquefied Natural Gas (LNG) as fuel for ship engines is being studied in combination with an underwater exhaust system to reduce the ship's water resistance. Besides inert nitrogen gas, hydrocarbons and nanoparticles, the exhaust gas consists 5-8% of CO_2, which may significantly increase CO_2 levels in the water around the ship. Apart from the assessment of the impact on the local environment, we investigated if underwater released exhaust gas could be used as anti-fouling strategy for ship hulls, as alternative to the traditional coatings that are often highly toxic to non-target marine organisms. Barnacles and biofilm were exposed for 25 days in seawater to a wide range of elevated CO_2 concentrations (pH 6.3 - pH 7.8). With decreasing pH from 7.8 to 6.3, the development of biofilm biomass was significantly reduced and a shift in taxonomic composition was observed. It clearly indicated that elevated CO_2 concentrations can slow down the formation of the initial biofilm, which could also have implications for the settlement of fouling invertebrates like barnacles and mussels. Barnacles tolerated acidic conditions up to pH 6.8. However, at the highest exposure condition (equivalent to pH = 6.3) feeding activity and growth were significantly inhibited and mortality increased. From these animals the adhesive power was reduced such that the water force of a relatively slow sailing speed of 12 km h^{-1} was sufficient to remove over 50% of the barnacles. Based on physiological features, it is expected that smaller animals, new larvae and fouling molluscs will be more sensitive. Our results findings suggest that CO_2 released along a ship's hull could prevalence of biofilm development and even combatting attached barnacles, although more research is needed to fully understand the mechanisms involved and the potential for practical application.

2330 Effects of *Cymbopogon nardus* (L.) Essential Oil on the Life Cycle and Midgut of *Ceraeochrysa claveri*

K. Caballero-Gallardo[1], E. L. Scudeler[2], B. Gastelbondo-Pastrana[2], E. Stashenko[2], D. Carvalho dos Santos[2], and J. Olivero-Verbel[3]. *[1]Universidad de Cartagena, Cartagena, Colombia; [2]Universidade Estadual Paulista, Botucatu, Brazil; and [3]Universidad Industrial de Santander, Bucaramanga, Colombia.*

The essential oil (EO) from *Cymbopogon nardus* is known as citronella oil, and it has been used as insect repellent, household fumigant, and fragrance agent in food commodities, soaps and cosmetics. The aim of this study was to characterize this EO by GC/MS, and evaluate its effects on the life cycle and midgut morphology of *Ceraeochrysa claveri* fed on eggs of *Diatraea saccharalis* (Lepidoptera: Crambidae). Fresh eggs of *D. saccharalis* were immersed in solutions of the EO (1-100 ppm in methanol, 5 s) or solvent (control) and dried at room temperature (30 min). Newly hatched larvae were randomly selected, divided into four experimental groups (n=15), and placed in polyethylene cups until the adults emerged. These were fed with an artificial diet (1:1 honey/yeast solution). One day after, insects were used to obtain their midgut. Larval and pupal stage duration, the emergence time of the insect, as well as the frequency of malformed organisms were recorded. Major constituents of the EO were citronellal (32.8%), geraniol (21.9%), citronellol (21.5%), germacrene D (3.3%), citronellyl acetate (2.9%) and geranyl acetate (2.1%). Insect mortality followed an EO concentration-response relationship. There was a significant change ($p<0.05$) in the duration of the third instar and prepupa stages, as well as in the total life cycle of insects exposed to the EO when compared to the control group. Observed alterations in the life cycle of *C. claveri* exposed to the EO included prepupa with no cocoon formation, death pupa inside cocoon, and malformed adults. Serious injuries on the midgut epithelium of exposed adults were observed, including detachment of columnar cells, leaving only swollen regenerative cells fixed on the basement membrane, and the formation of epithelial folds. In summary, these data suggest the EO of *C. nardus* has adverse effects on the life cycle of *C. claveri* and causes damage to its intestine. *COLCIENCIAS 567-2012; FP 44842-212-2018; Unicartagena, Resolution 01153, 2016.*

2331 Effects of Some Water Quality Parameters on Histological and Hematological Profiles of Two Important Fish Species from Ogun Waterside Lagoon System, Nigeria

A. A. Idowu[1], and S. O. Ayoola[2]. *[1]Federal University of Agriculture, Ogun State, Nigeria; and [2]University of Lagos, Lagos, Nigeria.*

Seasonal variations in physical and chemical parameters of Makun-Omi lagoon system and their effects on the health status of *Gymnarchus niloticus* and *Coptodon zillii* were determined using histopathological and haematological profiles. Water and fish samples were randomly collected during the dry and wet seasons and were analysed following standard procedures. Data collected were subjected to Analysis of Variance and correlation statistical analysis using SPSS (version 20). Duncan Multiple Range Test was used to separate the means at $p<0.05$. A significant difference ($p<0.05$) existed between seasons in the physical and chemical parameters of water samples. Recorded values of the water quality parameters for the dry and wet seasons were: Temperature 30.60±0.46 and 28.57±0.23 °C, pH 6.53±0.88 and 6.43±0.67, Dissolved Oxygen (DO) 2.80±0.12 and 3.03±0.88 mg/l, Electrical Conductivity 180.00±2.89 and 244.33±5.81 µS/cm, Salinity 1.00±0.00 and 0.93±0.07 ‰, Total Alkalinity 12.00±0.29 and 8.83±0.20 mg/l, Total Hardness 56.67±0.67 and 52.00±1.16 mg/l, Total Dissolved Solids 84.33±0.33 and 131.67±2.67 mg/l, Phosphate 0.001±0.003 and 0.002±0.003 mg/l, and Nitrate 7.70±0.12 and 5.97±0.09 mg/l respectively. The selected heavy metals concentrations (Cadmium, Chromium, Cobalt, Lead and Nickel) were below detection limit in the water samples during the wet season, compared to their varying levels of detection during the dry season. Nickel (Ni) concentration in water was 0.264±0.00 mg/l; Cobalt was below detection limit in the tissues of experimental species in both seasons, while concentrations of other metals varied with season and in the tissues. The gills of *C. zillii* and liver of *G. niloticus* had concentrations of 0.190±0.03 mg/kg and 0.136±0.01 mg/kg respectively. Haematological parameters of *G. niloticus* showed significant difference ($p<0.05$) between seasons. Packed cell volume (21.40±1.30 and 22.40±1.08%), Haemoglobin (7.40±0.41 and 7.38±0.33 g/dl) and Red blood cell ($1.89x10^{12}$±0.12 and $2.03x10^{12}$±0.11/L) for dry and wet seasons respectively. However, there were relatively high values of White blood cell, heterophils and lymphocytes ($10.92x10^{12}$±0.11/L, 43.80±1.96% and 58.80±1.88%, respectively) in the fish. A strong positive relationship existed between water and haematological parameters with r values of 0.77 and 0.75 for dry and wet seasons respectively ($p<0.05$). Histological results revealed moderate to acute alterations in the tissues of the examined fish species. The gills of both fish species had more alterations in the dry season as against the wet season, while the liver of *G. niloticus* showed more alterations in the wet than the dry season. Haematological and histopathological observations showed varying impacts on the blood and tissues of the fish species, given the extreme values of DO, nitrate and Ni concentrations in water. The study concluded that environmental monitoring of the water body is recommended in order to control the effects of water pollution which ultimately affects the health status of the fish species.

2332 Toxicity Assessment of Sediments from a River Watershed Impacted by Open-Pit Coal Mining in Colombia

M. Duran-Izquierdo, and J. Olivero-Verbel. *Universidad de Cartagena, Cartagena, Colombia.*

Coal mining is one of the most important economic activities at the Northern Colombia. However, mineral extractions are carried out near rivers that provide ecosystem services to riverside populations. Cesar River receives discharges from open-pit coal mines, as well as from other anthropogenic sources. The aim of this work was to assess the toxicity profile of the sediments from the Cesar River. Bottom sediment samples were collected from 12 points along the course of the river, including tributaries and a Ramsar site, the Zapatosa Marsh. Samples were freeze-dried, and the <75 µm fraction was employed to obtain 1:3 ratio aqueous extracts (K-medium). The biological effects of the sediments were evaluated using *Caenorhabditis elegans*. Wild-type Bristol N2 nematodes were exposed to the extracts, registering mortality, locomotion and growth as end points. Transcriptional effects associated with various toxicity mechanisms were assessed using GFP-related transgenic strains (mtl-2, sod-4 and gst-1). Trace elements were quantified employing ICP-MS, and mercury (Hg) was measured using a direct Hg analyzer. Sediment

extract-induced lethality was low (1.5-6.4%); however, nematode growth and locomotion decreased along the river, showing inhibition rates up to 23.3 and 35.4%, respectively. Extracts induced over expression of all tested genes, with greater values for sites receiving domestic sewage and mining outputs. Some trace metals enriched along the course of the river, especially Hg and V. Cobalt was positively associated with the mRNA expression of metallothioneins and gst-1. Greatest biological impacts from sediments extracts were observed downstream the coal-mining area and in Zapatosa Marsh. These data suggest coal mining areas should be closely monitored for trace-element release and their impact on biota. The Colombian government should implement laws, and programs aimed to protect key ecosystems from mining activities, as a commitment to sustainable development goals. *UniCartagena 096/2018.*

2333 Genotoxicity, Histopathological Examination, and Heavy Metals Assessment of *Chrysichthys nigrodigitatus* at Makoko Fish Landing Site, Lagos, Nigeria

S. O. Ayoola. *University of Lagos, Lagos, Nigeria.*

A total of sixty (60) Samples of *Chrysichthys nigrodigitatus* were collected for four months from the Makoko area of the Lagos lagoon. Water, sediment, fish liver and blood samples were collected from three selected stations in Makoko fishing area and assessed. Physicochemistry, heavy metals (Zn, Pb, Cu and Fe), liver pathology and erythrocytes abnormalities were assessed. Total of sixty (60) (five from each station at each sampling period) were collected. Heavy metals in water and sediment media were analyzed using atomic absorption spectrophotometer. Six nuclear abnormalities in erythrocytes were considered; Micronucleated, Binucleated, Blebbed, Notched, Dumbbell and Irregular. Hepatopathological Alteration Index (HAI) and Hepatosomatic Index were also estimated. All the measured variables were still within WHO limits (1989) with station 2 having the highest BOD and DO concentrations; Mean±SD, 6.69±0.32 mg/l and Mean±SD, 6.11±0.15 mg/l respectively. The surface water in the three stations had copper, iron and zinc but very low lead. These metals were within WHO limits except for zinc in August, 2018, Mean±SD, 3.19±5.19 (mg/l). There were higher concentrations of the metals (Fe, Cu, Zn and Pb) in sediment as compared to surface water. These concentrations were below WHO limits. There were high frequencies of nuclear abnormalities in erythrocytes of *Chrysichthys nigrodigitatus* collected each month at the sampled areas. August had the highest frequency with total sum frequencies of abnormalities in cells as 110 with sum average frequency of 21.8 and the trend, August>October>July>September. The distribution of the frequencies of abnormalities across the months were significant at 0.05 level, Chi-Square, X^2 (3) = 12.613, $p<0.05$. The frequency of Binucleated cell was the highest nuclear abnormalities with total frequency of 118 and average frequency of 23.4 and the trend Binucleated >Multinucleated >Notched >Blebbed>Irregular> Dumbell. Lead and copper concentrations in the sediment correlated negatively with the frequency of Binucleated cells in *Chrysichthys nigrodigitatus* ($r = -0.705$, $p<0.05$ and $r = -0.630$, $p<0.05$ respectively). More so, sediment zinc ion correlates with sediment copper ion ($r = 0.628$, $p<0.05$). August had the highest surface water metal load, suspected to be an industrial discharge, with zinc concentration above WHO limit. There was relationship in certain nuclear abnormities and histological alterations in the fish and certain heavy metals in the surface water and sediment media due to pollution.

2334 Wildlife Toxicity Assessment for 2,4-Dinitroanisole (DNAN)

G. Reddy, M. A. Williams, M. S. Johnson, and M. J. Quinn. *Army Public Health Center, Aberdeen Proving Ground, MD.*

2,4-Dinitranisole (DNAN), also known as 1-metoxy-2,4-dinitrobenzene is used in explosive mixtures. Currently, it is being investigated as a component in replacements of other conventional energetic Military munitions. It is used as a component of insensitive munition explosive (IMX) formulations. For example, IMX-101, which is comprised of nitrotriazolone (NTO); DNAN; and nitroguanidine is a comparatively less sensitive explosive formulation than many conventional formulations. When fielded, DNAN may be detected in soil, surface water, and potentially in animal and plants at manufacturing facilities and where training operations occur. We have reviewed the acute and sub-chronic toxicity data of DNAN in mammalian, avian, reptilian and amphibian species. Despite limited wildlife exposure data in animal studies, we have attempted to derive points of departure (PODs) from dose-response data reviewed from target organ-specific studies. US Army Public Health Center Technical Guide 254 - Standard Practice for Wildlife Toxicity Reference Values (TRVs), guided our development of class-specific TRVs. Recently developed data are available for mammals, avian, and some amphibian species. The data relevant to reptiles are absent. Tentatively derived PODs (mg/kg-day) were derived from a sub-chronic study conducted in rats, and Benchmark dose (BMD) values were derived from studies of exposure to DNAN by ingestion in mammals. A BMD or ED10 of 1.78 mg/kg-day, and a lower-bound BMDL10 or LED10 value of 0.93 mg/kg-day was determined for the class Mammalia. For inhalation exposures, a LOAEL-based TRV of 165 mg/m^3 and a NOAEL-based TRV of 4.1 mg/m^3 for the class Mammalia were determined. For ingestion TRVs for the class Aves, a LOAEL-based TRV of 7.5 mg/kg and a NOAEL-based TRV of 1.5 mg/kg were derived following oral exposure to DNAN. For amphibian species, a NOAEC TRV of 0.24 mg/L and a LOAEC TRV of 2.4 mg/L were derived following a 28-day DNAN exposure. Tentative TRVs were based on data from the most sensitive species available, and are intended to be protective of the entire class of wildlife species with broad utility in ecological risk assessment

2335 Regioselective Effects of OxyPAHs on Red Blood Cell Concentrations in Japanese Medaka Embryos

P. Tanabe, C. A. Mitchell, V. Cheng, D. C. Volz, and D. Schlenk. *University of California Riverside, Riverside, CA.*

Previous studies in zebrafish have demonstrated that exposure to oxygenated polyaromatic hydrocarbons (oxyPAHs) at critical developmental time points can impair red blood cell (RBC) concentrations in a regioselective manner, with 2-hydroxychrysene being more potent than 6-hydroxychrysene. Japanese medaka embryos were exposed to 2 or 6-hydroxychrysene (0.5, 2, or 5μM) or 70μM phenanthrene (a positive control) from 4h post-fertilization (hpf) to 7d post-fertilization (dpf). Following exposure, RBC concentrations were quantified by staining fixed embryos with *o*-dianisidine (a hemoglobin-specific dye), imaging stained embryos using brightfield microscopy, and analyzing images within ImageJ. Exposure of embryos to all three concentrations of 2-hydroxychrysene resulted in a significant decrease in hemoglobin concentrations compared to vehicle controls, while there were no effects observed following exposure to 6-hydroxychrysene at all tested concentrations. Embryonic uptake rates for 2 and 6-hydroxychrysene were also evaluated by determining body burden at multiple timepoints of exposure by liquid-liquid extraction and LC-fluorescence analysis and there was no significant difference between the rate of uptake for both compounds. Medaka embryos were exposed to 2-hydroxychrysene at the beginning of four different developmental stages (13-15hpf, 38-41hpf, 82-95hpf, 95-101hpf) to identify a window of sensitivity for toxicity. Unlike initiation of exposure at 4hpf, none of these exposures resulted in the no-blood phenotype nor mortality. However, when Medaka embryos were exposed to 2-hydroxychrysene for 24, 48, 72, and 96 hours beginning at 4hpf, the 48, 72, and 96h exposure durations resulted in significant changes in phenotype and survival. These data indicate that regioselective toxicity is not due to differences in uptake and indicate other mechanisms may be involved. *This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER2).*

2336 Intergenerational Toxicity of Nonylphenol Ethoxylate (NP-9) in *Caenorhabditis elegans*

A. De la Parra-Guerra, and J. Olivero-Verbel. *Universidad de Cartagena, Cartagena, Colombia.*

The ethoxylated isomers of nonylphenol (NPEs, NP-9) are one of the main active ingredients of many nonionic surfactants used in herbicides, cosmetics, paints, plastics, disinfectants and detergents. These chemicals and their metabolites are commonly found in environmental matrices. The objective of this work was to evaluate the intergenerational toxicity of NP-9 in *Caenorhabditis elegans*. The survival rate and locomotion were investigated in the larval stage L4, while length, width and longevity were assessed using the L1 stage of the wild strain N2. Green fluorescent protein (GFP) transgenic strains were employed to estimate changes in relative gene expression. RT-qPCR was utilized to measure mRNA expression for different genes associated with neurotoxicity (unc-30, unc-25, unc-49, dop-3, dat-1, mgl-1, eat-4, glt-3 and glt-6) and oxidative stress (mtl-1 and mtl-2). Data were obtained from exposed parent worms (F0) and the first non-exposed generation (F1). Lethality of the nematode was concentration-dependent, with 24 h-LC50 values of 3.2 and 2.0 mM for F0 and F1, respectively. Non-lethal concentrations of NP-9 reduced locomotion and longevity, whereas non-monotonic concentration-response curves were observed for body length and width in both generations. The gene expression profile in F0 was different from that registered in F1, although the expression of sod-4, hsp-70, gpx-6 and mtl-2 increased with the surfactant concentration. In F0, NP-9 induced non-monotonic responses for genes related to oxidative stress, GABA, dopamine and glutamate; whereas in F1, most genes displayed classical concentration-response curves. In summary, NP-9 induced intergenerational responses in *C. elegans* through mech-

anisms involving ROS and alterations of the GABA, glutamate and dopamine pathways. *Colciencias-UniCartagena, 727, 2015. Vice-Rectory for Research. 2017-2019.*

2337 Establishment of Yeast-Based Reporter Gene Assay Using Methoprene-Tolerant of European Honey Bee, *Apis mellifera*

M. Ogawa[1], S. Ito-Harashima[2], E. Sano[2], K. Kitazumi[1], T. Kyoya[1], M. Terada[1], M. Kawanishi[2], and T. Yagi[2]. *[1]Kumiai Chemical Industry Co. Ltd., Shizuoka, Japan; and [2]Osaka Prefecture University, Osaka, Japan.* Sponsor: M. Ogawa, Japanese Society of Toxicology

Juvenile hormones (JHs) are one of the hormones that control growth and development of arthropods. In social insects including honey bees, JHs influence the caste differentiation and regulation of division of labor. Honey bees are important organisms responsible for pollination of various agricultural crops. Recently, colony collapse disorder, in which honey bee colonies lose worker bees, are concerned as serious problem for ecosystem. *Krüppel homolog-1* (*Kr-h1*) is target gene of JH receptor Mehoprene-tolerant (Met) in insect. In *A. mellifera*, a correlation between behavioral development of worker bees and expression of *Kr-h1* was previously reported. Therefore, chemicals with JH-like activity used for pest control may affect the endocrine system of bees, leading the decrease of population. In this study, we established yeast strains expressing Met of *A. mellifera* to detect JH-like substances in the environment. *A. mellifera* Met, *A. mellifera* steroid receptor coactivator (SRC), and L*acZ* reporter plasmid carrying putative JH response elements with E-box (CACGTG) located in upstream region of *A. mellifera Kr-h1* were constructed. Three plasmids were transformed into *Saccharomyces cerevisiae* W303 using standard lithium acetate method. Established reporter gene assay showed dose-dependent responses to an endogenous ligand JHIII via E-box-containing sequence of *Kr-h1* gene. In larvae of *A. mellifera*, mRNA levels of *Kr-h1* were significantly increased after JHIII treatment. These results indicate that *Kr-h1* is a target gene of Met in *A. mellifera* as well as other insects, and this assay is useful as an easy, rapid and cost-effective primary screening tool to detect JH-like activity for *A. mellifella* Met. *First and second authors contributed equally to the work.*

2338 Whole-Transcriptome Sequencing of Lake Trout Epidermal Mucus as an Exposure Assessment Tool following Low-Level Additions of Diluted Bitumen in a Boreal Lake

N. E. Andrzejczyk[1], V. P. Palace[2], L. Hrenchuck[2], and D. Schlenk[1]. *[1]University of California Riverside, Riverside, CA; and [2]International Institute for Sustainable Development—Experimental Lakes Area, Winnipeg, MB, Canada.*

To prevent further disruption of wild populations, development of noninvasive sampling methods has become increasingly important when studying toxicological effects of environmental pollutants on aquatic organisms. In fish, analysis of epidermal mucus is a promising route for development of noninvasive sampling methods. In a previous study in our lab, whole-transcriptome sequencing of mahi-mahi (*Coryphaena hippurus*) epidermal mucus following slick oil exposure revealed that transcriptional responses in the mucus paralleled those in whole-embryo homogenates. Furthermore, hierarchical clustering of samples created separate clades for each treatment group, suggesting that sequencing of mucus is able to robustly capture transcriptional profile differences among individuals. To further assess the efficacy of mucus as an exposure assessment tool, RNA sequencing was performed on mucus collected from lake trout (*Salvelinus namaycush*) residing in a boreal lake that received low-level additions of diluted bitumen (dilbit), a form of crude oil, at the Experimental Lakes Area. Sequencing results from exposed fish will be compared to sequencing results from fish prior to dilbit exposure as well as from fish from a nearby non-exposed lake. Through sequencing, we will identify differentially expressed genes in dilbit-exposed individuals which will provide insight on biological pathways and functions that are altered following dilbit exposure. Along with this, we will assess whether mucus transcriptional profiles are able to robustly distinguish exposed from non-exposed fish. Overall, results of mucus sequencing will provide further insight on the efficacy of mucus as a nonlethal exposure assessment tool in a whole-ecosystem setting. *This research was made possible by a grant from The Gulf of Mexico Research Initiative. Grant No: SA-1520; Name: Relationship of Effects of Cardiac Outcomes in fish for Validation of Ecological Risk (RECOVER2).*

2339 Embryonic Development in Fish Is Hindered by Exposure to Environmentally Relevant Concentrations of Glyphosate

D. Killian, X. Wang, and R. K. Bhandari. *University of North Carolina at Greensboro, Greensboro, NC.*

Glyphosate-based herbicide use is increasing yearly to keep up with the growing demand of the agriculture world. Although glyphosate-based herbicides target the enzymatic pathway in plants, the effects on endocrine systems of vertebrate organisms, particularly fish, are widely unknown. The present study examined the effects of glyphosate exposure on embryo development and the thyroid system of the Japanese Medaka fish (*Oryzias latipes*). The Hd-rR medaka embryos were exposed to Roundup containing 0.05, 0.5, 5, 10, and 20 mg/L glyphosate (glyphosate acid equivalent) from the 8 hours post-fertilization stage through 14 days post-fertilization stage. Phenotypes observed include delayed hatching, increased developmental deformities, growth, and embryo mortality. The lowest concentration (0.05 mg/L) and the highest concentration (20 mg/L) of glyphosate induced similar phenotypes in embryos and juveniles. Gene expression analysis revealed a significant decrease in acetylcholine esterase (*ache*) mRNA levels and thyroid hormone receptor alpha (*thra*) mRNA levels in juveniles exposed to 0.05 mg/L and 20 mg/L glyphosate. Quantification of epigenetic alterations of glyphosate is currently in progress. The present results demonstrate that glyphosate via exposure to Roundup affects early development of medaka in a non-monotonic dose response manner and that environmentally relevant concentrations of Roundup can be toxic to fish embryos and juveniles. *Supported by Biology Department, University of North Carolina Greensboro.*

2340 Determination of Pharmaceuticals in Water and Biofilm Samples from the Hudson River

T. Acosta, K. Good, S. Cheng, and M. Concheiro-Guisan. *John Jay College of Criminal Justice, New York, NY.*

Pharmaceuticals are poorly degraded during conventional wastewater treatment, and may persist and accumulate in the receiving environment (biofilm). Despite the presence of a wide suite of pharmaceuticals in the Hudson River water, we are aware of no published studies on the presence of pharmaceuticals on Hudson River biota. The primary objective of this study was to develop a qualitative analytical method in river water and a quantitative analytical method in biofilm samples to detect 12 pharmaceuticals of high potential for environmental harm. The second objective was to investigate the pharmaceuticals' presence in these types of samples, collected from six locations along the Hudson River at three different time points throughout 2018 (n=18). These locations were chosen due to the proximity of a wastewater treatment plant and combined sewer overflows locations (n=8). One-hundred mL water samples were acidified and filtered. Biofilm samples (0.25 g) were homogenized via bead mill in 8 mL methanol. Both water and biofilm samples were further purified by mixed mode solid phase extraction. Samples were analyzed by liquid chromatography tandem mass spectrometry, utilizing positive electrospray ionization in multiple reaction monitoring mode. All compounds were analyzed simultaneously by reversed-phase in gradient mode with 0.1% formic acid in water and in acetonitrile as mobile phases. Biofilm quantitative method validation included linearity (1-100 ng/g), limit of detection (0.5 ng/g), imprecision (<20%), accuracy (80-120%), matrix effect and extraction efficiency. Water qualitative method achieved cut-offs of 10, 50 or 100 ng/L, depending on the compound. Two biofilm and 18 river water samples collected from six locations along the Hudson River tested positive. Biofilm samples were positive for sulfamethoxazole (n=1, 6 ng/g) and oxycodone (n=1, 0.4 ng/g). River water samples tested presumptively positive for atenolol (n=18), metoprolol (n=18), fluoxetine (n=1) and alprazolam (n=2). This study developed and validated sensitive and specific methods for the detection of 12 pharmaceuticals in biofilm and river water samples. Two pharmaceuticals, oxycodone and sulfamethoxazole, were detected with concentrations up to 6 ng/g in the biofilm samples from the Hudson River, and 4 pharmaceuticals, atenolol, metoprolol, fluoxetine and alprazolam were detected in river water samples.

2341 Control of Burrowing Shrimp: Modes of Action and Efficacy

K. H. Sahota, and C. Grue. *University of Washington, Seattle, WA.* Sponsor: K. Sahota, Society of Environmental Toxicology and Chemistry

For 70 years, growers of Pacific oysters (*Crassostrea gigas*) in Washington State have found it necessary to control burrowing shrimp (*Neotropea californiensis*) on intertidal shellfish beds as they destabilize sediments resulting in poor survival and low yields. The carbamate, carbaryl (an AChE inhibitor) was used

to control shrimp until 2014 following litigation over non-target effects. The neonicotinoid, imidacloprid (IMI) was identified as an alternative, but the State has not approved its use citing the potential for non-target effects and growing concerns over the use of neonicotiniods. An outcry, primarily from chefs in Seattle and local shellfish buyers, over the use of the neurotoxin on beds from which oysters are harvested, coupled with poor efficacy, contributed to the controversy. As a result, Pacific County has declared an "Economic Emergency". For more than a decade, undergraduates at the University of Washington have conducted research on the toxicity of IMI to adult and juvenile shrimp as well as alternatives: emamectin benzoate (EB) and un-iodized table salt (TS). Studies in seawater (SW) indicate shrimp are extremely sensitive to IMI with 1-h EC50's (paralysis) in SW of 45 ppb for juveniles and 116 ppb for adults. However, lethal exposures exceed 12,000 and 1 mil ppb, respectively; exposures unlikely to be realized in the field at the maximum allowable application rate. Mortality of adults in sediment results from paralysis leading to burrow collapse and asphyxiation, but only if the paralysis lasts 54-78 h (i.e., IMI exposure dependent). Nicotinic ACh receptors are primarily located in the gastric mill (stomach) of shrimp, likely explaining the poor observed efficacy. In contrast, EB targets the primary neurophysiology of shrimp (glutamate/GABA) and has a US marine registration (SLICE®) as a feed additive for the control of sea lice (*Caligus* and *Lepeophtheirus* spp.) on farmed salmon. Exposures of adult and juvenile shrimp to EB (as Proclaim®) in SW yielded 96-h LC50s of >100 ppb and 18 ppb, respectively, with the former approaching the 96-h LC50 for juvenile salmonids, non-target species of concern. More promising are recent studies with TS. Adult and juvenile shrimp are very sensitive to acute changes in salinity with mortality occurring rapidly within 6 h when exposed to 2-3x ambient salinity. Studies in 2020 will focus on TS and juvenile shrimp within native sediment as they occupy the upper 10-15 cm, as well as juvenile Dungeness crab, a non-target species of concern.

2342 Benthic Ecotoxicological and Seafood Risk Assessment in Hangzhou Bay, China

C. Bao[1,2], A. J. Murk[1], and Q. Cai[2]. *[1]Wageningen University, Wageningen, Netherlands; and [2]Yangtze Delta Region Institute of Tsinghua University, Zhejiang, Jiaxing, China.*

The Hangzhou bay region has the fastest growing economic development and is one of the most contaminated coastal region of China. Recent research reveals high levels of toxic compounds in the sediments in this region. This implies many potential adverse consequences for the benthic ecosystem health and services it can provide, benthic eco-toxicity, seafood safety, and whole benthic ecosystem stability. This study aims to study the eco-toxicological effects in the field, apply chemical analysis and bioassays for monitoring the toxic potency of the sediment and to assess the toxicological risks for seafood originating from this region. The study firstly collected and analyzed historic monitoring data about marine sediment quality and benthic animals' species variety. Results revealed the key benthic pollutants are arsenic, copper, chromium and cadmium. More than 60% of benthic species are disappeared in last 20 years. Crustacean group animals are mostly survived compare to other species and have a big concern for contamination accumulation in the seafood crustacean species like swimming crabs. The second section of the study applied *in vitro* bioassays to quantify genotoxicity potencies of toxic compounds in marine sediments and benthic animals. The bioassay employs a multiplex of four reporter strains (key proteins) covering seven recognized DNA damage repair pathways. Via GFP fusion proteins this genomics assay enables quantification of the potency to activate multiple DNA damage mechanisms by compounds extracted from sediments and from benthic animals. Chemical analysis was performed for calibration of the bioassay. Results illustrated swimming crab samples showed a very high response to umuD and lexA genes and it can strongly relate to genotoxicity effects. Late chemical analysis proves crabs' samples showed gene response does contain high PAHs levels compare to the safety level. In the third section of this research, sediment and swimming crabs are assessed seafood and ecological risk. The assessment of sediment showed moderate ecological risk mainly caused by multiple heavy metals. Food risk assessment illustrated Cadmium and Naphthalene from swimming crab has very high food risk to humans in the acute and chronic period. All in all, the study found Hangzhou bay the region does have many ecological and seafood concerns in the benthic ecosystem. Arsenic, chromium, and cadmium are exceeding safety levels and more than half benthic animal species are disappearing in the last twenty years. Genotoxicity is found in seafood samples and moderate risk is assessed from sediment. Meanwhile, *in vitro* bioassays and risk assessment were proved can be alternative tools in the region to find out all the hidden hazards and support quantitative risk study.

2343 Changes in Embryonic Zebrafish Cardiac Gene Expression following Crude Oil Exposure

D. S. De Alwis[1,2], J. Cameron[1], and J. Incardona[1]. *[1]National Oceanic and Atmospheric Administration, Seattle, WA; and [2]University of Maryland, College Park, College Park, MD.*

Crude oil and its degradation byproducts are known to have cardiotoxic effects on early life-stage fish including commercial species such as tuna and salmon. Exposed fish often exhibit pericardial edema and impaired heart function at very low exposure concentrations. This study examined the timed induction of several genes in response to crude oil exposure, including cytochrome P450 (*cyp1a*) and bone morphogenic protein 10 (*bmp10)* in embryonic zebrafish (*Danio rerio*), a model organism. *Cyp1a* is a widely studied gene involved in the metabolism of xenobiotic (foreign) substances. *Bmp10* is a cardiac gene involved in Ca^{2+} signaling, and is a likely contributor to oil-induced cardiac abnormalities. However, the timing of cardiac gene induction after crude oil exposure is unknown in both zebrafish and commercially important fish species. In this study, zebrafish were continuously exposed to a crude oil water-associated fraction (WAF) starting at 24 hours post fertilization (hpf) with four replicates per treatment including water-only controls. Twenty embryos were sampled per replicate at seven timepoints between 24hpf and 48hpf. RNA was extracted from each sample and converted to cDNA. Using a comparative Ct method, expression changes in genes of interest were measured using real time quantitative polymerase chain reaction (rt-qPCR), and analyzed using various statistical tests in R. Statistically significant upregulation of calcium signaling genes support a decrease in fitness of early life-stage zebrafish after exposure to low concentrations of crude oil. Likewise, this study has direct implications to the health and viability of commercially important fish exposed to oil spills in marine environments.

2344 Route of Exposure Influences Pesticide Body Burden and the Hepatic Metabolome in Post-Metamorphic Leopard Frogs

D. Glinski[1], R. Van Meter[2], S. T. Purucker[3], and W. M. Henderson[4]. *[1]NRC Postdoctoral Fellow with US EPA, Athens, GA; [2]Washington College, Chestertown, MD; [3]US EPA/CCTE, Research Triangle Park, NC; and [4]US EPA/CEMM, Research Triangle Park, NC.*

Pesticides are being applied at a greater extent than in the past due in part to availability of advanced formulations and/or new marketed varieties. Once pesticides enter the ecosystem, many environmental factors can influence their residence time. These interactions can result in processes such as translocation, environmental degradation, and metabolic activation upon exposure to target and non-target species. Most anurans start off their life cycle in aquatic environments and then transition into terrestrial habitats. Their time in the aquatic environment is generally short; however, many important developmental stages occur in this environment. Post-metamorphosis, most species spend many years on land but migrate back to the aquatic environment for breeding. Due to the importance of both the aquatic and terrestrial environments to the life stages of amphibians, we investigated how the route of exposure (i.e. uptake from contaminated soils vs. uptake from contaminated surface water) influences pesticide body burden (for bifenthrin (BIF), chlorpyrifos (CPF), glyphosate (GLY), and trifloxystrobin (TFS)) and the hepatic metabolome in adult leopard frogs. For water exposures, 50 mL of pesticide contaminated water was added to a Pyrex® bowl and for soil exposures a thin layer of soil was added to the bottom of a bowl, followed by the pesticide application using an aerosolized spray bottle, final exposure concentrations were 1 µg/mL. Body burden concentrations for amphibians exposed in water were significantly higher (ANOVA $p < 0.001$) compared to amphibians exposed to contaminated soil across all pesticides. Furthermore, the metabolite TFS acid was also significantly higher in water than in soil (ANOVA $p < 0.05$). The pesticide with the highest concentration in frogs was CPF in the water exposures while the lowest pesticide body burdens were determined for BIF and TFS in the contaminated soil exposures. Ultimately, this research will help fill regulatory data gaps, aid in the creation of more accurate dermal exposure and uptake models for amphibians and inform risk assessment efforts for these and other non-target species.

2345 Screening of Metals in Andean Condor Feathers: Possible Influence of Vulcano Eruption

A. Di Marzio[1], F. Barbar[2], S. A. Lambertucci[2], A. J. García-Fernández[1,3], and E. Martínez-López[1,3]. *[1]Universidad de Murcia Faculty of Veterinary Medicine, Murcia, Spain; [2]INIBIOMA (CONICET-UNComa), Bariloche, Argentina; and [3]Biomedical Research Institute of Murcia (IMIB-Arrixaca), Murcia, Spain.* Sponsor: G. Font

Northern Patagonia is a sparsely populated area, where volcanic eruptions represent an important source of metals (heavy metals and metalloids) pollution. The great eruption of the Puyehue-Cordón Caulle volcanic complex (PCCVC) (Chile) in 2011 reached the surroundings of Bariloche (Argentina) (> 100 km). The effects of ash exposure on wildlife and humans have been sparsely studied and biomonitoring studies with higher species (e.g. Andean condor; *Vultur gryphus*) have never been conducted. The main objectives of our study were the metal screening and evaluate a possible relation between the levels of metals in the Andean condor population and the volcanic activity of the area. We investigated the effects of the eruption of the PCCVC in 2011, using samples of molt primary feathers of the Andean condor, collected in nine roosts around Bariloche, Argentina (maximum distance 85 km). The information we currently have made us hypothesize that the molt of the primary feathers of the Andean condor has duration of 6 years. We carried out sampling before (2007, 2009) and after (2017) the volcanic eruption. The feathers sampled in 2017 should have been developed in 2011-2012, reflecting the environmental situation of the period immediately following the eruption of the PCCVC. For the first time we have screened metals in 48 molted primary feathers of Andean condor, showing the levels of 9 metals and metalloids (Si, Cr, Cu, Zn, As, Se, Cd, Pb, Hg). Si, Zn, As, Cd, showed higher levels in the feathers sampled after the eruption. This fact seem to confirm the volcanic contamination (Si represent 70% of the PCCVC ashes). The levels of Cr and Pb (although apparently not related to the volcanic eruption) in some samples are compatible with potential adverse effects in living beings. The screening results represent an important database (first for this species) that can be used in in future studies for comparative purposes.

2346 Proteomic Analysis of Anatoxin-A (±) in Zebrafish (*Danio rerio*)

L. M. Langan[1], L. M. Lovin[1], R. Taylor[1], K. Chambliss[1], S. Chatterjee[2], T. J. Scott[1], and B. W. Brooks[1]. *[1]Baylor University, Waco, TX; and [2]University of South Carolina, Carolina, SC.*

Cyanobacteria have a broad geographical distribution and can be found in both freshwater and marine environments. Multiplying quickly in surface waters, they form blooms when favorable conditions prevail with > 2000 species occurring globally in aquatic habitats. It is estimated that of blooms which form rapidly, 25-70 % may be toxic. Anatoxin-A and its analogues are potent neurotoxins produced by several genera of cyanobacteria. Examination of the literature results in a failure of toxicity studies to differentiate between enantiomerically or chemically pure anatoxin-a. A recent study summarized that of 33 studies examined for toxicity data, 18 reported on the use of the racemic mixture. However, little is known about the toxicological impact of this mixture at the protein level. Using nano LC-MS/MS protocol through a 2D-nanoAcquity UPLC with dilution coupled to a quadrupole time-of-flight (Q-Tof) Synapt G2 MS, protein differences were characterized in larval Zebrafish following a 96 h exposure at environmentally relevant concentrations. Altered proteins were predominantly down-regulated with respect to control samples (~129-278, 5 % FDR). Altered proteins identified had varying functions in carbohydrate metabolism and energy production, stress response, ATP synthesis and cellular development. The study provides valuable insights into how Anatoxin-a exerts its toxicity in fish.

2347 Oxidative Degradation of Waterborne Microcystins: Studies of Ozone-Mediated Degradation of Methyl 2-Acetamidoacrylate to Model Oxidative Inactivation of Microcystin-LR

O. A. Agu, C. J. Deere, S. Kasibhatla, and R. M. Uppu. *Southern University and A&M College, Baton Rouge, LA.*

Water resources for humans and farm animals are becoming increasingly scarce in recent years, in part, due to algal blooms. Fresh water algal blooms involving cyanobacterial species (e.g., *Anabaena and Microcystis*) result in the formation of microcystins (MCs), the most toxic one being microcystin-LR (MC-LR). The unusually high toxicity of MCs is often attributed to the presence of N-methyldehydroalanine (Mdha) moiety present as part of oligopeptide ring system. Mdha serves as the principal electrophilic center in reactions of MCs with protein phosphatases resulting in their irreversible inactivation. In view of its potential relevance to oxidative inactivation of MC-LR and other MCs present in potable water, in the present study, we have examined reactions of ozone (O_3) with methyl 2-acetamidoacrylate (M2AA), the latter being used as a model for Mdha moiety in MCs. It was found that the M2AA-ozone reactions performed at pH 2.0 and 7.0 have nearly identical changes in the absorption spectrum as those performed in deionized water. The pH-independent nature of the O_3-mediated oxidation and the presence of a single isosbestic point for reactions of M2AA with O_3 suggest that the reaction is a simple process wherein the initial step involves the formation of a primary ozonide (1,2,3-trioxolane) between O_3 and the olefinic (C=C) group of M2AA. From that stage, there is normal breakdown of the primary ozonide to carbonyl oxide and the aldehyde (or ketone) primary/secondary products. The reversed-phase HPLC analysis of the ozonation mixtures showed little or no evidence for the formation of secondary ozonide(s) of M2AA resulting from the retroaddition of carbonyl oxide and the adehyde product. The O_3-mediated oxidation appears to remove M2AA by >99% and results in the formation of aldehyde and ketone products, viz., methyl 2-acetamido-2-oxoacetate (analyzed by high resolution MS) and formaldehyde, i.e., in addition to H_2O_2. The formation of methyl 2-acetamido-2-oxoacetate and H_2O_2 were found to be stoichiometric with the yields of oxidation of M2AA. Based on the results presented, we believe several different oxidant systems consisting of either singly or in combinations of hypohalous acids, dichlor, trichlor, O_3/H_2O_2 and H_2O_2/UV, used during the pre- or post-treatment processes of potable and reclaimed water, can be studied similarly using M2AA to arrive at the most efficient method(s) of inactivation of MCs.

2348 *In Vitro* and *In Silico* Assessments of Dioxins for Polar Bear Aryl Hydrocarbon Receptor Transactivation Potency

J. Hwang[1], K. Kannan[2], T. J. Evans[3], H. Iwata[4], and E. Kim[1]. *[1]Kyung Hee University, Seoul, Korea, Republic of; [2]University at Albany, Albany, NY; [3]US Fish and Wildlife Service, Washington, DC; and [4]Ehime University, Matsuyama, Japan.*

Some of polar bear (*Ursus maritimus*) populations accumulate dioxins and related compounds (DRCs) including polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), and coplanar dioxin-like polychlorinated biphenyls (DL-PCBs) over thousands times of human OECD provisional tolerable monthly intake (70pg TEQ/kg bw). The aryl hydrocarbon receptor (AHR) mediates most of toxicities of DRCs. To evaluate the sensitivity and responses to DRCs via AHR in polar bears, we assessed the transactivation potencies of DRCs through polar bear AHR (pbAHR) by *in vitro* and *in silico* approaches. We constructed an *in vitro* reporter gene assay system that pbAHR expression plasmid and a reporter plasmid containing CYP1A1 promoter were transfected in U2OS cells. The treatment with each of nine DRC congeners induced dose-dependent responses in the *in vitro* assay system. The pbAHR was as sensitive to DRCs as C3H/*lpr* mouse AHR which is known to be highly sensitive to DRCs. Comparison of pbAHR transactivation potencies indicated that 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF had high induction equivalency factors (IEFs). Considering the accumulation levels of DRCs in polar bears, PCB126 was predicted to be the most active to pbAHR. The *in vitro* transactivation potencies of ligands for pbAHR exhibited a significant relationship with *in silico* ligand docking energies in a pbAHR homology model constructed from the human HIF-2α template, 3H7W. The protein ligand interaction fingerprint (PLIF) analysis suggested that several amino acids, which are highly conserved among mammals, may be involved in the species-specific responses to DRCs via backbone interactions with neighboring amino acid residues, which are specific to pbAHR.

2349 Metabolomic Profiling to Inform Use of Surrogate Species in Ecological Risk Assessments

R. F. Seim[1], D. A. Glinski[1], J. A. Awkerman[2], B. L. Hemmer[2], P. Harris[2], S. Raimondo[2], and M. W. Henderson[1]. *[1]US EPA/ORD, Athens, GA; and [2]US EPA/ORD, Gulf Breeze, FL.*

The US Environmental Protection Agency (US EPA) routinely uses avian and fish toxicity data to set protective standards for amphibians in ecological risk assessments. However, this approach does not always adequately represent aquatic-dwelling and terrestrial-phase amphibian exposure data. While there are multiple amphibian families within the US EPA's ECOTOX database, a lack of concordance of standardized tests used to collect amphibian data limits the ability to estimate the ecological effects of pesticides in these species and affirm the use of surrogate species data. For instance, it is widely accepted

that early life stage tests for fish are typically sensitive enough to protect larval amphibians, but metamorphosis from tadpole to a terrestrial-phase adult relies on endocrine cues that are less prevalent in fish. These differences suggest that more robust approaches are needed in order to adequately elucidate the impacts of pesticide exposure in amphibians across critical life stages. Therefore, in the current study, the perturbations in the metabolomic response of larval zebrafish (*Danio rerio*), a surrogate species frequently used in ecotoxicological studies, are compared to those of African clawed frogs (*Xenopus laevis*) and southern toad (*Anaxyrus terrestris*) tadpoles following exposure to high-use pesticides. These species were exposed to pesticides including, but not limited to, atrazine, bifenthrin, chlorothalonil, metolachlor, tebuconazole, or trifluralin over a targeted range spanning reported values beneath those eliciting acute toxicity. For metabolomic profiling, liver tissues or whole organisms were liquid-liquid extracted, derivatized and analyzed by gas chromatography coupled with mass spectrometry. Following spectral alignment and preprocessing, multivariate analysis was utilized to identify dose-dependent changes in the metabolome for each species and each pesticide. Numerous biochemical pathways, such as fatty acid synthesis, amino acid metabolism and the citric acid cycle are frequently impacted by pesticide exposure. Ultimately, data gathered will help inform the applicability of the use of surrogate species in establishing the risk pesticide exposure poses to amphibians and potentially other non-target species.

PS 2350 Development of Knockout Zebrafish (*Danio rerio*) to Understand the Protective Role of Rho-Class Glutathione *S*-transferase in Chemical-Induced Oxidative Stress

Y. Jo, R. Ramsden, M. Mills, and E. P. Gallagher. *University of Washington, Seattle, WA.*

Glutathione *S*-transferases (GSTs) are major detoxification enzymes important in cellular protection by metabolizing endogenous and exogenous substrates such as chemotherapeutic agents, insecticides, herbicides, and by-products of oxidative stress. Most higher organisms express a number of GST isoenzymes, including *alpha*, *mu*, *pi*, *omega*, *theta*, and *zeta*, but an additional GST class (GST rho, *gstr*), is found only in fish and other aquatic organisms. In this study, we developed zebrafish (*Danio rerio*) *gstr* knockout lines, then conducted sublethal and lethal dose toxicity studies using tert-butylhydroperoxide (TBHP) to determine the toxicological relevance of the *gstr* isoform in chemical-induced oxidative stress. Mutant zebrafish *gstr* knockout lines were developed through genome editing using CRISPR/cas9 targeting the coding sequence of zebrafish *gstr*. Wild-type and knockout zebrafish were exposed to TBHP at 96 hpf (hours post fertilization), and percent survival was documented every 24 hours. Fluorescence microscopy of acridine orange staining was used to image apoptotic cells in larval zebrafish 72 hours post toxicant exposure. Following a 72 hour exposure, *gstr* knockout zebrafish exhibited a distinctly steeper survival curve compared to that of wild-type zebrafish 168 hpf at 110 mg/L TBHP following 72 hours of exposure. Furthermore, following exposure to a sublethal concentration (70 mg/L) of TBHP, 168 hpf knockout zebrafish expressed increased presence of apoptotic cells in the body cavity, and were more likely to develop physical deformities such as spinal curvature and uninflated swim bladders. Ongoing studies are examining the effects of *gstr* of other of environmental chemicals that induce oxidative stress. Our studies indicate that the rho class GST isoform unique to aquatic organisms is likely a major antioxidant enzyme that mediates protection against oxidative stress. *Supported by NIEHS Superfund ES04696.*

PS 2351 Generation and Characterization of Monoclonal Antibodies against Killifish, *Fundulus heteroclitus*, AHR1a, AHR1b, AHR2a, AHR2b, and AHRR

K. A. Anderson[1], C. D. Rice[1], M. E. Hahn[2], and S. I. Karchner[2]. *[1]Clemson University, Clemson, SC; and [2]Woods Hole Oceanographic Institution, Redfield, MA.*

The AHR is a member of the basic helix-loop-helix (bHLH-PAS) superfamily of proteins and functions as a ligand-activated transcription factor for multiple responsive gene products. Most notable of these include phase I and II drug-metabolizing enzymes and transporters. Other gene products include proteins associated with cell cycle arrest, such as p21, p57, and p27. The AHR repressor (AHRR) is a negative feedback regulator of AHR signaling by competing with AHR for its dimer partner, ARNT. The AHR also binds NF-κβ, and is a tumor suppressor gene. Four aryl hydrocarbon receptor (AHR) genes (AHR1, AHR1b, AHR2, AHR2b) and a single gene for the repressor (AHRR) have been identified in the Atlantic killifish, *Fundulus heteroclitus*. The role of AHR(s) in the ability of killifish to adapt to environments polluted with PCBs and PAHs has been the subject of intense research. To date, data strongly indicate that AHR2 has the most prominent role in the killifish's ability to adapt to PCBs and PAHs, and primarily through genetic mutations in the ligand binding domain. Tissue-specific protein localization of the AHRs and AHRR in killifish have not been examined using monoclonal antibodies (mAb), and thus the impedance for us to generate a panel of mAbs. Monoclonal antibody 5B6 was generated against recombinant AHR2, mAb 7B8 against recombinant AHR1, and mAb 9R71 against recombinant AHRR. To generate non-cross reactive mAbs against recombinant AHR1b and AHR2b, synthetic immunogenic peptides were designed, yielding mAb 4A3-2 and mAb A2B-2, respectively. Using immunohistochemistry, we show that AHR2 is ubiquitously expressed in all tissues, and highly expressed in the liver, intestines, and brain. AHR2 is also highly expressed in some chemically induced liver tumors in fish sampled from the wild. Using mAb 5B6, we show that AHR2 is also detected in *F. Grandis*, a sister species. AHR1 was detected in the early stages of larval growth and confined to areas of intense bone formation. AHRR was detected in adult livers, and seems to be concentrated near, or within the bile canaliculi. To date, we have not detected AHR1b and AHR2b protein in adult killifish, though it is possible these proteins are expressed differentially during development. **1R15ES016905, **P42ES007381.*

PS 2352 Impact of Phenothiazine on *Fundulus heteroclitus*

C. L. McGinnis, J. B. Chiari, J. M. Laperche, J. M. Laperche, R. Patel, N. March, and G. Calvitto. *Quinnipiac University, Hamden, CT.*

Phenothiazine (PTZ) is a heterocyclic thiazine compound used for industrial and medical purposes. Through environmental surveillance studies PTZ was found being discharged into a local river in Connecticut. Phenothiazine has been shown to act as an endocrine disrupting chemical. This study sought to identify sex specific hormone receptor changes, a marker for endocrine disruption, in *Fundulus heteroclitus* in response to PTZ. *Fundulus heteroclitus,* also known as mummichog, are small fish native to the Atlantic coast of the United States and Canada. They reside in brackish waters and can survive harsh toxic environments. This model organism is native to the polluted waters found in Connecticut. In this study fish were exposed to concentrations of phenothiazine of 0.5ppm, 1.0ppm, and 2.0ppm for one week. Following exposure brain, liver, and gonad tissues were harvested; cDNA was synthesized; and mRNA expression was assessed for six different hormone receptors. When compared to vehicle control (ethanol) differences in mRNA expression levels of hormone receptors were observed in various tissues from male and female fish. Many of the tissues assessed showed changes in expression level, while only female liver and testis showed no change. These results implicate phenothiazine as an endocrine disrupting compound to mummichog at environmentally relevant concentrations.

PS 2353 Monitoring Colonial Waterbirds as Indicators for Reproductive and Immunological Impairments at Contaminated Great Lakes Sites during 2010-19

K. Grasman[1], L. Dykstra[1], G. Gardner[1], A. Triemstra[1], L. Williams[2], M. Annis[2], and C. Eakin[2]. *[1]Calvin University, Grand Rapids, MI; and [2]US Fish and Wildlife Service, East Lansing, MI.* Sponsor: K. Grasman, Society of Environmental Toxicology and Chemistry

This monitoring program assessed effects of contaminants, primarily PCBs and PCDDs, on immune function and reproduction in fish-eating birds in the Saginaw Bay and River Raisin Areas of Concern (AOCs) and Grand Traverse Bay in 2010-19 under the Great Lakes Restoration Initiative and AOC programs of the US Fish and Wildlife Service and US EPA. Saginaw Bay sites included two herring gull colonies (Confined Disposal Facility (CDF) and Little Charity Island), two Caspian tern colonies (CDF and Charity Reef/L. Charity Island) and one black-crowned night heron colony (CDF). Herring gulls were studied in the River Raisin AOC at the Detroit Edison Monroe Power Plant on the western shore of Lake Erie and on Bellow Island in Grand Traverse Bay. Reference sites were in the lower St. Mary's River (gulls on Pipe Island Twins and terns on Two Tree Island), on Tahquamenon Island in Whitefish Bay (terns), and on Chantry Island, Lake Huron (herons). Gull embryos were assessed during late incubation using a viability detector sensitive to heartbeat and movement. Relative risk ratios for embryonic nonviability were significantly elevated 2-3 fold at contaminated sites compared to the reference site (2.1 for the Saginaw Bay AOC, 2.6 for the River Raisin AOC, and 2.8 for Grand Traverse Bay). Infertility was the primary cause of nonviability at the reference site. Elevated infertility and mortality contributed to nonviability in contaminated sites. Deformities associated with PCBs and PCDDs were found in several individuals at contaminated sites (3 gull chicks at Monroe, 2 tern chicks on L. Charity, 3 gull embryos on the CDF, 1 gull embryo on L. Charity, and 1 gull embryo on Bellow). Chick productivity in terns in Saginaw Bay (mean of 0.76 chicks/nest) was signifi-

cantly below that of reference sites (1.19 chicks/nest). In the River Raisin AOC, productivity of gull chicks was poor in 4 of 10 years, with complete reproductive failure in 2010. In gull chicks the mean phytohemagglutinin (PHA) skin response for T-cell mediated immunity was suppressed 55-56% at both AOCs and 50% in Grand Traverse Bay. This response was suppressed 49% in terns and 39% in herons in Saginaw Bay. Mean antibody responses in gull chicks at the River Raisin AOC and in Grand Traverse Bay 1.6-2 fold lower than at the reference site. Ongoing immunological and reproductive impairments at these contaminated sites are consistent with the effects of persistent pollutants such as PCBs and PCDDs.

PS 2354 Occurrence and Toxicity of Metals and Polycyclic Aromatic Hydrocarbons in Marine Sediments from Cartagena Bay and Grand Marsh of Santa Marta (Ramsar Site), Colombia

K. Caballero-Gallardo[1], A. Juan Garcia[2], and J. Olivero-Verbel[1]. *[1]Universidad de Cartagena, Cartagena, Colombia; and [2]Universitat de València, Valencia, Spain.*

Cartagena Bay (CB) is considered an important industrialized site in Colombia. The aim of this study was to analyze the presence of metals of toxicological importance and polycyclic aromatic hydrocarbons (PAHs) in marine sediments from CB and in the Grand Marsh of Santa Marta (GMSM), a Ramsar coastal lagoon, used as a reference site (RS). The samples were collected in 15 stations (12 in CB and 3 in the GMSM) during dry and rainy seasons. In addition, the *in vitro* cytotoxicity of methanolic extracts from gathered sediments was assessed using HepG2 cells. The characterization of the sediments from the sampling sites was performed through the analysis of metals (Cr, Cu, As, Cd, and Pb) by Inductively Coupled Plasma Mass Spectrometry (*ICP-MS*), Hg was measured using a Hg analyzer, and PAHs were analyzed by capillary Gas Chromatography-Mass Spectrometry in Selected Ion Monitoring mode (GC-MS/SIM). Most contaminated sites in Cartagena Bay corresponded to stations related to repair and maintenance of ships, with high concentrations of Cr, Cu, As and Cd. Stations receiving inputs from petrochemical and fertilizer plants displayed high content of Pb. Maximum Hg levels were obtained near an extinct chlor-alkali plant. At least 70% of the samples from CB presented Cr, Cu, and As levels that were greater or equal to the Threshold Effect Level (TEL) and the Effects Range Low, suggesting adverse biological effects could occur occasionally. Potential ecological risk values revealed that Hg and Cd may generate deleterious effects on aquatic life. The Bay was classified as a site with low to moderate PAHs pollution. These compounds were especially observed in a station near a petrochemical industry. PAH concentrations in some stations from CB were greater than the TEL, while in the GMSM none of the stations exceeded this guideline. Some sediments from CB were able to reduce cell viability (<50%) in HepG2 cells. The data highlight the need to investigate the ecotoxicological implications of the evaluated pollutants in the environmental quality of these ecosystems. *Grant FP448442-197/2017 (COLCIENCIAS-University of Cartagena), COLCIENCIAS 567-2012, the General System of Royalties of Colombia, SGR, Government of the Department of Bolivar and University of Huelva.*

PS 2355 Clinical Syndromes of Mushroom Poisoning-A Five-Year Experience in North East India

I. Tiewsoh. *NEIGRIHMS, Shillong, India.* Sponsor: V. Kale

Mushroom poisoning is one which is frequently encountered in the tribal areas of the country of India as wild mushroom forms part of the diet in the ethnic tribes of the country. However at the same time a huge variety of these wild mushroom are known to be poisonous and one of the cause of fulminant hepatitis for which the definitive treatment being liver transplant .The case reports of mushroom poisoning has been reported in North India and South India among the tribes of the areas with the intake of wild mushrooms unintentionally. In the north east India little is known about the type of syndrome presentation in patients with mushroom poisoning and little awareness is being provided about the non edible mushroom in this region. Here we are prerenting the clinical syndrome which we have encountered in the last 5 years from 2015 till August, 2019 in our tertiary hospital of the state of Meghalaya, which is a situated in the north eastern part of the country. All patients admitted to the hospital with history suggestive of mushroom poisoning were included as cases January 2015 to August 2019 and all relevant information were recorded in a structured performa. A descriptive analysis of all collected variables was carried out. Over 39 cases of mushroom poisoning presented to our hospital in the last 5 years, mainly in the the raining season (March- May) and autumn season (August -October). All cases were from the tribal areas of the four neighbouring 4 districts of the state. The wild mushrooms were self picked from the forest. 25 patients had developed early symptoms (less than 6 hours) and were less fatal, however 16 patients developed the symptoms after 6 hours of consumption, and were more seriously ill out of which 6 cases expired due to acute hepatic failure. The clinical syndrome presentation were acute gastroenteritiswith liver failure in 11 cases (suspected *Aminata* poisoning), 20 cases of acute gastritis and gastroenteritis (suspected mushroom species *Chlorophyllum molybdites*, *Clitocybe nebularis*, *Omphalotus illudens*), one case of Acute renal failure (suspected *Cortinarius violaceus* species), one case showing Disulfiram like reaction (suspected *Coprinus atramentarius*, *Clitocybe clavipes* species), 5 cases of Cholinergic mushroom poisoning (suspected *Citocybe dealbata*, *O. illudens*, *Inocybe fastigiata* species) and one case presented only with migraine. The mortality from mushroom poisoning resulted mainly due to fulminant hepatitis in 6 cases. Conclusion: With the five years observational study of mushroom poisoning in this part of the country the cause is mainly due to consumption of wild poisonous mushrooms, with amanita species type being responsible for most of the fatalities. From the clinical syndrome presentation and on visiting the affected areas, the *Aminata* species seems to be common, a variety of the other poisonous mushroom are also present as evident from the clinical presentation. The *Aminata* like species has been identified at the affected villages with our insight to their anatomical structure. With this study we aim to carry out toxicological analysis of the blood and urine samples of patients we present in future mainly for the amatoxin.

PS 2356 The ECOTOXicology Knowledgebase: Updating Literature Search and Review Processes for Identifying and Curating Toxicity Data for Risk Assessments

C. Elonen[1], J. Olker[1], A. Anderson[2], A. Pomplun[2], C. Suomi[2], B. Kinziger[2], A. Pilli[2], and D. Hoff[1]. *[1]US EPA, Duluth, MN; and [2]GDIT, Duluth, MN.* Sponsor: M. Hornung

The ECOTOXicology Knowledgebase (www.epa.gov/ecotox) is a nationally and internationally recognized source of curated single-chemical toxicity data for aquatic life, terrestrial plants, and wildlife. This publicly available database provides industry, federal and state regulators, and researchers with a cost-effective, non-duplicative means of locating high-quality ecological effects data to support chemical decision making. Through its 30+ year history, ECOTOX has developed systematic and transparent procedures to conduct comprehensive literature searches, title/abstract screenings, application of acceptance criteria, and data extraction of all pertinent study and effects information. The current rate at which chemicals are reviewed and data evaluated requires modernization and improved efficiency in the well-established ECOTOX review protocols, as well as to increase effectiveness of the user interface and interoperability across multiple sources of toxicity, chemical, and species data. Here we present efforts to refine and implement tools to improve current procedures, integrate ecological data with human health evidence mapping, and incorporate information of study quality into ECOTOX. Steps in the literature search process now include consistent application of search terms which allow resulting references to be used for evidence mapping, systematic reviews, scoping documents, risk assessments, and regulatory decisions. These efforts were followed by development and application of semi-automatic processes to document literature search terms, and modification of literature acquisition and systematic review tools. Further efforts to improve efficiencies have incorporated study quality information through identification of those used for regulations (e.g., Water Quality Criteria documents, EFED Risk Assessments). Finally, new and enhanced additions to the user interface will enhance the interoperability with other databases and tools. The updated functionality and interoperability will provide the regulated industry and researchers more effective methods to search and use existing toxic effects data to determine thresholds and conduct risk assessments.

PS 2357 Consumption of Contaminated Aquatic Species Alters the Mammalian Gut Microbiome

R. Kim[1], D. Saxena[2], S. Pushalkar[2], and T. Gordon[1]. *[1]New York University Langone Health, New York, NY; and [2]NYU College of Dentistry, New York, NY.*

Strong evidence suggests that fish and crabs inhabiting the Passaic River/ Newark Bay area, a superfund site in NJ, are contaminated with toxic agents including heavy metals and polycyclic and polychlorinated aromatic hydrocarbons. Despite published warnings to avoid consumption of contaminated fish, this practice continues in high numbers, particularly amongst anglers and their families in low-income communities. We hypothesized that consumption of "dirty" fish produces alterations in the GI tract microbiome. The GI tract microbiome encompasses metabolic, immune, and endocrine com-

munication and function in the host. It contributes to the maintenance of health, and when altered, can significantly influence susceptibility to, and phenotypes of diseases like CVD, obesity, and diabetes. While microbiota disruption is common in humans, the response to environmental stressors like dioxin, PCBs, and heavy metals has not been well characterized. To test our hypothesis, we utilized mice that were fed a 7-day baseline diet. This was followed by 10 days of autoclaved diets supplemented with a 2.5% or 7.5% "contaminated" or "clean" eel, sourced from the Passaic River or pristine Upper Delaware River, respectively. 16s ribosomal RNA was isolated from feces and sequenced at ~10,000 reads per sample using Illumina MiSeq. Principal Component Analysis (PCA) was used to examine the effects of diet and sex on GI tract microbial diversity in the mice. On day 1 of the dirty eel supplement, the community structure began to diversify. By day 9, a significant difference in microbiota makeup was seen in mice fed the 7.5% dirty eel diet. This effect was sex- dependent and the greatest changes were seen in male mice. These data demonstrate that consumption of contaminated aquatic species alters the mammalian gut microbiome. A similar experiment was conducted to explore microbiome changes in mice exposed to e-cigarette aerosols. Together, our data suggest that everyday environmental exposures can result in significant composition shifts of key bacterial communities that maintain host health.

2358 Toxicogenomic and Reproduction Effects in *Tribolium castaneum* Herbst after Exposure to Volatile Aromatic Compounds

N. P. Pajaro-Castro[1], K. Caballero-Gallardo[2], and J. Olivero-Verbel[2]. *[1]Universidad de Sucre, Sincelejo, Colombia; and [2]Universidad de Cartagena, Cartagena, Colombia.*

Volatile organic compounds (VOCs) such as naphthalene and benzene are widely used. Naphthalene is still being employed as a moth repellant; it is sold at supermarkets, and benzene is employed in diverse chemical and industrial processes. The aim of this study was to evaluate the toxicological effects of these VOCs against *Tribolium castaneum*. Exposure of adult insects at different concentrations of naphthalene (0, 40, 80, 120, 160 and 200 mg/L air) and benzene (0, 40, 80, 120, 160 and 240 µL/L air) were impregnated on filter paper disks, and placed on the underside of the screw cap of a glass vial. Ten insects were introduced in each vial without media before the cap was screwed tightly. The number of dead insects was counted after 24 and 48 h. LC_{50} values were calculated. Also, adult insect two-week-old were fed a diet of ground oatmeal and oat flakes 70:30, supplemented with naphthalene. Rearing of insects was performed in a glass jar with a maximum of 40 animals. The crops from insects were reviewed every 4 days, evaluating the number of larvae, size and observation of abnormalities. The LC_{50} for naphthalene and benzene to 48 h of exposure were 72.52 mg/L and 115.87 µL/L, respectively. At the highest concentration, these chemicals caused more than 80% of insect mortality. Furthermore, Real Time PCR analysis revealed the activation of oxidative stress and metabolism, and reproduction markers for insect exposure on naphthalene at concentrations of 80 mg/L at 4 hours of exposure. Adults exposed to benzene (80 µL/L at 4 hours) overexpressed genes related to neurotransmission, and reproduction. Naphthalene affected development producing abnormalities in larval and pupal stages. In the larval stage, it induced changes in the formation of limbs, swelling in the chest and lower sclerotized appendages. In the case of the pupae, induced occurrence of abnormality in the formation of limbs, wings, and abdomen. The data presented here provide evidence that VOCs inhalation in our experimental conditions is able to induce alteration of reproduction, oxidative stress, and death of the insect. *The National Program for Doctoral Formation (Colciencias, 567-2012).*

2359 Assessment of the Toxicological Effects of Young Landfill Leachate on *C. zizanioides* and Its Phytoremediation Ability

F. L. Toscano-Mouthon, A. Doria-Manzur, L. P. Mallarino-Miranda, and L. P. Tejeda-Benitez. *Universidad de Cartagena, Cartagena, Colombia.*

Landfill leachates have a complex composition, which includes organic matter, ammoniacal nitrogen, heavy metals, among others. Without being treated, they could be an imminent source of contamination of surface and groundwater, thus, studies and advances in sustainable technologies are required for this purpose. This research assessed the potential of the macrophyte *Chrysopogon zizanioides* in the phytoremediation of young leachate. For this, morphological changes and metal uptake of Cadmium, Lead, Nickel and COD of the plant was measured after exposing it to concentrations of 25%, 50%, 75% and 100% of synthetic young leachate. Using the specified concentrations, plant growth was affected, decreasing in more than 50% for concentrations of 25% and 50%, compared to control. On the contrary, higher concentrations showed exponential growth during the experiments, plus, plants health and color improved in these concentrations. Metal uptake of Cadmium was up to 98,4%, 94,4%, 95,8%, 96,1%, Nickel 94,8%, 97,7%, 98,7%, 97,6%, and Lead 98%, 92.7%, 97%, 94%, suggesting the plant is a suitable model for phytorremediation of landfill leachate.

2360 Toxicological Effects and Phytoremediation of Zinc Oxide Nanoparticles in Hydroponically Grown Sorghum (*S. bicolor*) and Alfalfa (*M. sativa*)

A. Doria-Manzur, Y. Hernandez, D. Vargas, F. Toscano-Mouthon, and L. P. Tejeda-Benitez. *Universidad de Cartagena, Cartagena, Colombia.*

Nanomaterials have gained rising popularity in recent years thanks to their numerous applications and use thanks to their tiny size and high surface area, such is the case of Zinc oxide nanoparticles, which are among the most popular engineered nanoparticles as a result of its antioxidant and antifungal capacities. This rising popularity has led to their massive production and thus to an increase in its accumulation in the environment, especially in soils and consequently crops. In comparison to their bulk size, nanomaterials have different toxicological effects related to not only their size but also to their aggregation and sorption capacities, provoking their biopersistence and biomagnification. The goal of this study is to determine the toxicological effects which occur during the exposition to Zinc oxide nanoparticles (ZnONPs) using hydroponically grown Sorghum (*Sorghum bicolor*) and Alfalfa (*Medicago sativa*) as biomarkers, as well as its effects on the zinc uptake of both plants to evaluate their phytoremediation capacities. The seedlings were hydroponically grown using Hoagland's medium of half strength and exposed to concentrations of 0, 50 and 100 ppm of ZnONPs for a period of 7 days. Physiological data were taken for both plants before and after exposition, as well as data related to the water consumption of the plants. After the contamination stage, the remaining biomass was exposed to a digestion process for the quantification of the zinc content of the plant and the contaminated medium through atomic adsorption. All treatments presented symptoms of both chlorosis and necrosis, as well as root browning and growth inhibition. The alfalfa plant exhibited worse toxicological effects than sorghum, in both physical appearance as well as in growth, while sorghum, in spite of presenting growth inhibition and partial chlorosis, seemed to have a better resistance with the ZnONPs. The Zinc uptake in both plants was related to the ion release capacity and behaved similarly, however the alfalfa plant had higher uptake of the zinc ion due to its affinity with the metal, however this affinity led not only to an accumulation but also to an increase on its toxicity. Finally, the ZnONPs have moderate toxic effects in both plants, being more remarkable in the alfalfa plant but also giving hints of a remediation process making it an useful resource for zinc removal.

2361 Ultraviolet B Radiation-Induced DNA Damage in Southern Oak Tree Species

S. Kasibhatla, V. Ferchaud, Y. Qi, and R. M. Uppu. *Southern University and A&M College, Baton Rouge, LA.*

Ultraviolet B radiation (UV-B) is a great cause for concern due to its role in DNA damage. This is especially true for plants because of their sessile nature. UV-B interacts strongly with DNA and this, among other things, results in the formation of two kinds of DNA damage products, namely, cyclobutane pyrimidine dimers (CPDs) and 6,4-photoproducts (6,4-PPs). If left unrepaired, these DNA lesions can impede replication and transcription, thereby causing cytotoxicity and *mutations*. In plants specifically, these DNA damage products can suppress photosynthesis and protein biosynthesis. This can lead to stunted growth, reduced yield, productivity and development. Towards understanding the nature of UV-B-induced DNA damage and the possible UV-B tolerance, we have collected leaf samples from six different broad leaf species on the Southern University campus in Baton Rouge, Louisiana during the spring (March and April), summer (June and July), and fall seasons (October and November) in the year 2017. In spring, new budding leaves, for summer, mature leaves and for fall senescing leaves were selected. In each season, the tree branches were clipped randomly from the most sun-exposed part. Following cleaning with wet wipes or 1% bleach (if required), the leaves were randomly selected, and their chlorophyll content was measured (Spad chlorophyll meter) to make sure all the leaves selected for analysis were in the same growth phase. The leaves (10-50) per species were placed in zip-lock bags and stored at -80ºC until further experimentation which included DNA extraction (Qiagen) and analysis of CPDs and 6,4-PPs (ELISA). The CPDS and 6,4-PPs were analyzed typically using 500 pg DNA. The results indicated that all six different oak species studied, namely, *Quercus virginiana* (southern live oak), *Q. acutissima* (sawtooth oak), *Q. nigra* (water oak), *Q. phellos* (willow oak), *Q. shumardi* (Shumard oak) and *Q. nuttalii* (nuttal oak) had evidence of DNA damage which varied with the tree species studied and the seasons (spring, summer and

fall) in which the samples were collected. This study gives an idea into better understanding of the UV-B tolerance developed by different species to cope with the intense and unrelenting solar UV-B radiation, especially in light of the enhanced UV-B radiation level due to ozone holes developed in the Earth's stratosphere.

2362 Skin Microbiome-Survey of Cosmetic Products on the US Market

O. Rentsendorj, V. Tsai, L. Katz, and N. Sadrieh. *US FDA, College Park, MD.*
Sponsor: Z. Wang

With probiotics becoming widely commercialized in foods and drugs, we have started to see its appearance in cosmetics. From 2013-2017, the US Food and Drug Administration (US FDA) has observed an increasing number of cosmetics claiming to contain ingredients that may potentially impact the skin microbiome. Mintel Market Research, in this same time period, reports that the use of *LactoBacillus*-based probiotic skincare products increased by 98% in the US To gain a better understanding of this growing market, US FDA conducted an evaluation of US launched cosmetic products that target the skin microbiome between 2003 and 2018, using the publicly available Global New Product Database (GNPD) by Mintel. We found 255 cosmetic products marketed during this time frame claiming to use probiotics. In examining the data further, we found that probiotic skincare products in the US more than doubled in 2018 compared to 2017 (70 vs 29 products, respectively). Many of the products claim to use probiotics and probiotic-derived ingredients. Our analysis also shows that there are three distinct approaches being used by the cosmetic industry to target the skin microbiome: 1) probiotics (the infusion of live cultures), 2) prebiotics (non-viable nutrients intended to promote "good" skin microbiota), and 3) postbiotics (non-viable soluble factors or metabolic by-products secreted or released after bacterial lysis, such as ferments, lysates, filtrates or extracts). Interestingly, regardless of which approach is stated in the ingredient list (probiotic, prebiotic or postbiotic), approximately 90% of the 255 cosmetic products were found to contain postbiotics. Product label reviews showed that *LactoBacillus* is the genus most often used as the probiotic ingredient or probiotic derivative. While 93/255 (36%) "probiotic" products claim that they have no additives or preservatives, further analysis revealed that the majority (95%) contain a combination of different preservation systems.

2363 Optimized Long-Term Skin Organ Cultures to Assess Dermal Toxicity Risks

R. Li[1], A. Jamin[1], H. Dacq[1], S. Rohou[2], C. Lejamtel[2], B. Lopez[2], S. Martin[2], K. Cuddapah[3], R. Friis[3], D. Steen[4], and C. Chesne[1]. *[1]Biopredic International, Saint Gregoire, France; [2]Eurosafe, Saint Gregoire, France; [3]Curio Biotech SA, Visp, Switzerland; and [4]Biopredic Inc., Kansas City, KS.*

Skin organ culture technology can play an integral role in all aspects of skin biology and skin damage research. Different skin models, such as 3D-reconstructed skin or standard 2D monolayer cell culture, have been used for biological skin studies and for ingredient or finished product testing. However, the major limitation of those models is the lack of skin native complex architecture because of containing at best 2 or 3 cell types. Skin native explants remain the relevant physiological model that best mimic *in vivo* situation, but skin explants can be cultivated only in a short-term period at 32°C. Therefore many efforts were made on developing an optimized culture medium for maintaining long-term skin explant/organ cultures and so that for providing a suitable *in vitro* model for prediction and classification of skin irritation, corrosion, sensitization as well as skin metabolism. Regarding irritation and xenobiotic metabolism studies, the well maintained and physiological skin organ culture can be a key condition. We aimed at developing a novel defined and animal component free skin culture medium 1) for long-term of skin explant culture, up to 2 to 5 days of transport/storage at 4°C followed by 14 days at 32°C with good skin structure integrity and physiological functions; 2) for an optimized *in vitro* skin culture model to predict dermal toxicity risks and metabolism capability. Results: We observed 1) a prolonged viability of skin explants and well-preserved epidermis-dermis junction in optimized medium up to 14 days; 2) a variations of impedance during transport/storage and culture in both media; 3) a good predictivity of induced irritation and a stable metabolic activity to the long-term skin culture compare to short-term skin culture. Optimized animal component free skin long term culture medium maintained a better preservation of explants up to 14 days of skin culture in comparison to that of the classical medium (3-5 days only). This optimized medium appears to be a relevant solution for long term-tested pharmaceutical and cosmetic products. The dermal toxicity and metabolism testing results obtained from the skin cultured in optimized long term medium are comparable to those of short term skin culture.

2364 An *In Vitro* Cell Model for Toxicity Studies and Pigmentation Regulation Utilizing hTERT Immortalized Neonatal Dermal Melanocytes

M. Spencer, J. Huuskonen, and L. G. Rodriguez. *ATCC, Gaithersburg, MD.*

Skin pigmentation is a complex process; melanocytes produce melanin and package it into melanosomes that are in turn exocytosed, then endocytosed by neighboring keratinocytes. Numerous genes play roles in controlling pigmentation at various levels of melanin production. Mutations in these genes are characteristic of multiple skin disorders, including hyperpigmentation, hypopigmentation, and mixed hyper-/hypopigmentation. Additionally, extrinsic factors secreted by the surrounding resident cell types also regulate the melanin expression in melanocytes. Human primary cells can be a useful model for elucidating melanocyte biology and their toxicity to dermal agents. However, primary cells have their limitations such as donor variability and limited lifespan. Consequently, a need exists for a more robust human cell model system for the study of skin pigmentation and agents which are toxic to melanocytes. In this study, we immortalized primary epidermal neonatal melanocytes by expressing human telomerase reverse transcriptase (hTERT) in cells that were isolated from a neonatal donor. The immortalized primary melanocytes were cultured continuously for more than 35 population doublings without any signs of replicative senescence, yet retained melanin production. The immortalized primary melanocytes maintained a consistent expression of the melanocyte-specific marker TRP-1, and lacked expression of the fibroblast-specific marker TE7. In addition, we demonstrate the capability of these immortalized primary neonatal melanocytes to transfer melanosomes to keratinocytes utilizing a 3D human dermal organotypic culture, and the ability to modulate melanogenesis with depigmentation agents and these agents' effects on cell viability. Taken together, the hTERT immortalized primary neonatal melanocytes described here provide a versatile *in vitro* cell model for the study of cosmetic agents, their toxicity and melanogenesis regulation.

2365 Tetramethylammonium Hydroxide (TMAH) Contamination on Human Skin Explants *Ex Vivo*

L. Mathieu[1], F. Burgher[1], L. Peno-Mazzarino[2], E. Lati[2], H. I. Maibaach[3], and A. H. Hall[4]. *[1]Laboratoire Prevor, Valmondois, France; [2]Laboratoire BIO-EC, Longjumeau, France; [3]University of California San Francisco, San Francisco, CA; and [4]Toxicology Consulting and Medical Translating Services, Azle, TX.*

Tetramethylammonium hydroxide (TMAH) is a quaternary ammonium compound and strong corrosive base. It dissociates into TMA^+ and OH^- ions, causing chemical skin/eye injuries and sometimes fatal systemic toxicity. Dermal injury from the OH^- ion may increase TMA^+ tissue penetration. This study was performed to evaluate general morphology effects of TMAH contamination on human skin explants *ex vivo*. With informed consent, 60 human skin explants were prepared from an abdominoplasty sample and preserved *ex vivo* in BIO-EC's Explant Medium at 37° C in a humid atmosphere containing 5% CO_2. Explants were divided into 13 groups: (1) untreated controls, (2-13), explants exposed to 25% TMAH solution for different time periods - 1, 5, 10, and 20 minutes, 1, 2, 4, 8, and 24 hours. TMAH was applied on a 9mm filter paper saturated with 30 µL. Duplicate explant samples were taken from all groups on Day 0, and compared with triplicate samples from all groups at 24 hours post-exposure. Samples were either fixed in buffered formol or preserved frozen at -80°C. Samples were prepared for histological evaluation. Sample preparation: dehydration and impregnation into paraffin using a Leica PEARL automatic dehydrator, then cut into blocks with a Leica EG 1160 coating station. 5 µm slices were prepared with a Leica RM Minot-type microtome and mounted on glass Superfrost® slides. Slides were stained with the Goldner variant of Masson's Trichrome. Optical microscopy was performed with a Leica-type DML-B or Olympus BX42. Photomicrographs were taken with an Olympus DLP72 and Cell software. After a 25% TMAH contact time of 1 hour, the general morphology of epidermis and dermis were totally altered. With longer contact times, 2 of 3 explants were very significantly altered. However, alterations were irregular (2 of 3 explants). Alterations were observed at 24 hours after a 20 minute contact time. Based on these results, for future studies in this model, a 25% TMAH solution contact time appears to be the best option and >3 samples could minimize possible sample heterogenicity.

2366 Increasing Dose Recovery from Unoccluded Static Diffusion Cell Studies

C. Dalton, J. Kearn, and S. Graham. *Dstl, Salisbury, United Kingdom.*

Determination of percutaneous penetration is typically achieved using *in vitro* skin diffusion cell methodology. A number of protocols and guidelines have been published to ensure the reliability of results obtained by this method. Perhaps the most useful of these is the Organisation for Economic Co-operation and Development (OECD) guideline 428 and its associated guidance documents, which set the standard as to what is acceptable when conducting *in vitro* skin penetration studies using diffusion cells. These guidelines attempt to ensure that *in vitro* studies are carried out appropriately and aim to reduce variability from laboratories within different organisations. One of the guidelines concerns dose recovery and stipulates a recovery requirement of 100 +/- 10% of the applied dose. For unoccluded studies, using volatile chemicals, this is not feasible unless vapour capture methodology is used. The current work evaluated a charcoal filter system as a means of vapour capture. *In vitro* percutaneous absorption experiments were performed with Franz-type glass diffusion cells with an area available for diffusion of 2.54 cm^2. The receptor fluid used was 50% aqueous ethanol. A total of 8 cells were assembled for each test condition (control unoccluded; Tin foil occluded; charcoal filter). A 10µl droplet of 14C-methyl salicylate was applied to each piece of dermatomed human skin (500 µm thickness, obtained with informed consent from reduction surgery). Samples of receptor chamber fluid were removed at regular intervals up to 24 h post exposure. A full dose distribution was performed at study completion. The presence of the charcoal filter increased total recoveries from 30% for the unoccluded control to 95% allowing the study to meet OECD guidelines. The presence of the charcoal filter also increased the skin penetration of methyl salicylate relative to the unoccluded control. This increased penetration was not as pronounced as for the cells occluded with tin foil. It is important to understand the potential consequences of incorporating vapour capture technologies into diffusion cell systems.

2367 *In Vitro* Dermal Absorption of Carfentanil

E. M. Lent[1], K. Maistros[2], and J. Oyler[2]. *[1]Army Public Health Center, Aberdeen Proving Ground, MD; and [2]US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.*

There is growing concern regarding potential occupational exposures to the ultra-potent synthetic opioid carfentanil. However, little data are available on the toxicity of carfentanil in humans, particularly for dermal exposures. To begin to address this, permeation of carfentanil formulated in three vehicles, water, ethanol, and hand sanitizer was measured under infinite-dose conditions in an *in vitro* static diffusion cell system using the EpiDerm™ (EPI-606-X) RhE model. The permeation rate was fastest for carfentanil in water (3.9×10^{-3} cm/hr), followed by hand sanitizer (1.2×10^{-3} cm/hr), and slowest for carfentanil in ethanol (0.2×10^{-3} cm/hr). In both ethanol and hand sanitizer, a lag-time between exposure and permeation of approximately 1.5 hours was observed, while lag-time in water was approximately half an hour. Flux at steady-state was greater at 50.6 µg/ml than at 5.3 µg/ml for both water and ethanol; however, the percent of dose absorbed did not differ between doses for either vehicle. Slight differences in percutaneous permeation of carfentanil were observed between two brands of hand sanitizer, likely due to differences in relative proportion of alcohol and skin penetration enhancers. These data indicate that small skin exposures may not result in rapid, significant toxicity as previously reported.

2368 Suitability of *In Vitro* Skin Assays for Acrylic and Methacrylic Monomer-Based Adhesives

A. Hoerst[1], K. R. Mewes[1], A. K. Cuevas[2], and M. Hermann[1]. *[1]Henkel AG & Co. KGaA, Duesseldorf, Germany; and [2]Henkel Corporation, Stamford, CT.*

In vitro skin irritation assays based on reconstructed human epidermis (RhE) models are widely accepted to accurately identify non-corrosive and corrosive chemicals and mixtures in accordance with UN GHS. It is known that undiluted acrylic and methacrylic monomers are often either corrosive or irritating to skin due to their acidity. To assess the skin corrosion potential of certain monomers and adhesives, skin corrosivity tests according to OECD Test Guideline (TG) 431 were performed using the Open Source Reconstructed Epidermis (OS-REp) model. Technical proficiency was demonstrated for all twelve Proficiency Substances listed in OECD TG 431. All substances, amongst them six acids, were correctly classified and subcategorized as Cat. 1A or 1B/C corrosives. None of the monomers interfered with the OECD TG 431 assay by unspecific MTT reduction or pH-dependent shift of the MTT formazan absorption maximum. Existing *in vivo* data demonstrate that acrylic acid, methacrylic acid, and 2-hydroxyethyl methacrylate phosphate are skin corrosives. However, already a concentration of only 2% acrylic acid and methacrylic acid, respectively, triggered a corrosive classification when tested in OECD TG 431. In addition, the irritant compound methyl methacrylate was incorrectly predicted as corrosive. All tested adhesives with methacrylic acid and methyl methacrylate yielded corrosive results. No correlation was found between the content of corrosive ingredients and the extent of corrosive effect. Surprisingly, histopathological evaluations and determination of cell viability by means of lactate dehydrogenase measurement do not always confirm the corrosive results of OECD TG 431. The current study demonstrates that the OS-REp skin model can be used for corrosivity testing in OECD TG 431 to assess product safety. Our results also indicated that adhesives materials such as acrylic and methacrylic monomers might fall outside the applicability domain of this test guideline.

2369 Formal Validation of the GARD™potency Assay for Subclassification of Chemical Skin Sensitizers—Ring Trial Results of Predictive Performance and Reproducibility

R. Gradin[1], A. Johansson[1], A. Forreryd[1], E. Roggen[2], and H. Johansson[1]. *[1]SenzaGen AB, Lund, Sweden; and [2]3RsMC Aps, Kongens Lyngby, Denmark.*

The advancement of non-animal approaches for hazard assessment of skin sensitizers have generated a variety of alternative assays that covers relevant aspects of the known sensitization mechanisms, and that exhibits discriminatory properties competitive with those of accepted *in vivo* methods. However, hazard identification is rarely sufficient and information permitting the relative ranking of chemicals' skin sensitization potency is desired. For example, the globally harmonized system of classification and labelling of chemicals (GHS/CLP) extends the binary hazard assessment with a qualitative subcategorization to distinguish weak skin sensitizers from strong. Though substantial efforts have been made towards developing alternative methods for potency assessment, none have gained regulatory acceptance. In contrast, the regulatory accepted *in vivo* method, the murine Local Lymph Node Assay (LLNA), provides a quantitative readout that is relevant for potency assessment. Considering the ethical aspects and the implementation of new regulations, the development of improved alternative assays is of high priority. The genomic allergen rapid detection (GARD™) is an *in vitro* testing platform for assessment of chemical sensitizers. Though originally developed for skin sensitization hazard assessment, recent developments allowing for subcategorization of chemicals in accordance with GHS/CLP categories showed promising results. To validate the GARD™ assay for assessment of skin sensitizer potency (GARD™potency), a ring-trial study was carried out in compliance with the OECD guidance document No. 34. Reproducibility estimates of the assay ranged between 62.5% and 88.9% within participating laboratories. Between laboratory reproducibility was calculated to 61.1%. The predictive performance estimates ranged between 76.5% and 94.4% for individual laboratories, and the cumulative accuracy was summarized to 88.0%. The results suggest that the GARD™potency assay could be a valuable tool for hazard characterization of skin sensitizer potency. The assay is included in the OECD Test Guideline Programme (TGP 4.106) and is suitable for submissions under REACH.

2370 Elucidating Mechanism of Toxicity of Contact-Sensitizing Hair Dye Components by *In Silico* Approach

T. Krsmanovic[1], K. Jankovic[1], D. Mitic Potkrajac[1], G. Apic[1], and R. B. Russell[2]. *[1]Metisox, Cambridge, United Kingdom; and [2]Heidelberg University, CellNetworks, Heidelberg, Germany.*

More than 15% of the general population have allergic contact dermatitis as a clinical manifestation of contact sensitization, making this skin disease a major health problem. Screening for contact-sensitizing chemicals is highly relevant, particularly in dermatology. Ethical considerations, need for high-throughput screening and legislation (e.g., for cosmetics in the European Union) are limiting the use of animal tests for this purpose. Although hair dye substances, that are strong or extreme sensitizers, are very common in consumer hair dye products on the European market, at present it is not possible to accurately estimate the overall burden of hair dye allergy in dermatitis patients. Dermatitis patients are generally patch tested with one substance only, namely p-phenylenediamine. The goal of the study was to develop knowledgebase and software tool that can be used to predict potentially harmful interactions between chemicals as an alternative to animal test

methods. From the public domain and proprietary company datasets, we collected data on chemicals contained in a variety of consumer products such as health and beauty aids, household products, drugs and food. We generated computable networks of interacting chemicals, genes, proteins, pathways, and biological effects, providing extensive information on chemicals and their biological effects on organisms. To validate our approach, we used the three ingredients commonly used in permanent hair dye formulations (p-phenylenediamine, PPD; Resorcinol, RES and hydrogen peroxide, H_2O_2), and demonstrated how simultaneous exposure may result in one chemical augmenting the toxic effects of the other. Our computational tool shows that RES and PPD target molecules that are involved in inflammation and allergy reactions like cytochrome P450 protein CYP1A1, CYP3A4, prostaglandin synthase PTGS2, chemokine receptors CXCR4, CCR6 and cytokines IL8, IL5. Further, our system identified correlation between these two chemicals and various skin conditions such as skin sensitization and skin inflammation. Bioinformatics analysis provides the underlying mechanism of how exposure to these hair dye components can induce skin sensitization, and assumed explanation of additive and/or synergistic effect observed with these three chemicals.

2371 Effectiveness of h-CLAT, an *In Vitro* Skin Sensitization Test Method, in Evaluating Respiratory Sensitizers

T. Ashikaga[1], K. Narita[2], H. Okutomi[2], K. Kawakami[2], and H. Sui[2]. *[1]National Institute of Health Sciences, Kawasaki, Japan; and [2]Food and Drug Safety Center, Hatano Research Institute, Hatano, Japan.* Sponsor: H. Kojima

Respiratory sensitization induced by chemicals is an important occupational and public health issue because it is associated with allergic asthma or other pulmonary symptoms. However, there are no validated test methods which can identify respiratory sensitizers. In this study, in order to investigate behavior of respiratory sensitizers in skin sensitization test method, 14 known respiratory sensitizers such as diisocyanate, acid anhydride, platinum salts, aldehyde, ethylenediamine, reactive dye and flavoring agent were tested with h-CLAT. h-CLAT (listed in OECD TG442E) is an *in vitro* skin sensitization test, which evaluate dendritic cell activation by measuring the expression of the cell surface CD86 and CD54 antigens in THP-1 cell line. As a result, 7 of 14 respiratory sensitizers were resulted in positive with h-CLAT. Especially in diisocyanates which are very important industrially compounds as polyurethane materials, all four respiratory sensitizers were positive. Furthermore, for 3 acid anhydrides which showed negative results in h-CLAT, we also performed modified h-CLAT (short time exposure method using liquid paraffin) and phthalic anhydride was positive with the modified method. Among 7 false negatives in h-CLAT, at least 4 chemicals are known to be positive in DPRA (other *in vitro* skin sensitization test method listed in OECD TG 442C). These results suggest that h-CLAT could be useful non-animal test method with respect to respiratory sensitizers if combined with other test methods like DPRA.

2372 Applicability of GARD™skin for Accurate Assessment of Challenging Substances in the Context of Skin Sensitization Testing

J. Schmidt[1], A. Forreryd[2], and H. Johansson[2]. *[1]SenzaGen Inc., Raleigh, NC; and [2]SenzaGen AB, Lund, Sweden.*

Proactive identification of chemicals with skin sensitizing properties is a key toxicological endpoint within hazard testing. To date, several *in vitro* assays for assessment of skin sensitizers have been proposed, some of which have gained various levels of regulatory acceptance. However, certain subsets of the chemical space relevant for testing remain challenging to accurately assess. Such challenging substances may include substances with severe membrane-damaging properties, pre- and pro-haptens, or substances with high logP-ratios. The GARD™skin assay (Genomic Allergen Rapid Detection) is a state-of-the-art non-animal-based testing strategy which evaluates the transcriptional patterns of endpoint-specific genomic biomarker signatures in a human dendritic-like cell line following exposure, in order to provide machine learning-assisted classifications of tested substances. The assay was recently subjected to a formal validation procedure (OECD TGP 4.106) and reported reproducibility between laboratories of 92%, as well as a predictive accuracy of 94%. Here, we provide data demonstrating the applicability of GARD™skin in such a challenging chemical space, using an overlapping subset of chemicals previously tested in an integrated tested strategy (ITS) based on validated, aqueous *in vitro* assays, as well as in a series of RHE-based assays. In a case study covering nine unique challenging substances, GARD™skin exhibits a predictive accuracy of 78%, compared to human data. Corresponding performances of RHE-based models ranged between 27-73%, while the ITS had an accuracy of 45%. In conclusion, we demonstrate that GARD™skin constitutes an accurate method for assessment of skin sensitization, also in the context of substances otherwise regarded as challenging.

2373 Development and Application of a Next-Generation Risk Assessment Framework (NGRA) for the Evaluation of Skin Sensitization of Cosmetic Ingredients

M. Klaric[1], N. Alépée[2], F. Boisleve[3], D. Bury[4], E. Clouet[5], N. Gilmour[6], S. Hoffmann[7], P. Kern[8], J. Kuehnl[9], J. Lalko[10], K. Mewes[11], M. Miyazawa[12], H. Nishida[13], A. Osmani[14], S. Sekine[13], E. van Vliet[1], and D. Petersohn[11]. *[1]Cosmetics Europe, Brussels, Belgium; [2]L'Oréal Safety R&I, Aulney sous Bois, France; [3]Chanel, Neuilly-sur-Seine, France; [4]L'Oréal Safety R&I, Clichy, France; [5]Pierre Fabre, Toulouse, France; [6]Unilever, Colworth, United Kingdom; [7]SEH Consulting + Services, Paderbon, Germany; [8]Procter & Gamble, Strombeek-Bever, Belgium; [9]Beiersdorf AG, Hamburg, Germany; [10]Estée Lauder, Melville, NY; [11]Henkel AG, Düsseldorf, Germany; [12]Kao Corporation, Tochigi, Japan; [13]Shiseido, Kanagawa, Japan; and [14]LVMH, Saint-Jean-de-Braye, France.*

Cosmetics Europe has compiled a database of non-animal skin sensitization data and has used it to evaluate the defined approaches included in the OECD IATA case studies project. In the next step we have run case studies where the participants were asked to use these data as basis for their safety assessment. The sharing of case studies at a workshop demonstrated that the available Defined Approaches (DA) can form an integral part of the New Generation Risk Assessment (NGRA) but alone are insufficient to draw a conclusion. Due to the variety of risk assessment needs and complexity in types of information that should be integrated in the skin sensitization risk assessment, a framework is needed to support NGRA for cosmetic ingredients. Here we present an NGRA framework for the evaluation of skin sensitization which is based on the classical risk assessment workflow and relies upon the principles developed by the International Cooperation on Cosmetics Regulation (ICCR). The key elements are that the risk assessment should address a clear question. It must be human relevant, exposure led, hypothesis driven and designed to prevent harm. A tiered, iterative approach should be applied, starting with a thorough review of all of the available existing information. Available data from non-animal test methods can be utilized within any of the available DA, the choice of DA applied might depend on the information available and the risk assessment question. To demonstrate the practical application of the framework we performed a series of case studies with a diverse set of chemicals including lactic acid and methyl dibromo glutaronitrile that were based only on *in vitro* and *in silico* data. This exercise demonstrated that the framework is useful to structure the next generation risk assessment and it increased the confidence in decision making using *in vitro* and *in silico* data. The remaining challenges, as identified via the case studies, will be discussed. In conclusion, significant progress has been made in development and application of non-animal approaches in NGRA for skin sensitization. We have shown that the workflow presented here can help harmonize the risk assessment process while allowing sufficient flexibility for integrating different data and a diverse chemical space.

2374 A Risk Assessment of the Skin Sensitization Induction Potential of Personal Care Product Preservatives Ethylhexylglycerin and Phenoxyethanol

A. Urban[1], K. Towle[1], E. Fung[2], and A. Monnot[1]. *[1]Cardno ChemRisk, San Francisco, CA; and [2]Cardno ChemRisk, Aliso Viejo, CA.*

Preservatives are commonly added to personal care products to prevent microbial contamination as well as to prevent potential health effects associated with use of adulterated products. However, it is important to understand if the addition of these preservatives is associated with health risks. The goal of this analysis was to perform a quantitative risk assessment to evaluate the skin sensitization potential of two preservatives used in a commercially available hair cleansing conditioner product. Specifically, ethylhexylglycerin and phenoxyethanol are preservatives used in a hair care product that was alleged to cause adverse events in users including skin rashes, redness, and irritation. As part of our assessment, we calculated an estimated daily consumer exposure using the amount of hair cleansing conditioner applied per application, the number of applications per day, a maximal dermal exposure parameter, a rinse-off retention factor, the maximum concentration of the preservatives in the product, and the skin surface area of the scalp. We calculated margin of safety (MOS) values by comparing the estimated consumer exposure levels with the no expected sensitization induction level (NESIL) for ethylhexylglycerin and phenoxyethanol (derived from the dermal sensitization threshold

[DST] approach). A sensitization adjustment factor of 100 was applied to the NESIL prior to the MOS calculation (10 for human variability, three for matrix variability, and three for use variability). The MOS for both preservatives was above 1.0 (range of 1.1 to 9.0), indicative of a low likelihood of skin sensitization induction. This evaluation provides evidence that use of the products under the examined exposure scenarios would not increase a consumer's risk of skin sensitization induction due to exposure to the preservatives ethylhexylglycerin and phenoxyethanol.

2375 Evaluation of Irritation Potential of Topically Used Compounds in High-Throughput Reconstructed Human Epidermis and Bio-Printed Full Thickness Skin Tissue

Z. Wei[1], X. Liu[1], M. Ooka[1], L. Zhang[1], M. Song[1,2], R. Huang[1], N. Kleinstreuer[3], A. Simeonov[1], M. Xia[1], and M. Ferrer[1]. *[1]NIH/NCATS, Bethesda, MD; [2]NIH National Eye Institute, Bethesda, MD; and [3]NIEHS/NTP, Research Triangle Park, NC.*

The use of *in vitro* model as an alternative to animal testing for the safety evaluation of both products and ingredients in cosmetics and consumer products is already mandated by law in the European Union and other countries. The study presented here aims to assess the irritation potential of topically-used compounds in skin cellular models with different complexity, ranging from 2D monolayer culture of keratinocytes to 3D bio-fabricated skin tissue equivalents. A set of 451 topically-used compounds was tested for cytotoxic effects in primary neonatal keratinocytes and immortalized human keratinocytes. The 46 most cytotoxic compounds in the monolayer culture systems were further tested in biofabricated reconstructed human epidermis (RhE) and full-thickness skin (FTS) tissues in a 96-well plate format. Tissue viability, transepidermal electrical resistance (TEER), and secretion of cytokine IL1α and IL18 as markers of inflammatory and cellular immunity responses were measured after compound treatment. Among the known irritants, high concentrations up to 200 μM of methyl violet and methylrosaniline chloride decreased tissue cell viability, TEER and increased IL1α as expected, but low concentrations of these compounds increased IL18 without affecting IL1α secretion or reducing tissue viability or TEER in FTS, which suggests concentration-dependent sensitization and irritation potentials for these two compounds. Results from this study provide initial datasets to evaluate the effects of topically-used compounds in *in vitro* and *ex vivo* models and benchmark different endpoints to identify dermal hazards.

2377 Human Epidermal Cell Responses to Wood Combustion Products: Cornified Envelope Formation

L. Lin, M. S. Denison, and R. H. Rice. *University of California Davis, Davis, CA.*

Air pollution poses many serious risks to public health. As a barrier between the human body and the external environment, the skin is constantly challenged by many air pollutants, including polycyclic aromatic hydrocarbons (PAHs), volatile organic compounds (VOCs), particulate matter, and oxidants. Those air pollutants can have considerable effects on skin health and have been associated with skin aging, inflammation and cancer. Despite numerous studies on such effects, our knowledge regarding the mechanisms of action remains limited. We used cultured human epidermal keratinocytes treated with commercial liquid smoke (LS) to further investigate the toxicity of air pollution, specifically wood smoke, on epidermis. Produced by condensation of wood smoke from smoldering wood chips or sawdust, LS has been used widely as a seasoning to add a smoky flavor to recipes. Despite the refining process, LS contains many potentially harmful compounds found in wood smoke, such as VOCs. In our study, cornified envelope (CE) formation was assayed as a marker of keratinocyte cell death. Normally, formation of CE is the final step of keratinocyte cornification, a well programmed cell death in the epidermis. CEs, consisting of cross-linked proteins, are key structures for skin barrier function. Improper CE formation is a major cause of debilitating ichthyosis and may contribute to atopic dermatitis. To this end, keratinocytes were first treated with Mesquite or Hickory LS diluted 100- to 10000-fold in culture medium. At a dilution of 1 to 300, ≈20% of the cells (which were killed) formed CEs in one day while, at a dilution of 1 to 100, nearly all the cells formed CEs. However, the CE formation did not appear to occur through a normal cornification process, considering that expression of genes ordinarily involved in cornification were hardly altered by LS exposure. Moreover, Caspase 14, a protein that has been associated with cornification, was not activated. Finally, our initial proteomic experiments point to alteration of the CE protein profile by LS exposure, which could disrupt barrier function. Such effects provide a mechanism by which air pollutants could aggravate skin diseases.

2378 The Effects of Cleaning Petroleum Solvent or Tetrachloroethylene on the Expressions of Cytokines of Human Keratinocyte Cell Line Activated by Trychophytin

M. Tsunoda, C. Sugaya, and S. Suzuki. *National Defense Medical College, Tokorozawa, Japan.*

Cleaning petroleum solvent has been widely used for dry cleaning. Once, tetrachloroethylene was also used for dry cleaning in Japan. In several reports, remained these cleaning solvents was considered as causes of skin damages including dermatitis. In addition, environmental factors such as fungi has been focused for skin damage. Trychophytin, fungal antigen produced by Trichophyton, activates keratinocytes resulting in the increase in the productions of cytokines such as interleukin-8 (IL-8) and tumor necrosis factor α (TNFα). It is of interest whether or not activated keratinocytes are affected by cleaning solvents resulting in the alterations in mRNA expressions in cytokines. In this study, a human keratinocyte cell line HaCaT was used as an *in vitro* model for human skin. The effects of cleaning petroleum solvent or tetrachloroethylene on the mRNA expressions of IL-8 and TNFα in activated HaCaT cells by Trychophytin were evaluated to elucidate the toxic effects of cleaning petroleum petroleum solvent or tetrachloroethylene on skin. The HaCaT cells were activated by Trychophytin at 10^{-5} PNU/ml (1PNU = 0.01 mg of phosphotungstic acid precipitate) and exposed to cleaning petroleum solvent at 0, 25, 50, 100 μg/ml or tetrachloroethylene at 0, 50, 125, 250 μg/ml for 6 hours in 24-well cell culture plates. The mRNA expressions of IL-8 and TNFα were evaluated by real-time PCR. The mean values of relative expressions of TNFα among the activated cells were exposed to cleaning petroleum solvent were significantly lower than that among the control. The mean values of relative expressions of TNFα among the activated cells were exposed to tetrachloroethylene at 50 μg/ml was significantly higher than that the control and the cells exposed to 250 μg/ml. There were no significant differences in the IL-8 expressions among the activated cells exposed to cleaning petroleum solvent or tetrachloroethylene. It is suggested that the effects of cleaning petroleum solvent or tetrachloroethylene on the mRNA expressions of on the cytokine expressions of activated keratinocytes were not strong. The reported skin damages by these chemicals may be due to cytotoxic effects of these chemicals.

2379 The Effects of UVR Filters in Commercial Sunscreens on AhR Signaling in Mouse Skin

S. J. Dickinson (Phelan), and L. A. DeLouise. *University of Rochester Medical Center, Rochester, NY.*

Ultraviolet radiation (UVR) is a persistent part of the environment for most humans. UVR has the benefit of catalyzing the production of vitamin D in the skin and is used clinically to ameliorate a variety of inflammatory skin conditions (i.e. psoriasis, jaundice). However, UVR is also well known for its negative health effects, particularly its production of sunburns and DNA damage that may promote skin cancer. UVR filters formulated into commercial sunscreens are used to reduce these negative consequences, however, there is a growing body of literature suggesting that they can have off-target effects. The majority of this literature has examined hormone-disrupting effects of UVR filters. Based on their chemical composition, we were curious as to whether or not UVR filters could modulate Aryl hydrocarbon receptor (AhR) signaling. The AhR is a ligand activated transcription factor important for metabolism of exogenous and endogenous compounds, immune function, and cell proliferation. Our *in vitro* studies found that the UVR filter octinoxate (OT) potentiates the mRNA expression of AhR target genes greater than what AhR ligands alone elicit, and that this is due to inhibition of the cytochrome P450 1A1 (CYP1A1) and 1B1 (CYP1B1) genes. Our current efforts focus on determining if this phenomenon occurs *in vivo* and elucidating the potential consequences of it. We discovered that, in mouse skin, co-treatments of OT and the known AhR ligand 6-formylindolo-3,2b-carbazole (FICZ) lead to elevated levels of CYP1A1 and CYP1B1 mRNA levels that are greater than what FICZ alone elicits. FICZ is thought to be produced in the skin after UVR exposure, and UVR has been shown to activate the AhR and lead to increases in various target gene expression. Franz diffusion cell experiments were conducted to measure the permeability coefficient of OT through mouse skin and we discovered that OT permeates at approximately the same rate as nicotine. We additionally examined if co-treatments of UVR and OT had an impact on skin barrier. We measured transepidermal water loss (TEWL) on mice that were exposed to UVR with or without OT and found that co-treatments did not significantly impact TEWL levels 4 days after exposure. While there is still more to be done, our preliminary results suggest that the potentiation effect we observed *in vitro* also occurs *in vivo*, which may have important implications for human use. We are currently examining the effects of OT on contact hypersensitivity responses and cytokine production in mice.

2380 Polycyclic Aromatic Hydrocarbon Benzo[a] pyrene Exposure Exacerbates Skin Inflammatory Pathophysiology in a Mouse Psoriatic Model

J. A. Klein[1], S. K. Singh[1], D. G. Goswami[2,3], L. N. Braucher[1], H. N. Wright[1], E. L. Noland[1], R. Agarwal[3], and N. Tewari-Singh[1,3]. *[1]Michigan State University, East Lansing, MI; [2]Texas Tech University Health Sciences Center, El Paso, TX; and [3]University of Colorado Denver, Aurora, CO.*

A rapid increase in the global prevalence of skin inflammatory diseases like psoriasis cannot be attributed to genetics alone. Environmental factors including major ubiquitous organic pollutants like polycyclic aromatic hydrocarbons (PAHs) could contribute to their pathophysiology. Benzo[a]pyrene (BaP) is one of the PAH that is generated mainly from cigarette smoke, wood-burning, automobile exhaust etc. The molecular mechanisms that lead to inflammatory skin diseases following exposure to BaP are not well elucidated, though there are suggestions that these responses could be mediated by aryl hydrocarbon receptor (AhR), a xenobiotic sensor. To investigate the effect of BaP exposure on skin inflammation in a mouse psoriatic model, the dorsal skin of naïve C57BL/6 mice was shaved (48h prior to exposure) and exposed to 62.5mg of 5% imiquimod (IMQ) cream once daily for five days. For assessing the initiation or exacerbation of psoriasis from exposure to BaP, mice were exposed 64µg BaP in 50µl acetone for five days before IMQ application [BaP+IMQ] or for five days together with the IMQ [(BaP+IMQ)] application. Following the analysis and scoring of clinical lesions, mice were sacrificed, and skin sections were analyzed for inflammation-related histopathological and molecular changes. BaP exposure together with IMQ exacerbated IMQ-induced psoriatic inflammatory symptoms including the skin bi-fold thickness, epidermal and dermal thickness, hyperkeratosis, dermal fibrosis, neutrophil infiltration, neutrophil degeneration and mast cell degranulation. Based on these results, we are currently analyzing and quantifying the effect BaP on IMQ-induced alterations in neutrophil infiltration (myeloperoxidase assay), macrophages (F4/80 staining), inflammatory cytokines and metabolites (metabolomics). In other studies, defining the role of AhR in BaP-induced biological, molecular, and metabolic alterations in mouse skin, concomitant treatment with AhR antagonist CH-223191 was given before BaP+IMQ treatment. The antagonist treatment before the (BaP+IMQ) treatment abrogated the BaP-caused increase in epidermal and dermal thickness in psoriatic mice. The effect of the AhR inhibitor on other biological and molecular psoriatic parameters that are exacerbated on exposure to BaP are also being analyzed to decipher the role of AhR in BaP-induced and/or exacerbation in inflammatory skin diseases like psoriasis.

2382 Call for a Multi-Product Testing Strategy to Evaluate Potential Adverse Dermal Effects

M. T. Hoang[1], K. M. Towle[2], A. D. Monnot[2], and E. S. Fung[1]. *[1]Cardno ChemRisk, Aliso Viejo, CA; and [2]Cardno ChemRisk, San Francisco, CA.*

The average female and male uses 12 and 6 personal care products each day, respectively, with potential daily exposure to an average of over 100 unique ingredients. The considerable use of personal care and cosmetic products highlights the importance of product safety. Currently, the US FDA does not prescribe product safety testing requirements for either personal care or cosmetic products or their individual ingredients before the products enter the market. Moreover, cumulative or aggregate exposures that lead to additive or synergistic effects are rarely discussed or evaluated. The goal of this study was to evaluate a multi-product testing strategy and propose next steps to help establish such a strategy. Two products (one cleansing conditioner and one hair dye) with 14 and 19 unique ingredients, respectively, were selected for this study. Dermal irritation was selected as the endpoint of interest based on the intended use of the product. *In silico* evaluation using the OECD QSAR Toolbox was performed to identify ingredients with potential dermal irritation hazard. Subsequently, *in vitro* evaluation using the OECD 439 guideline test was performed with each test article alone and in combination (50/50 ratio) to predict *in vivo* dermal irritation outcomes. The *in silico* evaluation identified two structural alerts in the cleansing conditioner and six structural alerts in the hair dye ingredients. When tested *in vitro*, the cleansing conditioner alone did not cause an irritation response. The hair dye alone caused a reduction in tissue viability, but was not sufficient to be classified as an irritant. Interestingly, when tested in combination as a 50/50 mixture, the reduction in tissue viability was approximately half of the response observed with hair dye alone. The results of this study showed: 1) not all the hazards identified *in silico* led to an *in vitro* response; 2) treatment with cleansing conditioner alone did not elicit a response while treatment with hair dye alone reduced tissue viability that may lead to irritation at sufficient exposures; and 3) the two test articles did not interact synergistically. However, it is important to note that this study was unable to evaluate the undiluted effects when articles were tested in combination. Further development is necessary to truly evaluate aggregate or cumulative exposures from multi-product use.

2383 Targeted Protein Degraders: Considerations for Nonclinical Safety Assessment of a New Pharmaceutical Modality

J. Kinyamu-Akunda. *Novartis Institute for BioMedical Research, East Hanover, NJ.*

Targeted/induced protein degradation has emerged as a novel drug discovery approach with promise for drugging targets previously considered undruggable. Targeted protein degradation exploits the intrinsic cellular machinery for disposing of damaged, misfolded, or excess proteins. The approach consists of low molecular weight agents that enable tagging of a protein of interest by an E3 ubiquitin ligase for subsequent ubiquitination and degradation in the proteasome. Recently, the first targeted "degrader" entered into clinical trials in prostate cancer (Mallard A. *Nature Reviews Drug Discovery* 18:237), and multiple others are in preclinical development. There are a number of advantages for degraders over traditional low molecular weight inhibitors, including prolonged pharmacodymics due to lag time for protein resynthesis and increased potency due to a potential for one molecule to repeatedly catalyze ligand activity. Moreover, a broader spectrum of activity may result from whole protein degradation compared with protein inhibition. Presumably, this should result in need for lower therapeutic exposures, better selectivity, and improved margins of safety. This session seeks to introduce the SOT community to this new area of intense research in the pharmaceutical industry and share learning from experts. The presenters aim to start a discussion that gets the toxicology community ahead of this emerging science to define important parameters to consider for characterizing the safety of this new modality. After a brief introduction to targeted protein degraders, the first speaker will discuss ADME properties and considerations for PKPD and TKTD relationships. A number of the current degraders in preclinical development are derived from iMiDs (immunomodulatory modulatory drugs) such as thalidomide and utilize the ability of the glutarimide moiety to bind cereblon and provide a chemical anchor to the E3 ligase. Thalidomide is a well-known human teratogen, and other iMiDs likewise show thalidomide-like teratogenicity in animals. Recent publications report that iMiDs degrade SALL4, a zinc finger transcription factor shown to be causative for human syndromes characterized by malformations that phenocopy thalidomide malformations (Kohlhase et al. 2003). The second speaker will discuss recent advances in understanding thalidomide teratogenicity and how this informs strategies for safety assessment of protein degraders. Finally, the third and last speaker will discuss general safety considerations for protein degraders, highlighting case examples.

2384 ADME and PKPD Considerations for Targeted Protein Degraders

D. Hainzl. *Novartis Institutes for BioMedical Research, Cambridge, MA.* Sponsor: J. Kinyamu-Akunda

Most of the degraders currently in development contain three parts: the targeted protein-binding moiety, the ligase binder, and a linker that connects the two. These structural requirements and the desire for high binding affinity and specificity make the molecules complex and large, leading to molecular properties that make development challenging. IMiD drugs that function as molecular glues may overcome some of these challenges as they combine the two binding domains without the use of a linker and thus minimize the size of the molecule. This talk will discuss the opportunities and challenges when addressing and optimizing the absorption, metabolism, distribution, and elimination (ADME) of the degraders and how this relates to considerations of PKPD and toxicity.

2385 SALL4 Degradation by Cereblon Ligands and Its Implications for Teratogenicity of Degraders

E. Fischer. *Harvard Medical School, Cambridge, MA.* Sponsor: J. Kinyamu-Akunda

Despite their teratogenicity, thalidomide and related IMiD drugs are now a mainstay of cancer treatment; however, the molecular basis underlying the pleiotropic biology and characteristic birth defects remains unknown. Recently, thalidomide and other iMiDs were shown to degrade of several C2H2 zinc finger transcription factors, including SALL4, a member of the spalt-like family of developmental transcription factors. Heterozygous loss of function mutations in SALL4 results in a human developmental condition that phenocopies thalidomide-induced birth defects such as absence of thumbs, phocomelia, defects in ear and eye development, and congenital heart disease. Thalidomide induced degradation of SALL4 in humans, primates, and rabbits, but not in rodents or fish, providing a mechanistic link for the spe-

cies-specific pathogenesis of thalidomide syndrome (Donovan et al. 2018). This presentation will focus on identification of SALL4 and the implications of these data in informing toxicology strategies for iMiD-derived protein degraders.

2386 Important Considerations for Safety Assessment of Targeted Protein Degraders

K. Datta. *Celgene Corporation, Summit, NJ.*

The safety of targeted protein degraders is primarily attributed to the pharmacologic mechanism of action. Thalidomide and other iMiDs act as molecular glue degraders that lead to degradation of cereblon-related protein substrates such as Ikaros and Aiolos, transcription factors involved in hematopoiesis. The toxicity associated with iMiDs is largely hematopoietic and likely on target; however, as mentioned previously, iMiDs are teratogenic in animals in the case of thalidomide in humans. Safety assessment of protein degraders entails conventional small molecule early safety profiling, and aspects specific to this mode of action, such as evaluation of degradation of intended protein(s) and potentially unintended proteins to minimize potential safety concerns. The speaker will present case studies highlighting the nature of species-specific toxicities in IMiD-treated animals. Additionally, effects of IMiDs on immune function, including responses to immunization, will be discussed.

2387 Communicating Risk in a (Mis)information-Rich World

A. Bernstein. *Michigan State University, Grand Rapids, MI.*

Understanding the risks and hazards consumers face has become an overwhelming task for them. Inaccurate, yet compelling, narratives and visuals promulgated via social media drown out science-based messaging and widen the gap between actual risks and risk perception, creating uncertainty and confusion for consumers. In a world where we are prone to cognitive leaps and scary stuff is always easier to believe, how can consumers make sense of complex information related to risk, especially in areas where there is uncertainty? As risk communicators, we are constantly challenged to operate in this complex environment. In line with SOT Strategic Priority to increase the Society's influence through science communication, this session brings together speakers with various perspectives to help attendees to better understand how the public recognizes and reacts to risk messaging and to find ways of proactively and effectively communicating in an information-rich environment to foster trust and critical thinking. For this panel session, our experts will (1) discuss how the media and social media shape public perceptions of science and risk; (2) showcase examples of how risk can be communicated in meaningful ways to diverse audiences, specifically as it relates to current issues in toxicology, including per- and polyfluoroalkyl substances (PFAS); (3) explore options (remedies) for empowering the public to think critically about exposures and toxicology; and (4) provide strategies and practical skills for attendees to apply in their own outreach and communication efforts to increase public awareness and understanding of risk in the context of toxicology. Each speaker will give a short talk drawing on their specific expertise and experience of the speakers in the world of science and risk communication. A wide range of topics will be covered, from the science of science communication, to how public perception of toxicology and risk is shaped, to the importance of collaboration with stakeholders in risk communication. This session also will discuss how errors in risk perception underlie much of public misunderstanding of science and how media coverage and social media algorithms skew public risk perception. Topics also will focus on the importance of collaboration between multiple stakeholders and interagency collaboration in the development and dissemination of public health messages, as well as strategies for effective communication that allow you not only to convey information, but also to engage and empower your audience to listen and respond. Talks will be followed by a moderated discussion on current issues in risk communication related to toxicology. Issues covered will include message development, strategies and practical skills for communicating complex risks in a timely manner, and accurately conveying uncertain risks when research is ongoing. Panelists will use current "hot topics" in toxicology (e.g., PFAS) to illustrate these concepts. PFAS are man-made surfactants (including PFOA, PFOS, GenX, and many other chemicals) found in a wide range of consumer products. They are persistent and bioaccumulate, and exposure can lead to adverse health outcomes in humans. The panel of science communication experts will share their knowledge, approaches, and experiences related to these important communications issues. Attendees will take away information that will help develop skills to apply in their own efforts to increase public awareness and understanding of risk in the context of toxicology.

2388 Current Status and Knowledge Gaps in the Use of Zebrafish in Risk Assessment

M. Behl. *NIEHS, Research Triangle Park, NC.*

Over the past five years, there has been much advancement in the use of zebrafish as a powerful alternative model in drug and toxicity screening. Extensive research has been done on understanding chemical space for which zebrafish is a good predictor in reliably prioritizing compounds for screening and in risk assessment, and cases where it cannot be used reliably (e.g., volatile compounds). This session summarizes advancements in the field with respect to similarities and differences between zebrafish and mammalian systems, presents strengths and limitations of the zebrafish in assessing safety and risk assessment to ensure reliable and good translational data, provides case examples of where the zebrafish has been a good predictor of toxicity and where it has not, and emphasizes the need for harmonization across laboratories conducting zebrafish research. It also will highlight stengths, lessons learned, and knowledge gaps in the current use of zebrafish as a complementary model in drug and toxicity screening and prioritization. The first presentation will introduce a risk assessment screening strategy used to identify candidates with developmental, and neurodevelopmental (DNT) or neurotoxicity, cardiotoxicity and hepatic toxicity utilizing a tiered screening approach. Utilizing a tiered screening approach, candidates will be able to be classified as cardiotoxic, hepatotoxic, developmental or neurodevelopmental and neurotoxic, after a funnel of toxicity assays designed based on previous validation and standardization data. Getting risk assessment data that can help in chemical prioritization and also translational to other animal models (like mammals), ending in safer candidates. The second speaker will present on a multidimensional zebrafish assay system to describe the systematic screening of flame retardant chemicals (FRCs), enhancing the protocol design's importance to get reliable and transferable data to other labs developing the same assays. The third presentation will highlight how developmental neurotoxicity assays coupled with analytical chemistry can be used to identify shared toxicity phenotypes arising from structurally similar per- and polyfluoroalkyl substances (PFAS). The final presentation will provide insight into using the zebrafish as a tool to screen environmental compounds for risk assessment and how the measurement of benchmark concentrations (BMC) may be used as a common data analysis method in comparing data across laboratories. Collectively, this session will capture the latest advancements in the design, execution, and analysis of zebrafish toxicity data to enable chemical prioritization and risk assessment with more efficiency.

2389 A CURE for the Common Classroom: Engaging Students and Faculty in Course-Based Undergraduate Research Experiences to Maximize Academic Success and Productivity

L. Williams. *Bates College, Lewiston, ME.*

Research in science is approached through asking novel questions with unknown answers. However, the way in which science has been historically taught at the undergraduate level is through cookbook labs with known and predictable methods and answers. Core competencies recommended by the 2011 report of the American Association for the Advancement of Science and National Science Foundation—*Vision and Change in Undergraduate Biology Education: A Call to Action*—have pushed educators to teach science in an authentic manner and expand research opportunities to a greater number of students. One model that has been widely adopted to meet these goals is that of Course-based Undergraduate Research Experiences (CURE). These courses, the research experience and cultivation of science identity of which can be incorporated into new or existing courses, can span from the first year of study to the upper level. While these courses take a variety of forms, national assessment data have shown that CUREs increase content knowledge, analytical and technical skills, and persistence in science for all students, but especially for students underrepresented in STEM. In addition to student benefits of this model, faculty report increases in their own research productivity. In this session, we will report CURE models from the first year of study to the upper level at both large research institutions and small undergraduate-only institutions and present the benefits of this model to students and faculty alike.

2390 Environmental Carcinogenesis: Effect of Carcinogen Exposure on the Genome and Health Risks

I. Pogribny. *US FDA/NCTR, Jefferson, AR.*

Carcinogenesis in humans is a dynamic and complex phenomenon determined by the interface between two major etiological factors, genetics and environmental carcinogens, among which the exposure to natural and man-

made chemical and physical carcinogenic agents has a more profound impact on cancer development. Currently, it is well recognized that the most impactful approach to reduce the burden of cancer is the early detection and precision prevention strategy, which focuses on individuals who have not been diagnosed with cancer. The success of this approach deeply relies on a better understanding of the fundamental biology of early carcinogenesis, especially biomarkers of exposure and molecular drivers of preneoplasia that may not only define etiologic risk but also delineate interindividual heterogenicity in response to carcinogenic insults and cancer development. This Symposium will present current knowledge on the role of environmental chemicals in the cause of cancer and how environmental insults are involved in the carcinogenic process and illustrate the linkage between exposure and genome alterations as a central component of environmental carcinogenesis. Additionally, it will highlight new conceptual and technological advances in the field of carcinogenesis, outlining the importance of the evaluation of carcinogen-induced genome alterations not only in the carcinogen assessment process but also in the development of precise cancer preventive strategies.

S 2391 Understanding the Mechanisms of Chemically Induced Carcinogenesis in Application to Potential Human Risk

J. E. Klaunig. *Indiana University, Bloomington, IN.*

The mechanisms by which environmental agents induce cancer are important in developing meaningful, scientifically based human risk assessment. Cancer is a multistage process involving target cell mutation changes and selective proliferation of this mutated cell to a neoplasm. In rodents, the liver is a frequent target of these chemicals. Using the rodent liver model, the mechanisms of chemically induced carcinogenesis have been extensively studied and can be divided into genotoxic and nongenotoxic modes of action. Application of newer cellular and molecular techniques, including 'omic approaches, have contributed greatly to this understanding. The genotoxic mode of action involves interaction and damage to genomic DNA, while nongenotoxic mechanisms involve modification of gene expression—particularly those genes involved in growth control, metabolism, inflammation, and oxidative stress. In the case of the latter, excess reactive oxygen can result in damage to and modification of cellular macromolecules, most importantly genomic DNA that can produce mutations as well as modulate gene expression of downstream targets involved in DNA repair, cell proliferation, and antioxidants. In the liver this occurs through receptor-mediated processes (frequently involving CAR, PXR, PPAR-alpha, or AhR) or via cytotoxicity. For example, the induction of rodent hepatic tumors has been seen for a diverse and large group of chemicals that function through PPAR-alpha activation, including DEHP, PFOA, TCE, and clofibrate. While PPAR-alpha activation in the rodent liver results in changes in cancer-related gene expression including increases cell proliferation, similar cellular effects have not been observed in humans. Thus, while the cellular and molecular underpinning of the mechanisms involved in rodent liver cancer is similar in humans, dose-response and species differences in gene activation and the resulting apical endpoints important in the carcinogenesis process are seen that need to be considered when examining human cancer relevance to environmental chemicals.

S 2392 DNA Adductomics Technologies for Assessing Human Exposures to Carcinogens: Potentials and Challenges

R. J. Turesky, J. Guo, S. Walmsley, B. Yun, P. Murugan, C. J. Weight, and P. W. Villalta. *University of Minnesota, Minneapolis, MN.* Sponsor: I. Pogribny

Humans are frequently exposed to low levels of a wide mixture of environmental and dietary genotoxicants, and endogenously produced electrophiles. These reactive species can damage DNA and form covalent modifications, known as adducts. DNA adducts formed at critical sites in tumor-related genes are believed to be the first step in chemical carcinogenesis. Historically, DNA adducts have been measured by targeted methods where one up to several adducts are monitored in an assay. However, the data often provide limited evidence for a role of a chemical in the etiology of human cancer. There is a critical need to develop "untargeted" methods that simultaneously detect many DNA adducts in the genome; some of which may induce mutations and lead to the onset of cancer. With the recent improvements in the sensitivity and scanning rates of high-resolution mass spectrometry (MS) instruments, such as quadrupole time-of-flight and hybrid Orbitrap MS, it is now feasible to screen for an array of DNA damage in the human genome using adductomics approaches. The loss of 2'-deoxyribose from the modified nucleoside upon collision-induced dissociation is a characteristic feature and the most commonly used transition in the screening of DNA adducts by targeted and nontargeted MS methods. We have adapted several advanced data-dependent (DDA) and data-independent acquisition (DIA) scanning techniques originated from proteomics and metabolomics and tailored them for DNA adductomics. These scanning methods have identified DNA adducts of carcinogens formed in tobacco smoke, cooked meats, traditional herbal medicines, and endogenously produced electrophiles in human bladder, renal cortex, and prostate tissues. DNA adductomics is a new and developing technology for human exposure assessment. As the analytical technology matures and bioinformatics tools become available for automated analysis of the mass spectral data, DNA adductomics can advance our understanding of the role chemical exposures play in DNA damage and cancer risk.

S 2393 Mutational Signatures of Carcinogen Exposures and Their Functional Impact

J. Zavadil. *IARC, Lyon, France.* Sponsor: I. Pogribny

The International Agency for Research on Cancer (IARC) aims to identify preventable cancer causes; to this end, the ongoing research programs employ innovative experimental models and computational approaches to investigate previously unrecognized mutagenic effects of human carcinogens. The selection of the studied compounds primarily reflects the priorities set for carcinogen evaluation by IARC. The effects of candidate substances are studied in clonally expanded cell lines that undergo biological barrier bypass to mimic early steps of cell transformation, and by massively parallel sequencing conducted at the genome scale. Complementary *in vitro* adductomics experiments as well as sequencing of rodent tumors arising from corresponding chemical exposures further elucidate the underlying mutagenic processes. The experimental results are matched with the sequencing data from human pan-cancer genome repositories, to identify relevant exposure fingerprints in humans. Several novel mutational signatures associated with dietary compounds, mycotoxins, therapeutic agents, and industrial chemicals will be presented, alongside mechanistic insights into the possible causes of particular cancer types. Furthermore, our cell models allow for comprehensive analysis of the exposure impact on the epigenome (e.g., chromatin structure/accessibility) and on gene expression regulation, in the context of carcinogen-induced cellular immortalization. Overall, this powerful approach has a considerable potential for improved understanding of extrinsic cancer causes and for cancer prevention efforts aimed at modifiable exposures.

S 2394 Use of Gene Expression Profiles to Facilitate Read-Across of Per- and Polyfluoroalkylated Substances in Human Primary Liver Cell Spheroids

E. Atlas, A. Rowan-Carroll, K. Leingartner, B. Kuo, R. Gagne, J. Bourdon-Lacombe, S. Labib, S. Ferguson, and C. Yauk. *Health Canada, Ottawa, Canada.* Sponsor: I. Pogribny

Per- and poly-fluoroalkylated substances (PFAS) are a class of chemicals ubiquitously found in the environment due to their wide variety of uses, their persistence, and their high mobility. Concerns for potential adverse health effects include liver and kidney toxicity, increased cholesterol levels, and effects on lipid metabolism. There is a growing body of evidence showing that PFOS (perfluorooctanesulfonic acid) and PFOA (perfluorooctanoic acid) are toxic and bioaccumulative; however, there is little available information on the many other PFAS found in the environment and humans. Acquiring information on data-poor substances for risk assessment has been a challenge for Health Canada and other regulatory agencies given the cost and length of traditional toxicological research. The goal of this project is to evaluate the biological perturbations induced by 20 prioritized PFAS and seven mixtures to explore mode of action/mechanistic similarities and compare potencies to inform read-across. One of the major target organs for PFOS and PFOA toxicity in rodent studies is the liver, where they are suspected carcinogens. Therefore, we employed gene expression profiling in human primary liver cell spheroids in response to PFAS using TempO-seq to identify biological effects in a concentration-response and time-series design (four time points). In parallel, we used microscopy to evaluate phenotypic changes related to liver pathology. We initiated the study using four prototype PFAS (PFOS, PFOA, PFDS, PFBS). Identification of differentially expressed genes (DEGs), hierarchical clustering, pathway analysis, and benchmark dose (BMD) analysis was conducted. PFOS was the most biologically active (most DEGs) and had the lowest gene and pathway BMDs, indicating that PFOS is the most potent of these PFAS. By day 14, however, the BMDs for PFOA and PFDS were highly overlapping with PFOS. In contrast, PFBS consistently had the fewest DEGs and highest median BMD for genes and pathways for all time points. Analysis of the affected pathways, in response to PFAS, showed effects on lipid metabolism and identified PPARα as an upstream regulator for all four PFAS. The data thus far indicate that these chemicals have similar toxicity in the liver cell spheroids and may have a common molecular target (PPARα), but their potencies differ.

2395 Use of Epigenomic Markers of Exposure in Carcinogen Detection *In Vivo* and *In Vitro*

I. Pogribny. *US FDA/NCTR, Jefferson, AR.*

Human exposure to certain natural and man-made chemical carcinogens is one of the major risk factors for cancer development. In a broad sense, the carcinogenic process may be induced through either genotoxic (agents that interact with DNA) or nongenotoxic (chemicals causing tumor formation by mechanisms other than directly damaging DNA) carcinogens. Currently, the identification of carcinogen-induced genetic changes such as DNA or protein adducts often is a first step in elucidating the potential role of a genotoxic chemical in the etiology of human cancer, and it is widely accepted that detection of DNA or protein adducts caused by exposure is an endpoint indicator in cancer risk assessment. In contrast, there are no regulatory accepted short- or medium-term tests that can predict nongenotoxic carcinogenicity. Through examples of epigenetic alterations caused by the exposure to model genotoxic (aflatoxin B1, benzo[a]pyrene, and acrylamide) and nongenotoxic (arsenic, furan, and methapyrilene) chemicals, this presentation will highlight the role of epigenetic events as the earliest markers of exposure and their role in carcinogen detection *in vivo* and *in vitro*.

2396 Epigenetic Mechanisms of Metal-Induced Cancer Stem Cell-Like Property and Carcinogenesis

C. Yang. *University of Kentucky, Lexington, KY.*

Several common metal carcinogens, including arsenic (As), cadmium (Cd), and nickel (Ni), are weakly mutagenic. This suggests that nongenotoxic mechanisms, such as epigenetic mechanisms, may play critical roles in carcinogenesis induced by these metals. Although generally considered a genotoxic carcinogen, studies show that Cr(VI) exposure also can trigger epigenetic alterations. This 165-minute Symposium convenes a panel of outstanding researchers in cancer epigenetics and metal carcinogenesis fields to discuss the critical roles of epigenetic deregulations in metal-induced cancer stem cell-like properties and carcinogenesis. The first presenter, an expert in cancer epigenetics research, will discuss epigenetic deregulation in cancer stemness, carcinogenesis, and cancer therapy. Next, four experts in the metals carcinogenesis research field will present their cutting-edge studies to show how epigenetic deregulation is critically involved in metal-induced cancer stem cell-like properties and carcinogenesis. This session differs from and expands on the previous year's metal carcinogenesis Symposium by (1) presenting research that discusses epigenetic mechanisms of four different metals (As, Cd, Ni, Cr), thereby reaching a wider audience of metal researchers; (2) including epigenetic mechanisms of metal-induced cancer stem cell-like properties and their role in metal carcinogenesis; and (3) including a presentation by a cancer epigenetics expert who will talk about the background of epigenetics and how epigenetic mechanisms are key in carcinogenesis and cancer therapy. Discussions about the knowledge gaps in epigenetics in cancer and therapies would appeal to many researchers, not just in metals and cancer, but in epigenetics in general. This Symposium session will be of interest to scientists involved in metals, stem cells/cancer stem cells, or cancer research and will be ideal for those who desire a better understanding of the epigenetic mechanisms involved in metals carcinogenesis.

2397 Environmental Exposures, Carcinogenesis, and Reprogramming of the Cancer Epigenome

J. Ohm. *Roswell Park Comprehensive Cancer Center, Buffalo, NY.* Sponsor: C. Yang

In disease, the term *epigenetic* refers to heritable changes in gene expression that are not caused by underlying mutations. Epigenetic mechanisms influence and regulate how the tumor interacts with its microenvironment, the immune landscape of cancer, and metabolic changes associated with tumorigenesis. Abnormal epigenetic reprogramming is a hallmark of all types of cancer, and unlike genetic changes in a cell, epigenetic changes are potentially reversible with targeted therapeutic strategies. Epigenetic drugs include DNA hypomethylating agents, histone deacetylace (HDAC) inhibitors, micro-RNA targeted therapies, and small molecule inhibitors of epigenetic modifying proteins, and many of these drugs are already being tested for some cancers, creating unique opportunities for therapeutic intervention. This presentation will provide an overview about epigenetics, epigenetics and carcinogenesis, and cancer therapy. Epigenetic regulation of cancer stemness and how environmental exposure deregulates epigenetics and promotes carcinogenesis will be highlighted. While our understanding of the reprogramming of the cancer epigenome has increased exponentially over the last two decades, there are still huge gaps in our knowledge of the genetic and environmental factors responsible for the initiation of epigenetic remodeling in cancer. Increasing our understanding of epigenetic mechanisms of environmental carcinogenesis is essential to developing appropriate targeted therapies and prevention strategies for those with environmental exposures.

2398 Metabolomic and Epigenetic Signatures of the Arsenic-Induced Cancer Stem Cells

F. Chen. *Wayne State University, Detroit, MI.*

Exposure to environmental arsenic, especially trivalent inorganic arsenic (As3+), either from natural drinking water contamination, working place air pollution, using of certain types of pesticides, or consuming As3+-enriched food, has been linked to human cancers. However, the mechanism of arsenic carcinogenesis has not been well understood. Cancer stem cells are considered as cancer initiation cells playing important role in carcinogenesis. This presentation will first briefly discuss cancer stem cells and will then present studies showing that arsenic exposure produces cancer stem cell-like cells. By mimicking the human exposure using the environmentally relevant concentration of As3+ for a six-month consecutive treatment of the human bronchial epithelial cells, we not only observed malignant transformation of the treated cells but also noted that some of the transformed cells acquired characteristics of cancer stem-like cells (CSCs). Moreover, integrated transcriptomic and untargeted metabolomics analyses demonstrated a higher rate of glycolysis in CSCs. Unlike cancer cells and embryonic stem cells (ESCs) that use glycolysis for lactate production, the majority of the glycolytic intermediates in CSCs shunted into the siding pathways of glycolysis for hexosamine biosynthesis associated with protein O-GlcNAcylation, and the serine/glycine pathway linked to the generation of S-adenosylmethionine (SAM). ChIP-seq data revealed an enhanced enrichment of histone H3 lysine4 trimethylation (H3K4me3), an active epigenetic marker for gene transcription, among genes important for stemness and glycolysis. Additional biochemical analysis suggested that the metabolomics as well as epigenetic features of the arsenic-induced CSCs are partially dependent on the activation of Nrf2 and its downstream signaling.

2399 Epigenetic Effects of Cadmium in Carcinogenesis

E. J. Tokar. *NIEHS, Research Triangle Park, NC.*

Cadmium has been a well-established human carcinogen for decades; however, its mechanisms of action are not fully defined. Studies indicate that cadmium is, at most, weakly mutagenic in human cells, which suggests that carcinogenesis induced by this metal is mediated through epigenetic mechanisms. The first part of this presentation will review the epigenetic effects induced by cadmium that result in the acquisition of multiple hallmarks of cancer and malignant transformation. DNA methylation induced by cadmium can occur globally (hyper-/hypomethylation), in an agglomerative fashion (large chromosomal regions), or via methylation of specific genes known to regulate carcinogenesis. The dependence of these epigenetic effects on the duration of exposure, cell type used, and/or DNA methyltransferase activity will be described. Cadmium also can increase global methylation of histones (e.g., H3K4me3 and H3K9me2) by inhibiting the activities of their respective demethylases. These modifications alter the expression of cancer-associated genes or non-coding RNAs, appear to occur early in the carcinogenic process, and affect the expression of genes that regulate stem cells (SCs). The aberrant alteration of various miRNAs by cadmium can facilitate carcinogenesis and "recruit" SCs into a cancer SC-like phenotype. The presentation will end with a discussion of emerging evidence that suggests early-life (i.e., prenatal) exposures to cadmium can lead to long-term epigenetic dysregulation. While much of this evidence is suggestive in the context of cancer, it is compelling that many of the effects occur in SC- and/or cancer-associated genes and signaling pathways. The implications of these changes for possible later-life disease manifestation will be described.

2400 Nickel Exposure Causes Persistent Transcriptional Changes through Deregulation of the Epigenome

S. Cuddapah. *New York University, New York, NY.*

Nickel (Ni) compounds are environmental carcinogens associated with lung and nasal cancers in humans. However, the molecular basis of Ni carcinogenicity is not fully understood. Accumulating evidence suggests that epigenetic and transcriptional deregulations contribute to Ni carcinogenesis.

This talk will briefly present on the transcriptome and epigenome. Then, findings about how Ni exposure deregulates transcriptome and epigenome will be presented. To gain mechanistic insights into Ni exposure-caused cancer and other diseases, we comprehensively analyzed the transcriptome and the epigenome of Ni-exposed human lung epithelial cells. Our studies showed that the Ni exposure-induced transcriptional alterations persisted even after the cessation of exposure. By examining the persistent effects of Ni exposure, we show that Ni induces epithelial-mesenchymal transition (EMT) and that the mesenchymal phenotype remains irreversible even after the termination of exposure. Examination of the epigenetic features of Ni-exposed cells revealed genome-wide alterations to the histone modification profiles, which persisted long after the termination of exposure. Our results suggest stable alterations to the epigenomic landscape as the basis for long-term gene expression changes and EMT in Ni-exposed cells. Activation of EMT, during which the epithelial cells lose cell-cell adhesion and become migratory and invasive, plays an important role in the etiology of several lung diseases associated with Ni exposure, including asthma, pulmonary fibrosis, and cancer and metastasis. Therefore, our finding of long-term epigenetic changes due to Ni exposure and the acquisition of persistent mesenchymal phenotype have major implications in understanding Ni-induced cancer and other diseases.

S 2401 Epigenetic Mechanism of Chronic Hexavalent Chromium Exposure-Induced Cancer Stem Cell-Like Property and Tumorigenesis

Z. Wang. *University of Kentucky, Lexington, KY.*

Although hexavalent chromium (Cr[VI]) is a well-known and common environmental and occupational carcinogen, the mechanism of Cr(VI) carcinogenesis has not been clearly defined. While Cr(VI) is generally considered as a genotoxic carcinogen, studies showed that Cr(VI) exposure also causes nongenotoxic effects such as epigenetic changes. However, how epigenetics deregulation promotes Cr(VI) carcinogenesis remains largely unknown. This presentation will first briefly review the reported epigenetic changes caused by Cr(VI) exposure. Then, our studies about chronic low-dose Cr(VI) exposure-caused epigenetic changes and their role in Cr(VI)-induced cancer stem cell-like property and tumorigenesis will be discussed. We found that chronic low-dose Cr(VI) exposure caused epigenetic deregulations as evidenced by the increased levels of histone H3 repressive methylation marks (H3K9me2 and H3K27me3) and the related histone-lysing methyltransferases (HMTases). Knockdown of HMTases in immortalized human bronchial epithelial cells significantly reduced chronic low dose of Cr(VI) exposure-induced cancer stem cell (CSC)-like property and cell transformation. Mechanistic studies revealed that increased HMTase expression by chronic Cr(VI) exposure caused downregulation of the expression of microRNA-494 (miR-494). By bioinformatics analysis and literature searching, we found that the proto oncogene c-Myc is a target of miR-494. Western blot analysis revealed that c-Myc expression level is significantly increased in Cr(VI)-transformed cells. Stably knockeddown c-Myc expression in Cr(VI)-transformed cells significantly reduced their CSC-like property and tumorigenicity. Together, these findings suggest that Cr(VI)-caused epigenetic deregulation contributes significantly to Cr(VI)-induced CSC-like property and tumorigenesis.

S 2402 Immune Cell Polarization in Toxicology and Therapeutic Approaches

C. Rockwell. *Michigan State University, East Lansing, MI.*

Standard toxicity testing of the immune system does not currently include assays to evaluate immune cell polarization. However, there is considerable evidence to demonstrate that inappropriate immune cell polarization can result in disease. Whereas polarization of T cells into functionally distinct subsets is necessary for developing a targeted immune response that is tailored for a specific pathogen, inappropriate T cell polarization is causative in a number of diseases, including multiple sclerosis, psoriasis, asthma, allergy, and others. Likewise, macrophage phenotype switching is critical to tissue repair following injury. In addition, numerous studies have demonstrated that inflammatory macrophage phenotypes are associated with a number of different diseases. From a toxicological perspective, disruption of immune cell polarization by environmental toxicants has been well documented and can have wide-ranging functional consequences. Conversely, therapeutics that target immune cell polarization are clinically useful to restore immune homeostasis to treat immune-mediated diseases. This session will explore toxicity due to dysregulated immune polarization as well as therapeutic options for treating diseases that result from inappropriate T cell differentiation. The session aims to explore the breadth of xenobiotic effects on immune polarization resulting in different sequelae. The presenters will discuss how the industrial solvent TCE drives autoimmunity in a two-hit model by promoting Th1 and Th17 differentiation, and conversely demonstrate that activation of the xenobiotic sensor Nrf2 promotes Th2 differentiation and inhibits Th1 differentiation, resulting in exacerbated food allergy and suppressed host defense to influenza A. Taking a different perspective, the third presentation will provide some balance by showing how inhibition of ROR-gamma-t, the master regulator of Th17 differentiation, with a novel orally available drug is clinically useful in the treatment of collagen-induced arthritis and EAE, a mouse model of multiple sclerosis. The following presentation will expand the conversation to toxicant effects on Tfh, follicular helper T cells, and Th1 cells to demonstrate how inhibition of Tfh and Th1 differentiation by certain AhR ligands results in deficient CD8 and IgG response to influenza A infection. The final presenter will round out the session by demonstrating how acetaminophen toxicity results in defective M1/M2 macrophage switching—specifically, how M1/M2 switching is critical to repair and ultimately survival in acetaminophen-induced acute liver failure. The session also is designed to introduce different mechanisms by which toxicants dysregulate immune cell polarization.

S 2403 Epigenetic Regulation of CD4+ T Cell Polarization in a Model of Toxicant-Induced Autoimmunity

S. Blossom. *University of Arkansas for Medical Sciences, Little Rock, AR.*

Trichloroethylene (TCE) is an industrial solvent and a widespread water pollutant associated with CD4+ T cell-mediated hypersensitivity and autoimmune diseases in humans. Autoimmune-prone MRL+/+ mice after chronic TCE exposure develop an accelerated autoimmune disease associated with an increase in IFN-γ and IL-17-secreting effector CD4+ T cells. Our goal is to understand how TCE promotes the generation of these subsets to determine how these cells contribute to autoimmunity. Using whole-genome methylomics approaches in mouse effector/memory CD4+ T cells, TCE promoted hypermethylation of CpG regions that bind to polycomb group (PcG) proteins. One such PcG protein includes EZH2 that methylates histone H3 at lysine 27. Trimethylated histone H3K27 (H3K27me3) is a PcG-specific chromatin modification thought to play an important role *in trans*criptional repression. In T cells, EZH2 is highly expressed and important in regulating Treg function and effector cell differentiation and function. Based on our methylation results, we hypothesized that TCE alters EZH2 function, leading to the phenotype observed in our model. CD4+ T cell differentiation events are time dependent and difficult to elucidate *in vivo* in part due to the short half-life of effector CD4 T cells *in vivo*. One of the major oxidative metabolites of TCE, trichloroacetaldehyde hydrate (TCAH), was used as a TCE surrogate *in vitro* to test how the chemical disrupts cell differentiation processes in effector subsets that include drivers (Th1 and Th17) or protectors (Th2 and Tregs) of autoimmunity. Naïve CD4 T cells, when polarized *in vitro* in the presence of TCAH, altered many subset-specific genes associated with an autoimmune phenotype. EZH2-specific inhibitors decreased H3K27 trimethylation and altered the ability of TCAH to modulate Th1 and Treg phenotypes. These results will not only provide novel information but also underscore the potential utility of using *in vitro* differentiation assays as screening tools for chemicals that may promote hypersensitivity/autoimmunity to inform human risk assessment where current methodology is limited.

S 2404 Nrf2 Regulates Multiple Facets of T Cell Differentiation, Impacting Food Allergy and Host Defense

C. Rockwell, Y. Jin, R. A. Freeborn, and R. C. Kennedy. *Michigan State University, East Lansing, MI.*

Nrf2 is a transcription factor that is activated by numerous xenobiotics, including the food additive tBHQ. Our previous studies showed that Nrf2 promotes Th2 differentiation while suppressing Th1 differentiation. Our current studies indicate that Nrf2 directly upregulates gata3, the master regulator of Th2 differentiation. Our data show that Nrf2 binds two putative binding sites (antioxidant response elements, AREs) in the gata3 gene, as determined by DNA-binding ELISA and ChIP assay. These sites are transcriptionally active as shown by reporter gene assay. In addition to direct gene regulation, we also found that Nrf2 regulates a number of genes involved in T cell metabolism, suggesting a secondary mechanism by which Nrf2 regulates T cell differentiation. Th2 cells are known to be causative in allergy; we found that the increase in Th2 polarization by tBHQ *in vitro* correlates with worsened food allergy *in vivo*. Specifically, we found that tBHQ increases total and antigen-specific IgE and IgG1 during sensitization and exacerbates clinical symptoms of anaphylaxis, including a marked drop in body temperature following challenge. These effects correlate with increased mast cell degranulation and higher plasma concentrations of mMCP-1, as well as increased numbers and activity of Th2 cells. In contrast to Th2 cells, Th1 cells play an important role in host defense to intracellular pathogens. Our data show that the inhibition of Th1 differentiation by Nrf2 correlates with impaired host defense to influenza. We

found that mice on a tBHQ diet had increased lung inflammation as determined by histopathology, but diminished CD4 and CD8 T cell responses to primary influenza infection, which correlated with impaired viral clearance. Furthermore, we found that immunological memory was impaired by tBHQ, which caused a significantly greater drop in body weight following secondary exposure to influenza virus. Our most recent data indicate that Nrf2 also regulates Th17 differentiation, as evidenced by markedly higher production of Th17 cytokines by Nrf2-deficient CD4 T cells, suggesting that Nrf2 also may impair host defense against extracellular pathogens. Collectively, our studies demonstrate that the xenobiotic sensor Nrf2 regulates multiple facets of T cell differentiation and thus may represent a common pathway by which multiple xenobiotics may modulate immunity.

2405 RTA 1701 Is a Selective RORγt Inhibitor That Suppresses IL-17A Production and Is Efficacious in Mouse Models of Autoimmune Disease

S. Reisman. *Reata Pharmaceuticals Inc., Irving, TX.*

Th17 cells are a subset of IL-17A-producing CD4+ helper T cells that play a key role in autoimmune disorders. The nuclear receptor retinoic acid-related orphan receptor γt (RORγt) transcriptionally regulates the production of IL-17A and orchestrates the differentiation of Th17 cells. RTA 1701 is an orally bioavailable, selective RORγt inhibitor currently in clinical development. *In vitro*, RTA 1701 selectively inhibits the transcriptional activity of RORγt and does not inhibit the activity of the closely related transcription factors RORa and RORß. By inhibiting RORγt, RTA 1701 blocks Th17 differentiation of naïve CD4+ T cells and inhibits IL-17A production in both Th17-polarized CD4+ T cells and activated peripheral blood mononuclear cells (PBMCs) isolated from patients with psoriasis or rheumatoid arthritis. RTA 1701 treatment also reduces the expression of other RORγt target genes and Th17 signature genes (e.g., IL-17F, IL-21, CCL20) in Th17-polarized naïve CD4+ T cells. RTA 1701 exhibits oral bioavailability in rodents and cynomolgus monkeys, with dose-dependent increases in exposure over a wide dose range. In monkeys, oral administration of RTA 1701 suppresses *ex vivo* stimulation of IL-17A secretion in whole blood after single and repeat dosing. In animal models of autoimmune disease, including the collagen-induced arthritis (CIA) mouse model of rheumatoid arthritis and the experimental autoimmune encephalomyelitis (EAE) mouse model of multiple sclerosis, RTA 1701 attenuated disease symptoms. Together, these results suggest that RTA 1701 may have therapeutic potential in Th17-associated autoimmune disorders.

2406 The Aryl Hydrocarbon Receptor Regulates T Cell Differentiation

B. Lawrence. *University of Rochester Medical Center, Rochester, NY.*

Initially discovered because it mediates effects of toxicants from the environment, the aryl hydrocarbon receptor (AHR) also is now a fascinating potential target that could be used to modulate the immune system to treat disease. Exposure to AHR ligands modifies T cell differentiation and T cell-dependent immune responses; however, the consequences of different ligands differ across studies. To address this, we compared immunomodulation by AHR ligands that arise from different sources within the same *in vivo* disease model: infection of mice with human influenza A virus (IAV). Specifically, we used TCDD, a prototype exogenous AHR agonist; PCB126, a pollutant with documented human exposure; ITE (2-(1'H-indole-3'carbonyl)-thiazole-4-carboxylic acid methyl ester), a novel pharmaceutical; and FICZ (6-formylindolo[3,2-B] carbazole), a degradation product of tryptophan. During acute primary IAV infection, exposure to ITE, PCB126, and TCDD significantly reduced Th1 and Tfh cells, whereas FICZ increased their frequency. Similarly, TCDD, PCB126, and ITE, but not FICZ, reduced virus-specific IgG levels and CD8+ T cell responses. Yet, differences among ligands were not observed on all aspects of the response to IAV. For instance, virus-specific IgM levels, which are generally considered T cell-independent, were diminished by all four compounds. Moreover, in Cyp1a1-deficient mice, which metabolize AHR ligands more slowly, all compounds, including FICZ, reduced all metrics of the immune response to IAV. Conditional Ahr knockout mice, which lack Ahr in the entire immune system, revealed that all compounds require AHR within hematopoietic cells. Thus, ligand-specific differences in T cell-mediated responses to IAV likely reflect variances in quality, magnitude, and duration of AHR signaling. This indicates that binding affinity and metabolism are probably stronger predictors of immune effects than a compound's source of origin and that harnessing AHR will require finding a balance between dampening immune-mediated pathologies and maintaining sufficient host defenses against infection.

2407 Failed Phenotype Switching by Hepatic Macrophages Produces Persistent Inflammation in Acute Liver Failure by Acetaminophen

B. Copple, J. D. Strickland, and K. J. Roth. *Michigan State University, East Lansing, MI.* Sponsor: C. Rockwell

Acute liver failure resulting from acetaminophen toxicity remains a significant health problem with a high rate of mortality. Studies have revealed that acetaminophen-induced acute liver failure patients with the poorest outcome suffer from a systemic inflammatory response syndrome (SIRS) characterized by excessive production of immunomodulatory cytokines. Unfortunately, the cause of cytokine dysregulation in these patients remains poorly understood. Our studies have investigated the underlying cause of this in an animal model of acute liver failure. Treatment of mice with a dose of acetaminophen (e.g., 300 mg/kg), normally associated with full liver repair, increased expression of several proinflammatory cytokines, including tumor necrosis factor-a (TNF-a). Cytokine levels remained elevated at 48 hours in these mice but returned to baseline by 72 hours. In mice treated with a dose of acetaminophen (e.g., 600 mg/kg) that produces liver injury that fails to repair, cytokine levels were increased at 48 hours and remained elevated at 72 hours. This indicated a failure to terminate the inflammatory phase of wound healing, similar to what occurs in patients. Interestingly, in mice treated with 600 mg/kg acetaminophen, proinflammatory macrophages failed to traffic into necrotic lesions and thus were unable to clear dead cell debris by phagocytosis. Studies have suggested that phagocytosis of dead cells terminates cytokine production by proinflammatory macrophages. To evaluate this in acetaminophen overdose, proinflammatory monocytes/macrophages were isolated from the livers of mice treated 24 hours earlier with acetaminophen. Exposure of these cells to necrotic hepatocytes decreased expression of proinflammatory cytokines and other M1 macrophage markers and increased expression of arginase-1, an M2 marker. Collectively, these studies suggest that pharmacological stimulation of macrophage phagocytic pathways might be a novel approach to alleviate SIRS in acute liver failure patients.

2408 Organ to Silicon Chip: Emerging *In Vitro* and *In Silico* Tools for Evaluation of Cardiotoxicity

A. Bahinski. *GlaxoSmithKline plc, Collegeville, PA.*

There is a crucial need for new technologies that can quickly and reliably predict cardiovascular safety in humans due to drug and environmental exposure. Development of safe and effective drugs is currently hampered by the poor predictive power of existing preclinical models that often lead to failure of drug compounds late in their development, after they enter human clinical trials. Given the tremendous cost of drug development and the long timelines involved, as well as the need for evaluation of emerging environmental pollutants, the development of new technologies such as *in silico* platforms and novel *in vitro* platforms have the potential to provide more translational and human predictive models for cardiac toxicity. This Symposium will highlight innovative approaches to developing much-needed new toxicological methods for evaluation of cardiotoxicity beyond electrophysiology and arrhythmia. This Symposium brings together key experts from the fields of machine learning and artificial intelligence, microphysiological systems/organ-on-chips, and engineered cardiac tissues/precision medicine. They will highlight and discuss the advantages and challenges inherent in new innovative tools being applied toward identification and characterization of cardiotoxicity, in healthy and disease states, in pharmaceutical development and environmental safety.

2409 Novel Platforms to Interrogate Cardiac Physiology and Drug-Induced Changes in Contractility Using hiPSc-CM

K. Chaudhary. *GlaxoSmithKline plc, Collegeville, PA.* Sponsor: A. Bahinski

Cardiovascular safety liabilities are a leading cause of drug attrition in the pharmaceutical industry. Because contractility directly contributes to cardiac output and hemodynamics, it is important to ascertain drug-induced changes early on in pharmaceutical development. While changes in electrical repolarization can be modeled using heterologous expression systems, these substrates do not recapitulate contractile function of the heart. Primary cardiac myocytes are difficult to isolate, are prone to species-dependent differences, and are not amenable to higher-throughput drug screening strategies. In this discussion, we will focus on novel hiPSc-CM utilizing platforms to characterize cardiac contractile phenotype and drug-induced changes in contractility. Results from positive and negative inotropic agents will be presented, including clinically relevant drugs such as cardiac glycosides, L-type calcium

channel blockers, myofilament calcium sensitizers, and naturally occurring cardioactive hormones. Translation will be characterized by comparison with both *in vitro* (cellular/tissue contraction) and clinical efficacy (biomarkers of contractility). Both 2D and 3D formats will be highlighted, along with strategies for implementation to support drug development and patient safety.

S 2410 Engineering Functional Cardiac Microtissues for Human Disease Modeling and Drug Screening

M. McCain. *University of Southern California, Los Angeles, CA.* Sponsor: A. Bahinski

Myocardial tissue consists primarily of aligned cardiac myocytes that contract in synchrony to pump blood from the heart. The contractile output of myocardial tissue is dependent on many diverse factors, including cell and tissue microstructure, cell-cell coupling, intracellular calcium handling, ATP production, and the mechanical and biochemical properties of the extracellular matrix. Drugs and diseases that affect the myocardium can interfere with any number of these parameters. Thus, to broadly understand mechanisms of inherited and acquired forms of cardiac disease and to develop safe and effective therapies for the heart, we need modular platforms for engineering and functionally interrogating human cardiac tissue. This talk will describe how we combine tunable biomaterials, microfabrication techniques, and human cells (including stem cell derivatives) to engineer human cardiac microtissues with defined cellular and extracellular architecture. These microtissues are engineered on surfaces that enable measurements of multiple physiological outputs, including calcium handling, contractility, and metabolism. The form factor of these microtissues also is relatively scalable, such that they can be implemented for medium-throughput analyses to complement high-throughput screens and animal models.

S 2411 Cardiac Contractility *In Vitro*: From Patient-Specific to Air Pollution Studies

A. Grosberg. *University of California Irvine, Irvine, CA.* Sponsor: A. Bahinski

The heart's primary function to generate pressure to move blood throughout the body, via regular synchronized force generation by the myocardium, can be easily disrupted via toxic stimuli, such as harmful drugs or even air pollution, or because of an inherited genetic mutation that makes a patient more vulnerable to heart pathologies. An *in vitro* system that provides a mimic of heart contractile function can be a powerful tool to investigate patient-specific cardiac response as well as adverse effects of stimuli. In this work, we provide two examples of the "heart-on-a-chip" platform customized for (1) a patient-specific model of a Lamin A/C mutation and (2) use with multiday toxic exposure experiments. The nuclear lamina protein, Lamin A/C (LMNA), mutations can cause pathologies in multiple organs. For example, the progeria disease is associated with a mutation to the LMNA gene, and it leads to a devastating early aging and death. In contrast, other LMNA gene mutations do not cause early aging, but instead have a subtler effect, with patients presenting only with heart disease symptoms. Here, we demonstrate that a fibroblast cell line developed from a patient skin biopsy can be used to create patient-specific iPS-derived cardiomyocytes that recapitulate the pathogenic phenotype. These cardiomyocytes were engineered into tissues, and their contractile function was assessed by measuring developed stress in heart-on-a-chip devices. Cardiomyocytes derived from cells with the LMNA mutation show a clear reduction in the ability to develop stress when compared with cardiomyocytes with no mutations. Such patient-specific cardiomyocytes or primary cardiomyocytes can be easily used to construct heart-on-a-chip platforms to test a variety of acute stimuli. However, the inherent biological variability poses a challenge in testing stimuli that require multi-hour incubation times. To address this challenge, we have created a protocol to select films with a predictable change of stress as a function of time, providing a unique platform for testing pollution (or other stimuli) effects on cardiac function. The combination of these applications of the heart-on-a-chip platform can serve as a valuable set of assays to test toxicity of pollution, drugs, or other stimuli in a manner that targets specific subsets of populations that might have an inherent vulnerability.

S 2412 Using Weighted Gene Coregulation Network Analysis (WGCNA) to Decipher Temporal Dynamics in Cardiotoxicity

A. Rahman. *NIEHS/NTP, Morrisville, NC.*

Cardiotoxicity can be elicited through a variety of mechanisms, which lead to complex, temporally regulated compensatory processes at the molecular level. The sequence of molecular processes has evolutionary roots that, at a regulatory level, are analogous to highly complex agent-based models with self-organized behavior. One approach to delineating the evolved, self-organizational framework is to characterize the coordinated expression genes across a diverse set of toxicological perturbations using WGCNA. Here, we describe a cartographic exercise that uses WGCNA of the DrugMatrix heart gene expression data (1-5 days in duration, 101 test articles) from rat to reveal a map of gene-level co-expression relationships that are rooted in compensatory/adaptive processes associated with cardiotoxic stress. In total, the map reveals sets of genes tightly linked to well document biological processes such as cell cycle and ribosomal biogenesis, but also identifies sets of genes that are reflective of changes in cellularity and processes central to the differentiate functions of cardiac cells. We use the co-expression map as a base framework to explore the temporal dynamics of cardiotoxicity of a variety of prototype agents, such as anthracyclines, corticosteroids, and kinase inhibitors. The exercise reveals early agent-specific behavior that evolves into a general compensatory process that is likely intrinsic to the reparative function of the heart and is conserved across most test articles. We believe this analysis serves as a molecular-level point of reference that can be used to understand the capabilities and limitations of *in vitro* systems for modeling cardiotoxicity.

S 2413 Evaluation of *In Vitro* Structural Cardiotoxicity Using Deep Neural Networks

M. Maddah. *Dana Solutions LLC, Palo Alto, CA.* Sponsor: A. Bahinski

In vitro human cell models are emerging as promising platforms for preclinical drug safety testing. To fully leverage their potential, the development of robust and accurate assays is of the utmost importance. We present an innovative new tool, PhenoTox, which uses image-based artificial intelligence to quantify subtle and complex drug-induced structural changes that occur prior to noticeable cell damage or death. This method enables the interrogation of any cellular structure and provides a high level of sensitivity that has not previously been possible. The input to PhenoTox is a collection of microscopy images captured and grouped at multiple doses for the drugs of interest and a control set of images with only the vehicle applied. PhenoTox performs a series of 2-class deep convolutional neural network trainings on the input images and produces a set of metrics that quantify the degree of structural changes across all drug doses relative to controls. We present results for a panel of dugs with known cardiotoxicity profiles applied to human stem cell-derived cardiomyocytes, comparing structural toxicity measured by PhenoTox to the output of functional assays. Our preliminary results show that, for example, structural changes for Doxorubicin strongly correlate with decreased contraction displacement, whereas for Bortezomib they correlate with decreased relaxation duration, and there are no detected structural changes for Aspirin. We conclude by discussing the strengths, limitations, and future directions of the approach.

S 2414 TaRGET II Consortium: Elucidating Epigenetic Responses to the Environment across Target and Surrogate Tissues

D. Dolinoy. *University of Michigan School of Public Health, Ann Arbor, MI.*

It is increasingly recognized that exposures to chemicals affect health and disease not only by mutating genes, but also by modifying the epigenome, alterations to DNA that are mitotically heritable and lead to disease when deregulated. Thus, the US National Institute of Environmental Health Sciences (NIEHS) established the multi-phased Toxicant Exposures and Responses by Genomic and Epigenomic Regulators of Transcription (TaRGET) Program to identify epigenetic mechanisms that drive environmentally induced disease susceptibility. The second phase of the program, the TaRGET II Consortium, was established in 2016 and utilizes mouse models to evaluate when surrogate sources of DNA can be used in epigenetic epidemiology studies of human exposures and disease risk. Target tissues are those directly affected by environmental exposures (e.g., the brain by lead), while surrogate tissues are those that are easily accessible (e.g., blood). Epidemiology studies typically generate epigenetic data using surrogate tissues, but it is unknown whether associations with environmental factors observed in these surrogates correlate with those occurring in the tissues targeted by toxicants. Using perinatal exposure models of seven representative toxicants (lead, arsenic, air

pollution [$PM_{2.5}$], bisphenol A, tributyltin, dioxin, and di(2-ethylhexyl)phthalate), TaRGET II is generating epigenetic signature data in target and surrogate tissues and isolated cell populations at three life stages in mice. Epigenomic data include chromatin assembly via ATAC-seq, DNA methylation via whole genome bisulfite sequencing, and transcriptomics via RNA-seq. Through a series of talks discussing both individual and multiple perinatal exposures, the purpose of this Symposium is to familiarize the toxicological community with the consortium and discuss the impacts of these integrative analyses on the field of toxicoepigenetics. TaRGET II data are made publicly available and will enable further refinement of the design and analysis of human studies where target tissues are inaccessible and provide insight into epigenetic mechanisms behind the developmental origins of health and disease.

S 2415 Overview and Goals of the TaRGET II Consortium

F. L. Tyson. *NIEHS, Research Triangle Park, NC.*

Human reference epigenome maps have been generated by consortia, such as the National Institutes of Health Roadmap Epigenomics Project and the International Human Epigenome Consortium, allowing for discovery of cell type-specific epigenetic patterns and how these patterns may be altered during disease pathogenesis. However, epigenomic consortia have not previously sought to interrogate how epigenomic patterns are perturbed by environmental exposures and, in turn, influence susceptibility to environmental diseases. It is of paramount importance for the environmental health community to elucidate the mechanisms responsible for epigenome perturbation that may drive pathogenesis of chronic diseases. The TaRGET II Consortium was established to investigate conservation of perturbations in epigenomic marks across target tissues and cells (those adversely affected by environmental exposures) and surrogate tissues and cells (those that are easily accessible and reflect the environmental exposures), using mouse models of environmentally relevant exposures. Many human studies have begun to generate epigenetic data using surrogate tissues (e.g., blood). Data from TaRGET II will provide additional exposure-specific insights, and next-generation sequencing epigenetic signature data will enable further refinement of the design and analysis of human studies where target tissues are inaccessible. This presentation will provide an overview of the consortium's overarching goals and activities, taking advantage of next-generation sequencing approaches and integrative analyses.

S 2416 Integrated Analysis of Consortium-Wide Chromatin Structure and Gene Expression

B. Zhang. *Washington University in St. Louis, St. Louis, MO.* Sponsor: D. Dolinoy

Environmental toxicant exposures can alter the epigenome, including chromatin accessibility, histone modifications, and DNA methylation. The reprogrammed epigenome could lead to the dysregulated transcriptome and result in altered phenotypes and diseases, including developmental disorders and cancer. The TaRGET II Data Coordination Center (DCC) systematically integrated and analyzed 411 epigenomes and 803 transcriptomes generated by consortia members, which represented 530 liver and 305 blood samples associated with seven distinct toxicant environmental exposures, including TCDD, BPA, $PM_{2.5}$, DEHP, Pb, TBT, and arsenite, derived from mice of both sexes. We identified over 30,000 regulatory elements in the mouse genome that responded to the seven toxicant exposures and were associated with expression changes in over 3,000 genes at five months of age, approximately four months after exposure cessation. Our pan-exposure analysis suggested that DEHP and Pb only moderately affected the epigenome and transcriptome of liver and immune cells. However, BPA and arsenite dramatically reprogramed the liver and blood epigenome and resulted in significant transcriptomic changes. We further discovered strong sex-specific responses to BPA (male) and to arsenite (female). We also found air pollution ($PM_{2.5}$) significantly associated with altered epigenome and transcriptome in both liver and blood; however, different ingredients of $PM_{2.5}$ exposure resulted in distinct epigenetic and transcriptomic responses. We observed that individual animals may differ drastically in responding to the same exposure, such as TBT, underscoring individual-specific tolerance. By cross-comparing the liver and blood data, we defined the "exposure signatures" at epigenomic and transcriptomic levels for each exposure. Although most of the signatures are exposure specific, we identified a set of common signatures that were associated with multiple toxicant exposures.

S 2417 Imprinted Genes: Vulnerable Targets for Multiple Environmental Exposures?

M. Bartolomei. *University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.* Sponsor: D. Dolinoy

Early-life exposures to adverse environmental stresses, including environmental chemicals, are associated with disease later in life—the so-called Developmental Origins of Health and Disease hypothesis. While the mechanisms by which these *in utero* exposures cause adverse phenotypes long after the exposure resolves remain unclear, the TaRGET II Consortium led by NIEHS is investigating the hypothesis that alterations in epigenetic gene regulation are involved. Epigenetics refers to nongenomic modifications to DNA that result in heritable changes in gene expression. Epigenetic gene regulation employs DNA methylation of cytosine residues, histone post-translational modifications, and non-coding RNAs to implement these heritable gene expression changes. One class of genes that relies on epigenetic mechanisms for their unique pattern of parental-specific expression is imprinted genes. About 200 of these genes are found in the mammalian genome—these genes are located in clusters and regulated by allele-specific DNA methylation of imprinting control regions (ICRs) for their parental-specific expression. Importantly, differential DNA methylation of ICRs must survive the genome-wide programming that occurs right after fertilization in the early mammalian embryo. Using a mouse model, we have shown that imprinting can be perturbed by a number of environmental exposures during early gestational stages, including procedures used in Assisted Reproductive Technologies and the endocrine-disrupting chemical bisphenol A (BPA). With respect to BPA within the TaRGET II Consortium, offspring from dams exposed to physiological levels of BPA through feed from two weeks prior to mating through mid-gestation exhibited disrupted DNA methylation and imprinted gene expression in a variety of imprinted genes in the placenta and embryo as well as target and surrogate tissues. This presentation will explore the hypothesis that imprinted genes are vulnerable to environmental exposure and could serve as a sensitive biomarker for epigenetic dysregulation.

S 2418 Perinatal Exposure to Lead and Phthalates Results in Altered DNA Methylation in Adult Mouse Liver and Blood: Implications for Target versus Surrogate Tissue Use in Environmental Epigenetics

L. Svoboda. *University of Michigan, Ann Arbor, MI.*

DNA methylation is a critical epigenetic mechanism linking early developmental environment to long-term health. In humans, the extent to which toxicant-induced changes in DNA methylation in surrogate tissues mirror those in the target tissues is unclear. Thus, the TaRGET II Consortium was established by NIEHS to address the utility of surrogate tissues as proxies for toxicant-induced epigenetic changes in target tissues. Using a mouse model of perinatal environmental exposures, the objective of this study was to investigate the effects of exposure to lead (Pb) or diethylhexylphthalate (DEHP) on liver and blood DNA methylation in adult male and female mice. We hypothesized that Pb and DEHP exposure would each lead to persistent changes in DNA methylation and that a subset of differentially methylated loci would overlap between liver and blood. Dams were exposed to Pb (32 ppm) in drinking water, which results in a blood lead level of 32 μg/dL, or DEHP in chow, resulting in a blood DEHP level of 144 ng/mL. Dam exposure began two weeks prior to mating and continued until offspring were weaned at three weeks of age. At five months of age, enhanced reduced-representation bisulfite sequencing was used to assess DNA methylation. Sex-stratified modeling of differential methylation by exposure was conducted using an established bioinformatics pipeline. Although Pb and DEHP exposure ceased at three weeks of age, we observed thousands of stably modified, sex-specific differentially methylated regions in the blood and liver of Pb- and DEHP-exposed animals, including nine genomically imprinted loci. In Pb-exposed males, we discovered five sites that overlapped between blood and liver and exhibited changes in DNA methylation in the same direction in both tissues. In DEHP-exposed males and females, we discovered three and two overlapping sites, respectively, with concordant changes in methylation. These data demonstrate that perinatal exposure to Pb or DEHP induces sex-specific changes in hepatic DNA methylation that persist into adulthood, some of which are consistent in the blood.

S 2419 Systemic Effects of Perinatal Air Pollution and Arsenic Exposure on Target and Surrogate Tissues

S. Biswal. *Johns Hopkins University, Baltimore, MD.*

Type 2 diabetes (T2D) is increasing worldwide in epidemic proportions. Both epidemiological and experimental studies indicate that environmental factors like air pollution ($PM_{2.5}$) and chronic arsenic exposure may increase the risk of insulin resistance (IR) and T2D. In particular, arsenic exposure has been shown to cause oxidative stress in trophoblastic placental tissue by producing reactive oxygen species that may cause health effects. The molecular underpinnings for these perinatal effects of exposure are mostly unknown, but reprogramming of the epigenome is involved. We hypothesize that perinatal air pollution and arsenic exposure (via maternal drinking water) results in alterations in epigenomic marks that are associated with IR, T2D, and other diseases. As a part of the NIEHS TaRGET II Consortium, C57BL/6J dams were exposed to real-world inhaled concentrated $PM_{2.5}$ (~10x ambient level/~60-120 µg/m3) or filtered air (FA) using the concentrated ambient particle system (CAPS) for 6 h/day or 10 ppb inorganic arsenite (iAs) in the drinking water, two weeks before mating until three weeks of weaning of the offspring. Even after cessation of perinatal exposure to $PM_{2.5}$, we observed persistent IR as evident from results of the glucose tolerance test (GTT) and insulin tolerance test (ITT) predominantly in males at five months of age. However, there were no significant changes in body weight due to $PM_{2.5}$. We observed that iAs exposure led to obesity in males at five months of age. In contrast, female mice prenatally exposed to iAs showed decreased in body weight. There was no significant change in level of plasma leptin in male or female mice prenatally exposed to iAs. Insulin level was decreased in female but not male in As-exposed group. We performed multi-'omic analyses (WGBS, ATAC-seq, and RNA-seq) to examine the systemic effects of exposure on target (e.g., liver) and surrogate (blood) tissue from male and female mice. This presentation will discuss an integrated analysis of these data to understand the relationship of exposure on the reprogramming of the epigenome in target and surrogate tissues.

W 2420 Genetic Mutations of Manganese Transporters: Clinical Presentation and Neurotoxicity

S. Mukhopadhyay. *University of Texas at Austin, Austin, TX.*

Manganese (Mn) is an essential metal, but even modest increases in brain Mn concentrations induce severe neurological effects. Historically, as early as 1837, Mn neurotoxicity has been associated with elevated exposure in occupational settings, resulting in parkinsonian-like movement disorder with dystonia. More recent studies suggest that children exposed to elevated Mn from environmental sources such as drinking water also develop neurological effects that manifest as fine motor control, emotional, cognitive, and intellectual deficits. Further, it also is now appreciated that exposure to elevated Mn during developmentally critical early periods may permanently change the trajectory of neurodevelopment and induce lifelong neurological dysfunction. Moreover, Mn is excreted in bile and feces. Patients with hepatic dysfunction, due to alcoholic cirrhosis, fail to excrete Mn, accumulate Mn in the brain, and develop neurological deficits. Overall, Mn neurotoxicity is a public health problem of global proportions. Therefore, understanding the mechanisms of Mn homeostasis and the neuropathophysiology of Mn-induced neurological dysfunction is an essential step in developing effective treatment strategies. Over the last decade, our understanding of Mn homeostasis and neurotoxicity has been revolutionized by the discoveries of three genetic disorders of Mn metabolism that induce neurotoxicity or deficiency. The first disorder was described in 2012, when homozygous mutations in SLC30A10 were reported to cause Mn-induced neurological disease. Two other genetic disorders were subsequently described—mutations in SLC39A14 also were reported to cause Mn neurotoxicity, a*nd mutations* in SLC39A8 to cause Mn and Zn deficiency. These genes code for critical metal transporters that regulate systemic uptake (SLC39A8) or excretion (SLC39A14 and SLC30A10) of Mn. Studies of the biology of these transporters and of the underlying genetic diseases are transforming our understanding of Mn homeostasis, detoxification, and neurotoxicity. This session will bring together leading experts in the field and present a cohesive overview of the current state of knowledge in the field. Five presenters will discuss innovative new discoveries from their laboratories. Dr. Mukhopadhyay discovered the function of SLC30A10 and will present on how SLC30A10 and SLC39A14 cooperatively regulate Mn levels in the body by excreting Mn. Dr. Gospe identified the first patient with mutations in SLC30A10 and will present clinical findings. Dr. Broberg identified polymorphisms in SLC30A10 and SLC39A8 in the general population and will present on epidemiological associations of these polymorphisms with risks of Mn neurotoxicity. Dr. Knutson discovered the function of SLC39A8 and will present on the unexpected role of this protein in mediating Mn uptake. Finally, Dr. Guilarte discovered changes in behavior and neuropathology in SLC39A14 knockout mice and will present on the pathobiology of Mn neurotoxicity due to this mutation. In summary, this session will encompass fundamental basic science, animal models, and human clinical studies to present a comprehensive understanding of the latest cutting-edge research in the neurobiology of Mn. The basic science presentations will comprehensively cover the similarities and differences between results obtained in models systems with observations in human patients. Content will be of interest to other scientists in the Mn and metal toxicology fields, neuroscientists, and neurologists, as well as to a broader toxicology audience interested in understanding how gene-environment interactions induce human diseases.

W 2421 Manganese Excretion and Neurotoxicity: Insights from Rare Genetic Diseases

S. Mukhopadhyay. *University of Texas at Austin, Austin, TX.*

Over the last few years, homozygous loss of function in SLC30A10 or SLC39A14 was reported to induce severe Mn neurotoxicity. Our recent studies revealed that SLC30A10 is a Mn efflux transporter, which, at the cellular level, transports Mn from the cytosol to the cell exterior and protects against Mn toxicity. Further, SLC39A14 primarily transports Mn into cells. Despite transporting Mn in opposite directions, at the whole organism level, these two transporters cooperatively mediate Mn excretion. Our data, obtained from full-body and tissue-specific Slc30a10 or Slc39a14 knockout mice, indicate that SLC39A14 transports Mn from blood into liver and intestines, and SLC30A10 then excretes the intracellular Mn into bile and feces. Furthermore, our recent findings revealed that brain Mn levels are primarily controlled by the excretory activity of these transporters in the digestive system. This talk will give an overview of the current state of knowledge about the inherited disorders of Mn metabolism by providing an overview of the changes seen in human patients and highlighting similarities and differences observed in animal models. Subsequently, it will focus on the excretory function of SLC30A10 and SLC39A14 and discuss the unexpected finding that the primary mode of the homeostatic control of brain Mn is excretion via the digestive system. A major highlight will be to provide the mechanism of disease due to mutations in these transporters and relate these findings to manganese neurotoxicity evident in the general population.

W 2422 Hereditary Disorders of Manganese Homeostasis: Natural History, Genetics, and Treatment

S. Gospe. *University of Washington, Seattle, WA.* Sponsor: T. Guilarte

Over the past two decades, three inborn errors of metabolism associated with manganese homeostasis have been described. Two of these disorders are associated with extraordinary elevations of blood levels of manganese, while the third condition is associated with a reduction in manganese levels. Patients with biallelic pathogenic variants in SLC30A10 present with early-onset progressive extrapyramidal motor dysfunction together with polycythemia and progressive liver disease, while patients with biallelic pathogenic variants in SLC39A14 have disease isolated to the central nervous system. Both disorders are associated with marked hypermanganesemia together with central nervous system manganese deposition. In contrast, patients with biallelic pathogenic variants in SLC39A8 have low or undetectable blood manganese levels and present with infantile hypotonia, failure to thrive, and intellectual disability. This lecture will review the clinical, imaging, and genetic features of these three familial disorders of manganese homeostasis. Examples of the effective chelation treatment of patients affected by the disorders of hypermanganesemia will be demonstrated. The clinical data provide the starting point for the animal- and cell-based studies that have been performed over the past few years on these proteins. Therefore, this talk will complement other presentations in this session.

W 2423 Manganese Transporter Genetics Influence the Susceptibility to Environmental Manganese Exposure and Neurobehavioral Outcomes in Children

K. Broberg. *Lund University, Lund, Sweden.*

Homozygous loss of function mutations in SLC30A10, SLC39A14, or SLC39A8 are rare. However, our recent studies led to the identification of common single nucleotide polymorphisms in SLC30A10 and SLC39A8 that strongly modify biological Mn concentrations in humans. Further, by a Mendelian randomization study, we have shown that Mn exposure early in life has negative effects on children's neurodevelopment, including neurobehavioral phenotypes. The polymorphisms in Mn transporters contribute to differences in sen-

sitivity to Mn exposure from the environment, where girls that are genetically less efficient at regulating Mn may be a particularly vulnerable group. The focus of this presentation will be to bring forth this emerging epidemiological data, which suggest that common variants of SLC30A10 and SLC39A8 are widely prevalent in the general population and modulate outcomes of Mn neurotoxicity. In addition to the direct human health relevance, these epidemiological studies also provide additional justification for studying the function of these critical transporters. This presentation will fit well with the description of clinical findings in patients by Dr. Gospe and the other presentations focused on the function of these transporters in cells and rodents.

W 2424 Novel Roles of ZIP8 (SLC39A8) in Manganese Homeostasis

M. Knutson. *University of Florida, Gainesville, FL.* Sponsor: S. Mukhopadhyay

Patients with loss of function mutations in the transmembrane metal-ion transport protein ZIP8 (SLC39A8) exhibit very low blood Mn levels, impaired glycosylation, skeletal abnormalities, and severe mental retardation. Studies in ZIP8-inducible knockout (ZIP8 iKO) and hepatocyte-specific ZIP8 KO mice have revealed that ZIP8 plays an essential role in Mn homeostasis by functioning in the liver, where it reclaims Mn from the bile. Accordingly, loss of ZIP8 increases biliary Mn losses, resulting in Mn deficiency. In an effort to define extrahepatic functions of ZIP8 in Mn homeostasis, we crossed ZIP8-inducible knockout (ZIP8 iKO) mice with ZIP14 knockout (Zip14-/-) mice to generate double-knockout Zip14-/-;ZIP8 iKO animals. Zip14-/- mice display impaired hepatic uptake of Mn and impaired Mn excretion, resulting in hypermanganesemia and Mn accumulation in various tissues, most notably bone, brain, and kidney. We find that while Zip14-/-;ZIP8-/- iKO mice load similar amounts of Mn in the bone and kidney as do Zip14-/- mice, they show markedly lower concentrations of brain Mn, suggesting that ZIP8 is required for brain Mn accumulation. Consistent with this hypothesis, immunofluorescence analysis of mouse brain sections indicates that ZIP8 is abundantly expressed in the choroid plexus, a principal site of Mn entry into the brain when plasma Mn concentrations are elevated. Overall, these studies have begun to define extrahepatic roles of ZIP8 in Mn homeostasis; they also identify ZIP8 as a possible therapeutic target for disorders of brain Mn accumulation. In addition to describing this data, this presentation also will relate findings in our mouse model with clinical presentations seen in human patients suffering from Mn deficiency due to loss of function mutations in ZIP8.

W 2425 SLC39A14 Knockout Mice: A Genetic Model to Study Manganese Neurotoxicity

T. R. Guilarte. *Florida International University, Miami, FL.*

Exposure to excess Mn results in parkinsonism with dystonia and cognitive function deficits. SLC39A14 is now recognized as a Mn influx transporter. Homozygous loss of function mutations of SLC39A14 result in behavioral manifestations of parkinsonism with dystonia that is not responsive to typical drugs used to treat idiopathic Parkinson's disease (iPD). The use of the SLC39A14 knockout (KO) mice provides a powerful tool to study and describe the neuropathogenesis of chronic Mn exposure along the life span. Assessment of Mn concentrations in blood and striatum of postnatal day (PN) 60 SLC39A14-KO male mice indicates a highly significant increase in Mn concentrations when compared with wild-type (WT) mice. Blood: 46.9 ± 10.7 µg/L in WT versus 975.7 ± 70.9 µg/L in KO; striatum: 2.64 ± 0.158 µg/g in WT versus 12.3 ± 1.4 µg/g in KO. Behavioral characterization of the PN60 male mice showed significant locomotor impairment, which manifests itself as a decrease in distance traveled and rearing behavior. Furthermore, preliminary data from the pole descend test indicate that there is a significant decrease in the ability to descend in KO mice, when compared with WT. Analysis of striatal dopamine (DA) concentrations and its metabolites resulted in no significant difference in the concentrations of striatal DA, DOPAC, and HVA in PN60 SLC39A14-KO male mice. Tyrosine hydroxylase immunohistochemistry in the striatum of PN140-160 animals also showed no significant differences between SLC39A14-KO mice and WT, supporting the lack of nigrostriatal dopaminergic neuron terminal degeneration in the presence of significant locomotor impairment. These findings are consistent with nonhuman primate studies from our laboratory indicating a dysfunctional but intact nigrostriatal dopaminergic system. Collectively, these results indicate that the neuropathological changes resulting from Mn overexposure are different from those observed in iPD. Our results further suggest that other neuronal systems besides dopamine are involved in Mn-induced parkinsonism with dystonia. This presentation will cover this data and relate findings to human patients suffering from Mn neurotoxicity due to mutations in SLC39A14 as well as elevated exposure to provide a comprehensive model for neurotransmitter and neurodegenerative changes that we believe underlie Mn-induced motor deficits in mammals.

W 2426 Mechanisms and Multiple Exposures: Methods to Tackle Toxicology's Most Difficult Challenges Using Systematic Review Frameworks

A. Rooney. *NIEHS/NTP, Research Triangle Park, NC.*

Systematic review approaches are increasingly being adopted for hazard, risk, and safety assessment across many disciplines in toxicology and public health. The European Food Safety Authority (EFSA), National Toxicology Program (NTP), and US Environmental Protection Agency (US EPA) have all implemented systematic review methods in the conduct of hazard assessments and in some cases risk assessments for chemicals and foods. Systematic review frameworks provide a rigorous multistep process for identifying, selecting, critically assessing, and synthesizing scientific literature for reaching evidence-based hazard conclusions on specific research questions. While systematic review methods are ideal for assessing the evidence that a specific exposure is associated with a specific health effect, application of these methods to more complex, real-world situations is more challenging. Furthermore, because the relevant data are from diverse sources and study types, application of systematic review methods to questions in toxicology and environmental health requires an approach to integrate evidence from human, animal, and mechanistic studies in reaching conclusions. This session will present approaches that have been utilized to address two principal challenges for use of systematic review methods in toxicology: (1) integrating evidence across multiple exposures, and (2) integrating evidence from mechanistic data. People are exposed to hundreds of chemicals every day, and in this context, assessing hazards from exposure to chemicals one at a time is a limiting approach. While single exposure assessments may be easier to conduct, real-world exposure to chemicals in food or consumer products or through occupational or general environmental contact involves complex mixtures that are generally at low levels. These challenges are generally recognized, and although there are efforts to address complex exposures with systematic review methods, few evaluations have been completed to date. As with the challenge presented by complex exposures, the identification, appraisal, and integration of mechanistic data is one of the most well-recognized challenges in utilization of systematic methods. There are many chemicals with little to no human or experimental animal toxicology data. *in vitro* studies that focus on mechanistic endpoints (generally upstream from phenotypic outcomes) are increasingly available and may be the only toxicology data for many chemicals. The first talk will present an evaluation of health effects from traffic-related air pollution to demonstrate how the NTP Office of Health Assessment and Translation (OHAT) Approach for Systematic Review and Evidence Integration can be used to develop hazard conclusions across multiple exposures. Subsequent presentations will highlight the utility of mechanistic data in facilitating transparent decisions, particularly in scenarios where mechanistic evidence provides clarity to findings in other evidence streams, extrapolations across species, and filling data gaps traditionally assessed by experimental animal assays. The next presentation will highlight lessons for addressing environmental health questions from the pharmaceutical industry's decade-long experience qualifying and using the mechanistic data in decision-making and predicting adverse events in the absence of human data. A strategy for evidence integration using systematic review methods that relies on mechanistic data on the estrogenicity of alkylphenols is presented in a read-across context to reach decisions on alkylphenols with little toxicity data. This will include mapping of multiple levels of data across adverse outcome pathways ranging from initiating events, such as receptor binding, to apical outcomes, such as tissue and organ changes in functionality. Finally, several case studies will be presented that highlight the role of exposure considerations within the application of systematic review approaches for the identification, assessment, and integration of mechanistic evidence in human health assessments. The case studies will illustrate integration of multiple categories of mechanistic information, including data on initiating and key events from *in vivo* and *in vitro* studies, use of ToxCast/Tox21 high-throughput studies, and synthesis of mechanistic data across multiple species, including humans. Collectively, this session will demonstrate current progress and remaining challenges in assessing real-world, complex exposures and utilizing mechanistic data in systematic assessments of hazard and risk. The presentations focus on case examples where exposure and mechanistic data challenges have been addressed. Recognizing that major challenges remain in conducting systematic reviews where the relevant studies are dominated by mechanistic data and complex exposures, the speakers will be asked to highlight principal challenges and identify potential or emerging solutions during the panel discussion to close the session.

2427 Using Systematic Review to Reach Hazard Conclusions across Multiple Exposures

B. Beverly. *NIEHS/NTP, Research Triangle Park, NC.*

The use of systematic review methods has rapidly become the gold standard to address environmental health questions due to their rigor and transparency, and these approaches are now an integral part to the decision-making process for many federal and regulatory groups. However, the adaptation of the methodology to an environmental health context is still a relatively recent occurrence, with the development of systematic review frameworks in the last five years that consider the breadth of data relevant to environmental questions. To date, few evaluations have been completed and case studies are required to test methods, refine approaches, and spur methods development. The need for case studies or guidance on how to reach hazard conclusions on multiple exposures represents a critical gap in addressing "real-world" multiple-chemical exposures, mixtures, or cumulative exposures. NTP/OHAT recently evaluated the potential effects of traffic-related air pollution on hypertensive disorders of pregnancy. The assessment of this complex exposure was developed following the OHAT Approach for Systematic Review and Evidence Integration and evaluated health effects evidence for individual components of traffic-related air pollution (e.g., particulate matter) in a stepwise manner to reach hazard conclusions. Evidence was grouped into focused exposure-outcome pairs, individual study quality was assessed, and confidence ratings were developed on each of those exposure-outcome pairs. Then, the evidence was integrated along with consideration of the independence of datasets, independence of mechanisms for the individual components, and other mechanistic data that inform the overall broader exposure of traffic-related air pollution to reach a hazard conclusion on the overall exposure. This example will illustrate how evidence can be integrated across multiple exposures using the NTP/OHAT systematic review framework and highlight the need for more case examples to further refine methods.

2428 Mechanistic Safety Tests in Decision-Making in the Absence of Human Data: Using a Systematic Review Framework

K. Tsaioun. *Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.*

Most experts agree that the current mandatory testing paradigm for prediction of effects of chemicals on human health is not always adequate to ensure public safety. Major advancements in our understanding of mechanisms of toxicity resulted in development of a number of enabling technologies that measure endpoints that correspond to the mechanistic biomarkers of human toxicity. This resulted in a number of public databases and a growing body of published literature detailing the protocols, use cases, and "fit-for-purpose" qualification results of such tests, both of which lend themselves to systematic reviews. The presentation will show an example that uses mechanistic assays in decision-making on drug candidates and an example of using a systematic review framework to find toxicological information for approved drugs in the public domain. Normalizing both datasets to human exposure using existing human data from the systematic review of literature and calculated values using some PBPK models (physiologically based pharmacokinetic models) in cases when human information is not available (e.g., environmental exposures, early drug candidates without human data) will be presented using an example of drug-induced liver injury. Application of systematic review frameworks to assess the availability and applicability of *in vitro* mechanistic tests for specific purposes in the regulatory decision-making will be detailed.

2429 Evidence Mapping and AOP-Based Integration Strategies to Support Read-Across Hypotheses in Chemical Risk Assessment: A Case Study on Estrogenicity of Alkylphenols

K. Goyak[1], M. L. Green[1], D. Wikoff[2], and F. A. Grimm[1]. *[1]ExxonMobil Biomedical Sciences Inc., Annandale, NJ; and [2]Tox Strategies, Ashville, NC.*

Chemical interactions with the endocrine system are under increasing global scrutiny. To elicit an adverse response, endocrine-disrupting chemicals (EDCs) need to be able to perturb one or more key signaling events at the cellular level. Chemical interaction with the estrogen receptor (ER) is regarded as a key initiating event in this pathway. Among identified chemical xenoestrogens are certain alkylphenols, a group of chemicals with a wide range of industrial and consumer product applications. Among chemicals with publicly available toxicological data (i.e., the US EPA ToxCast inventory), a set of approximately 300 chemicals have been classified as alkylphenols and exhibit a continuum of ER bioactivity, suggesting that there are likely subgroups of alkylphenols that induce similar, overlapping, and possibly dissimilar biological effects. Our overall program is testing the hypothesis that the estrogenicity of alkylphenols can be predicted using an integrated computational toxicology approach combining available bioactivity screening data from the US EPA ToxCast and ToxValDB inventories, molecular docking simulations, and various data-integration techniques. This presentation will focus on the results from a comprehensive literature review and synthesis of available data to provide a map of the available evidence supporting linkages between molecular-level events (such as ER activation) and downstream adverse outcomes. Subsequent identification, categorization, and integration of mechanistic data from the peer-reviewed literature was guided by an adverse outcome pathway (AOP) framework and facilitated by an evidence-mapping approach. The utilities and challenges of software-assisted mapping tools were explored and will be discussed.

2430 Case Study Applications in the Identification, Assessment, and Integration of Mechanistic Evidence in Human Health Assessments: Consideration of Exposure in Developing Weight of Evidence Conclusions

D. Wikoff[1], G. Chappell[1], S. Fitch[2], and S. Borghoff[3]. *[1]ToxStrategies Inc., Asheville, NC; [2]ToxStrategies Inc., Dallas, TX; and [3]ToxStrategies Inc., Cary, NC.*

Mechanistic data provide valuable information regarding characterization of toxicological endpoints. Challenges in the evaluation and integration of mechanistic data are routinely described as related to heterogeneity of study designs and the lack of appraisal tools for *in vitro* studies. In recent practice of evidence-based methods, variability in construct and external validity relative to the research question and understanding of human relevance are recognized as more significant challenges. Using multiple case examples, we demonstrate the application of systematic review approaches for the identification, assessment, and integration of mechanistic evidence in human health assessments of assessing the potential for endocrine disruption and carcinogenicity (separately) and, in each, highlight the role of exposure considerations as part of problem formulation as well as appraisal and integration. By utilizing existing frameworks for organizing the evidence bases ranging from 1,000 endpoints informing potential pathways of activity based on varying complexity, including HTS data from ToxCast/Tox21 to data from observational and controlled trials in humans. In each approach, data are appraised for quality and reliability and subsequently integrated to assess the weight of evidence for each pathway or outcome using an adverse outcome pathway construct—and in some cases via quantitative methods. In addition to demonstrating various approaches for systematically integrating mechanistic data with other evidence streams, the utility and challenges in the implementation of these approaches are addressed. Possible solutions will be discussed, including consideration of exposure to help facilitate weight of evidence conclusions.

2431 Modulation of P-Glycoprotein and Breast Cancer Resistance Protein Transporter Activity by GenX (Ammonium 2,3,3,3-Tetrafluoro-2-(Heptafluoropropoxy) Propanoic Acid) *Ex Vivo* and *In Vivo* in Sprague Dawley Rats

A. C. Richards, A. W. Trexler, B. Sinha, G. A. Knudsen, R. E. Cannon, and L. S. Birnbaum. *NIEHS/NTP, Research Triangle Park, NC.*

Ammonium 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoic acid (GenX) is a replacement for perfluorooctanoic acid (PFOA) in the production of fluoropolymers. The blood-brain barrier (BBB) protects the CNS from toxic chemicals by way of tight junctions to limit paracellular flux and active transport via the function of ATP-binding cassette (ABC) proteins. This study examined the effects of GenX (0.1 pM-1 μM) on the transport activity and expression of P-glycoprotein (P-gp), Breast Cancer Resistance Protein (BCRP), and Multidrug Resistance Associated Protein 2 (MRP2) at the BBB. *In vivo* responses to GenX were determined in Sprague Dawley rats following a single gavage dose. ABC transporter activities were determined *ex vivo* by a confocal microscopy-based assay. Western blots were used to quantify protein levels of P-gp and BCRP. Cytotoxicity was measured *in vitro* using two human cell lines co-treated with GenX (100 nM) and cytotoxic P-gp and BCRP-specific substrates. GenX exposures *in vivo* and *ex vivo* rapidly decreased P-gp and BCRP transport activity in brain capillaries from both male and female rats; however, MRP2 transport was not affected. Upon removal from the media, GenX-mediated inhibition was reversible for P-gp but not for BCRP, indicating differential reg-

ulatory mechanisms. Decreases in transport activity of P-gp and BCRP were independent of GenX acting directly on the transport proteins in cell lines that selectively expressed the individual transporters. *In vivo* dosing of GenX by oral gavage decreased P-gp and BCRP transport activity at the BBB in male and female rats. GenX exposure inhibited P-gp and BCRP transport activity *in vitro* in cultured human cells by increasing the cytotoxicity of their respective substrates. GenX significantly inhibits the activity of both brain capillary P-gp and BCRP within 1-2 h at environmentally relevant concentrations (0.1-10 nM) independent of protein expression. Because xenobiotics and endogenous molecules can affect the rate of ABC efflux transport, altered disposition of two therapeutic drugs known to be transported by P-gp and BCRP (verapamil and prazosin, respectively) following GenX exposure is being investigated. *This research was supported by the NIH Intramural Research Program [ZIA BC 011476].*

PL 2432 High Content Screening in Zebrafish Identifies Perfluorooctanesulfonamide as a Potent Developmental Toxicant

S. Dasgupta, A. Reddam, Z. Liu, J. Liu, and D. C. Volz. *University of California Riverside, Riverside, CA.*

Per- and polyfluoroalkyl substances (PFASs) have been used for decades within industrial processes and consumer products, resulting in frequent detection within the environment and human body. Using zebrafish embryos, we screened 38 PFASs for developmental toxicity at a limit concentration of 50 µM and demonstrated that perfluorooctanesulfonamide (PFOSA) was the most potent developmental toxicant, resulting in elevated mortality and developmental abnormalities following exposure from 6- 24 h post fertilization (hpf) and 6- 72 hpf. PFOSA exposures initiated during early developmental stages (0.75, 6 and 12 hpf) resulted in a concentration-dependent increase in mortality and abnormalities, with surviving embryos exhibiting up to a >12-h delay in development by 24 hpf. Exposures initiated at 0.75 hpf also resulted in a concentration-dependent delay in epiboly at 6 hpf, although these effects were not driven by a specific sensitive window of development. To identify the potential association of PFOSA-induced developmental delays with impacts on the embryonic transcriptome, we relied on mRNA-sequencing and showed that, relative to stage-matched vehicle controls, pathways related to hepatotoxicity and lipid transport were disrupted in embryos exposed to 12.5 µM PFOSA from 0.75- 14 hpf and 0.75- 24 hpf. Therefore, we measured liver area as well as neutral lipids in 128-hpf embryos exposed to vehicle (0.1% DMSO) or 0.78 µM PFOSA from 0.75 to 24 hpf and clean water from 24 to 128 hpf, and showed that PFOSA exposure resulted in a decrease in liver area and increase in yolk sac neutral lipids at a non-toxic concentration of 0.78 µM. Overall, our findings show that early exposure to PFOSA adversely impacts embryogenesis, an effect that may lead to altered lipid transport and liver development.

PL 2433 Increased Toxicity and Retention of Perflourooctane Sulfonate (PFOS) in hCYP2B6-Tg Mice Compared to Cyp2b-Null Mice Is Relieved by a High-Fat Diet

M. C. Hamilton[1], M. Pfohl[2], E. Marques[2], L. Ford[2], A. L. Slitt[2], and W. S. Baldwin[1]. *[1]Clemson University, Clemson, SC; and [2]University of Rhode Island, Kingston, RI.*

PFOS is a flourosurfactant that has been banned in the United States, due to its toxicity. It has a half-life of about 5.5 years in humans and is associated with hepatotoxicity. Human Cytochrome P450 2B6 (CYP2B6) is expressed in liver and responsible for metabolizing xeno- and endobiotics, including polyunsaturated fatty acids (PUFAs). PFOS treatment, like high-fat diet feeding, is a potent inducer of CYP2B in human and rodent hepatocytes. Given the marked induction of CYP2B by PFOS, it was hypothesized that CYP2B is a contributor to PFOS-induced changes to liver, such as steatosis. Cyp2b-null and humanized CYP2B6 mice (hCYP2B6-Tg) were treated with PFOS (0, 1, or 10 mg/kg/day) via oral gavage with some mice receiving a typical chow diet (ND) and some receiving a 60% kCal HFD. The mice were euthanized after 21 days, and liver and serum were collected. On days 20-21, three mice died during the exposures; all three were ND-fed hCYP2B6-Tg female mice treated with 10 mg/kg/day PFOS, indicating that hCYP2B6-Tg mice were more sensitive to PFOS than the other groups. Interestingly, hCYP2B6 female mice retained significantly more serum and liver PFOS than Cyp2b-null mice. PFOS levels were typically higher in the HFD-fed mice; however, the HFD-fed hCYP2B6 females were protected from PFOS toxicity presumably due to greater white adipose tissue (WAT) and less wasting. In addition, PFOS caused a decrease in body weight due to WAT loss, and liver weights were indirectly correlated with body weight but directly correlated with PFOS concentration. Oil red O staining did not demonstrate a dose-dependent increase in liver lipid accumulation; however, PFOS in addition to a HFD exacerbated lipid accumulation. A serum and liver panel of 19 different parameters were evaluated by principle-component analysis (PCA) and indicated that PFOS severely impacted the liver with significantly elevated ALT and ALP levels demonstrating hepatotoxicity. In general, the PCA plot indicates that PFOS causes dose-dependent liver toxicity that is protected by a HFD, and that Cyp2b-null mice fed a HFD and treated with PFOS are pushed towards the cholesterol and LDH parameters, indicating a greater likelihood of cardiovascular disease. Gene expression of enzymes related to NAFLD are currently being evaluated, using a microarray, so the role of hCYP2B6 in PFOS toxicity can be better understood.

PL 2434 Per- and Polyfluoroalkyl Substance (PFAS) Concentrations in Human Placenta and Associations with Birth Outcomes

S. M. Hall[1], S. Zhang[1], K. Hoffman[1], M. Miranda[2], and H. M. Stapleton[1]. *[1]Duke University, Durham, NC; and [2]Rice University, Houston, TX.*

Per- and polyfluoroalkyl substances (PFAS) are a group of widespread and persistent environmental contaminants found in drinking water, food packaging, textiles, and other consumer products. PFAS are also persistent in the human body and have been detected in human serum, breast milk, and umbilical cord blood. PFAS exposure during pregnancy has garnered concern due to the potential developmental toxicity of PFAS and known placental transfer of these compounds to the developing fetus. Prior studies have noted associations between maternal serum PFAS concentration and low birth weight; however, it is possible that those associations were influenced by changes in glomerular filtration rates (GFR) during pregnancy. To date, no studies have investigated associations between placental PFAS levels and birth outcomes, and the placenta may be a better tissue for examining fetal exposures as it would not be influenced as strongly as maternal serum by changes in GFR. To gain a better understanding of the current *in utero* PFAS exposures, human placenta samples (n=120) collected at delivery in 2010-11 from women giving birth in Durham, North Carolina were analyzed for PFAS. Archived placental samples (~1 gram) were extracted, purified, and analyzed via high performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS) for a suite of 11 different PFAS analytes, including the analytes PFOS, PFOA, and GenX. Furthermore, using available metadata collected at birth (e.g., infant sex, birth weight, and gestational age), we examined whether PFAS concentrations in the placenta differed by infant sex or if levels were associated with birth weight or gestational age. Analyses were adjusted for maternal smoking, race, maternal education, parity, and maternal age. PFAS were detected in all placenta samples, illustrating the prevalence of PFAS exposure. The most abundant PFAS in the placenta were the long-chain PFAS, specifically PFOS, PFOA, PFNA, and PFDA, with a range of concentrations between 0.02-7.17 ng/g. No significant differences were observed in placental PFAS levels based on infant sex. We observed a negative association between placental PFOS concentration and birth weight, but only in male infants. This finding is similar to previously reported studies that examined associations between maternal serum PFAS and birth weight.

PL 2435 Replacement Per- and Polyfluoroalkyl Substances (PFASs) Are Potent Modulators of Lipogenic and Drug Metabolizing Gene Expression Signatures in Primary Human Hepatocytes

E. Marques[1], M. Pfohl[1], W. Wei[1], G. Tarantola[1], L. Ford[2], O. Amaeze[3], and A. Slitt[1]. *[1]University of Rhode Island, Kingston, RI; [2]Salve Regina University, Newport, RI; and [3]University of Lagos, Lagos, Nigeria.*

Per- and polyfluoroalkyl substances (PFAS) are a family of toxicants that are used in fire-fighting foams and as well as many heat-, stain- and water-resistant products. With about 4000 PFASs estimated to be in use in the commercial market, there is a serious lack of knowledge regarding the toxicodynamic effects and adverse health outcomes of replacement PFAS in humans. A subset of PFASs, called perfluoroalkyl acids (PFAA), are fully-fluorinated sulfonic and carboxylic acids, such as perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA). PFAAs have been shown to induce liver steatosis in rodents and monkeys. However, it is unclear whether PFOS or PFOA exposure causes steatosis in humans, with some existing evidence that PFOS and PFOA treatment can induce expression of lipid metabolism and synthesis genes in human hepatocytes. We hypothesized that PFOS and PFOA, along with other prevalent PFASs, could induce gene expression of lipid metabolism and synthesis along with lipid deposition in cryopreserved human hepatocytes. Cryostax 5-donor pool of cryopreserved human hepatocytes were plated onto 96-well plates. 24 hrs after plating, cells were treated with various PFAAs and replacement PFASs at various concentrations (0.25, 2.5, and 25 µM) or 0.1% DMSO vehicle in media. After 48 hrs of treatment, cell lysates were

collected and the relative abundance of 35 target transcripts and 4 housekeeping genes was measured using a custom QuantiGene 2.0 plex assay. A second set of hepatocytes were stained with DAPI and Nile Red and fluorescence was quantified. Treatment with different PFAAs (3 sulfonates and 12 carboxylates) and alternative PFASs for 48 hrs modulated gene expression for 6 nuclear factors related to drug metabolism and lipid regulation, as well as induction in 20 drug metabolism, lipid metabolism, cholesterol metabolism, lipid synthesis, and lipid transport genes. Shorter chain PFAAs (C4 sulfonate and C4-C7 carboxylates) and PFAS replacements induced significant liver lipid accumulation and had gene activation at much lower concentration than legacy PFAAs. Hepatic lipid accumulation was not observed in treatments with longer chain PFAAs (C6-C8 sulfonates and C6-C12 carboxylates, except C10, C13, and C14). Overall, PFAS were highly transcriptionally active. Although alternative PFASs have shorter half-lives, shorter chain PFAAs and replacement PFAS were much more potent in our assays, and this work suggests health effects of these compounds need to be more critically evaluated. We hope to correlate the observed trends in chain length to a biological processes that may help identify priority PFASs.

2436 Investigating the Toxic Effects of Perfluoroctanoates PFOA, PFOS, and PFHx on Hepatic Toxicity and Cytochrome P450 Metabolism

S. Kandel, J. Lampe, and R. McCullough. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

Per- and polyfluoroalkyl substances (PFASs) are a group of chemicals which have been extensively manufactured and used in a variety of consumer and industrial products. Because of their chemical properties, PFAS persist in the environment and bioaccumulate in the human body. Exposure to PFAS are associated with many adverse human health effects, including reproductive, developmental, liver, kidney and immunological effects in people as well as laboratory animals. While these chemicals are still widely used and persist in the environment, the mechanisms behind PFAS toxicity is not well understood. Here, we utilized three species of PFAS, including perfluorooctanoic acid (PFAS), perfluorooctanesulfonic acid (PFOS) and perfluorohexane-1-sulphonic acid (PFHx) to investigate specific toxicity to human hepatocytes *in vitro*. We find that exposures that range up to 250mM cause significant toxicity to HepG2 hepatocytes, as measured by LDH release assay. Moreover, we evaluated CYP3A7 and CYP19A1 (aromatase) activites following PFOS and PFAS exposure. Based on the perfluorooctanoates resemblance to endogenous lipid substrates, and their known inhibition of hepatic drug metabolizing CYP enzymes, it was our hypothesis that PFOA and PFOS would effectively inhibit the metabolism of CYP3A7 and CYP19A1. We found that both PFOA and PFOS inhibited the metabolism of the fluorescent substrate dibenzylfluorescein (DBF) by CYP3A7 and CYP19A1. The IC_{50} values for CYP3A7 inhibition were 21 μM for PFOS and 75 μM for PFOA. For CYP19A1 the IC_{50} value was 41 μM for PFOS. Interestingly, both PFOS and PFOA bound to CYP3A7 in a reverse Type I manner, suggesting possible displacement of the axial water ligand and ligation to the heme iron. Inhibition of the enzymatic activity of these two enzymes points to a mechanism of action in the liver. Overall, these data suggest that the direct effects of PFAS exposure may affect not only effect liver toxicity, but the overall ability of the tissue to perform essential metabolic function.

2437 Perfluorooctanoic Acid Induces Liver and Serum Dyslipidemia in a Humanized PPARα Mouse Model Fed an American Diet

J. Schlezinger[1], T. Hyötyläinen[2], C. Boston[1], W. Heiger-Bernays[1], and T. Webster[1]. *[1]Boston University School of Public Health, Boston, MA; and [2]Örebro Universitet, Örebro, Sweden.*

Americans are exposed daily to mixtures of perfluoroalkylated substances (PFAS) in drinking water, food, air, dust in their homes, and direct use of consumer products. Increased concentrations of serum total cholesterol and low density lipoprotein cholesterol (LDL-C) are among the best supported endpoints by epidemiology studies. Dyslipidemia (elevated triglycerides, decreased high density lipoprotein cholesterol) and increased serum LDL-C are major contributors to cardiovascular disease, the leading cause of mortality in the US. Despite evidence that human PFAS exposure is associated with dyslipidemia, these effects of PFAS have received little toxicological research focus, largely because there is no suitable animal model. Mechanisms by which PFAS cause lipid-disrupting metabolic effects are not well understood, but evidence for interaction with human peroxisome proliferator activated receptor α (PPARα), an essential mediator of cholesterol and lipid homeostasis is one logical molecular initiating event. Polymorphisms in human PPARα are associated with changes in serum cholesterol. Our data show that PFAS activate human PPARα transcriptional activity. Mice expressing human PPARα and fed a diet based on the "What we eat in America" analysis provide a new animal model needed for PFAS-induced dyslipidemia research. Perfluorooctanoic acid (PFOA) exposure in drinking water (3.5 mg/l) for 6 weeks resulted in a serum PFOA concentration of 48 ± 9 μg/ml, a serum level approximately 2-fold higher than that found in fluorochemical workers. PFOA exposure increased liver mass, increased lipid content, perturbed the liver and serum lipidomes and induced PPARα target gene expression with sex-dependent effects. Effects were significantly altered in PPARα knockout mice. A literature-based analysis of effects of PFOA on serum triglyceride and cholesterol across multiple mouse models revealed a non-monotonic dose response. The humanized PPARα mouse model fed an American diet is an important new model for examining PFAS-induced dyslipidemia.

2438 Ecological Toxicity Mapping of Per- and Polyfluoroalkyl Substances (PFAS) with Ecotoxicology Knowledgebase Protocols

J. H. Olker[1], C. Elonen[1], R. Wang[2], B. Kinziger[3], G. Elonen[4], A. Anderson[3], A. Pilli[3], and D. Hoff[1]. *[1]US EPA/ORD, Duluth, MN; [2]US EPA/ORD, Cincinnati, OH; [3]GDIT, Duluth, MN; and [4]BTS, Duluth, MN.* Sponsor: M. Hornung

Given the persistence and wide distribution of some per- and polyfluoroalkyl substances (PFAS) in the environment, there is a recognized need to characterize potential ecological impacts and risks of these substances. The goal of this work was to identify and describe available empirical evidence for ecological effects of PFAS using the systematic, well-established search and curation protocols of the ECOTOXicology Knowledgebase (ECOTOX, www.epa.gov/ecotox), and then identify potential toxicity pathways for this group of compounds. ECOTOX is a publicly available web-based database that has curated ecologically-relevant toxicity data for over 30 years to support chemical decision making. Comprehensive literature searches with over 300 chemical names and CASRNs were conducted in 2018-2019 to update PFAS data in ECOTOX. From the resulting 15,000 references, title and abstract screening identified over 500 papers that met inclusion criteria for ECOTOX (e.g., ecologically-relevant species, verifiable CASRN, endpoint and control reported). Full-text review has identified 250 acceptable papers to-date and is on-going. All pertinent study details were extracted from each acceptable paper [species, chemical(s), test methods, and toxicity results]. ECOTOX now contains fully curated ecotoxicological data for 96 PFAS from 437 references with 264 unique biological test species. Most data in these studies were for PFOS and PFOA in a handful of species (e.g., zebrafish, earthworm, chicken), with 30% traditional growth/reproduction/mortality toxicity endpoints and nearly 40% biochemical or genetic effects reported. With genotypic data for the common test species, *Danio rerio*, ontologies (e.g., Gene Ontology) and pathways databases (e.g., REACTOME, KEGG) were used to identify multiple candidate pathways potentially implicated in PFAS toxicity, including lipid metabolism, carbohydrate metabolism, and endocrine system. Where genotypes are not available, the toxicity responses will be mapped to pathways using ontology-based semantic analysis. The ecological toxicities for PFAS identified and curated through these efforts can inform ecological risk assessments, development of Adverse Outcome Pathways, species extrapolation, and other applications. *The contents of this presentation do not reflect US EPA policy.*

2439 Effects of Developmental Exposure to Perfluoroalkyl Substances on Brain and Heart Innervation in Northern Leopard Frogs

R. M. Foguth[1], T. D. Hoskins[1], G. C. Clark[2], M. Nelson[1], R. W. Flynn[1], C. de Perre[1], L. S. Lee[1], M. S. Sepulveda[1], and J. R. Cannon[1]. *[1]Purdue University, West Lafayette, IN; and [2]Morehead State University, Morehead, KY.*

Perfluoroalkyl substances (PFAS), such as perfluorooctane sulfonate (PFOS), are compounds that have been used in a variety of products like aqueous firefighting foams, stain and water repellents, nonstick cookware, carpets, and clothing. Discharge from manufacturers and usage has led to PFAS presence in drinking water and >99% of human serum, where half-lives are in the order of years. Research has shown PFAS accumulation in the brains of wildlife such as polar bears and North Atlantic pilot whales and that 10-100x more PFOS accumulates in the brain compared to other tested PFAS. However, research on the effects of exposure to these compounds on the brain, especially during development, is lacking. Prior work from our group showed that exposure to 100-1000 ppb PFOS selectively altered dopamine neurotransmission. We hypothesized that environmentally-relevant mixture doses would produce similar toxicity and decrease sympathetic innervation of the heart. To determine effects, we aqueously exposed Gosner stage (GS) 25 Northern Leopard frogs (n=25/tank, 4 tanks/treatment) to 10 ppb PFOS or a PFAS mixture (4 ppb PFOS, 3 ppb perfluorohexane sulfonic acid, 1.25 ppb perfluorooctanoic acid, 1.25 ppb perfluorohexanoic acid, and 0.5 ppb perfluoro-n-pentanoic acid).

Nine tadpoles per tank were sacrificed after 30 days of exposure for brain neurochemical analysis. Remaining tadpoles were collected at GS 42 and allowed to grow to GS 46 before the brain and heart were collected. Weight, length, GS, and time to development were recorded for each frog, PFAS were quantified using mass spectrometry, and neurotransmitters were quantified using High Performance Liquid Chromatography and with the Invitrogen Amplex Red Acetylcholine Assay. Preliminary data suggests that after 30 days, a significant decrease was evident in PFAS-treated frogs, whereas no significant differences in physiological data or other neurotransmitter levels were detectable. Trends toward decreased acetylcholine, 3,4-dihydroxyphenylacetic acid, and homovanillic acid (HVA) suggest further analyses. PFOS-exposed frogs were longer than controls at metamorphosis, although time to metamorphosis did not significantly differ among groups. There were no significant differences in neurotransmitters in the brain or heart, although there were trends to decreased dopamine and increased dopamine turnover in PFOS-treated brains and increased HVA and norepinephrine in hearts. Overall, preliminary data suggests that PFAS could be affecting growth and causing modest changes in neurotransmitter levels, which could lead to detrimental effects if exposed to another neurotoxic chemical.

PL 2440 The Effects of E-cigarette and Cigarette Use on the Nasal Microbiome

E. Hickman, B. Zorn, M. Rebuli, C. Robinette, M. Wolfgang, and I. Jaspers. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Electronic cigarettes (e-cigarettes) are gaining popularity as an alternative to smoking traditional cigarettes. E-cigarettes are often perceived as safer than cigarettes, but the effects of e-cigarette use on the respiratory system have not been fully characterized. One area of research that has not been explored in the context of e-cigarette use is the potential effect of e-cigarettes on the respiratory microbiome. The respiratory microbiome plays a key role in respiratory host defense, and alterations in the respiratory microbiome (dysbiosis) have been associated with diseases such as asthma, chronic obstructive pulmonary disease, chronic rhinosinusitis, and cystic fibrosis, as well as with smoking cigarettes. To determine whether e-cigarette use causes respiratory microbiome dysbiosis, we sampled the nasal microbiomes of adult e-cigarette users, smokers, and non-smokers using a non-invasive absorptive strip to collect epithelial lining fluid. We then used high-throughput sequencing of the bacterial 16S rRNA gene from the strips and microbiome analysis pipelines to identify bacteria present and analyze the bacterial composition of the nasal microbiome. Our results indicate that alpha diversity (within individual) is significantly greater in male subjects than in female subjects and that this relationship is particularly pronounced in the e-cigarette user group. We also found that beta diversity measures (between individuals) clustered significantly by sex and exposure group. We observed a significant increase in bacteria from genera *Staphylococcus, Streptococcus, Corynebacterium,* and *Propionibacterium* in cigarette users, which is in agreement with previous studies. In the e-cigarette group, there was a significant decrease in relative abundance of bacteria in the genera *Propionibacterium, Moraxella,* and *Shuttleworthia*. Our results indicate that e-cigarette use can alter the nasal microbiome and that this alteration is different from the microbiome dysbiosis observed in association with cigarette use. Overall, these data provide insight on the effects of sex as well as e-cigarette and cigarette use on the nasal microbiome, which contributes to our understanding of the respiratory effects of e-cigarette use.

PL 2441 Electronic Cigarette Aerosol-Induced, Oxidative Stress-Mediated Lung Epithelial Cell Injury Is Alleviated by N-Acetyl Cysteine

E. Hossain, A. Penn, and A. Noël. *Louisiana State University, Baton Rouge, LA.*

Emerging evidence indicates that exposure to electronic-cigarette (e-cig) aerosols induces vaping-associated pulmonary illness (VAPI), potentially leading to death. The cellular and molecular mechanisms underlying these effects, however, are unknown. We previously showed *via* an air-liquid interface (ALI) exposure model that exposure of human bronchial epithelial cells (H292) to butter-flavored e-cig aerosol increased reactive oxygen species (ROS) generation and up-regulated expression of *HMOX1*. N-acetyl cysteine (NAC) is an antioxidant that protects against ROS-mediated lung injury. In the present study we asked whether pre-treatment with NAC can alleviate e-cig aerosol-induced oxidative stress-mediated lung epithelial cell injury. H292 cells were pre-treated with or without 5mM NAC for 12 hours before a single 2-hour exposure to each of two different flavored-e-cig aerosols (butter and cinnamon). Cells were exposed to the e-cig aerosols at the ALI *via* a Vitrocell exposure system connected to a third-generation e-cig device. Cytotoxicity, epithelial cell barrier integrity (TEER), gene expression, and markers of oxidative stress and DNA damage were assessed. Exposures to butter- and cinnamon-flavored e-cig aerosols alone significantly reduced the numbers of viable cells and reduced TEER; cinnamon e-cig aerosols also increased levels of ROS and lactate dehydrogenase (LDH). NAC pre-treatment reduced all these responses to control levels. Further, cinnamon-flavored e-cig aerosols upregulated expression of α7*nAChR, CYP1A1*, *CYP1B1*, *ALDH3A1, NOX1, NOX2, DUOX2, CCL2,* and *TNF-α,* and downregulated expression of *NF-kB1, STAT6,* and *NRF2*. Dysregulation of all these genes was prevented by NAC pre-treatment. Only cinnamon-flavored e-cig aerosols augmented the cell media levels of heme oxygenase-1 (HO-1), a marker of oxidative stress, and 8-hydrodeoxyguanosine (8-OHDG), a marker of DNA damage. Those increases were prevented by NAC pre-treatment. Pre-treatment with NAC alleviate the oxidative stress-mediated damage to lung cells induced by e-cig aerosols. These data suggest that oxidative stress is critical to the mechanism of e-cig aerosol toxicity.

PL 2442 Chemical and Toxicological Characterization of Vaping Products from Different Viscosity Enhancers in E-liquids

H. Jiang[1], T. Martin[2], I. W. Oswald[2], C. Ahmed[1], J. Chen[1], K. Koby[2], A. Canchola[1], J. A. Garcia[1], and Y. Lin[1]. *[1]University of California Riverside, Riverside, CA; and [2]Abstrax Tech, Irvine, CA.*

There have been an increasing number of reports on the detrimental vaping-related incidents, such as lung injury, lipid pneumonia, and the occurrence of seizures, which illicit a great health concern regarding the usage of vaping products including e-cigarettes and cannabis. The prevalence of vaping among adolescents has increased dramatically within the past decade for the reduced consumption of nicotine and lack of combustion needed to consume the product during vaping. The major components of vape juices and e-liquids are the viscosity enhancers, the percentage of which can reach up to 100%. Previous studies have reported that the thermal degradation and oxidation of commonly used viscosity enhancers (e.g., propylene glycol) can produce a large amount of highly toxic aldehydes (e.g., formaldehyde and acetaldehyde). Recently, a variety of new viscosity enhancers have been introduced into the market. However, to date, the chemical compositions and toxicological characterization of vaping products from these viscosity enhancers are largely unknown. This pilot study aims to provide a molecular and toxicological characterization of e-cigarette vaping products from eight commonly used viscosity enhancers, including propylene glycol, glycerin, medium-chain triglyceride (MCT) oil, triethyl citrate, squalane, vitamin E (tocopherol), vitamin E acetate (tocopheryl acetate) and a popular terpene-based diluent. The vaping products in both gas and particle phase were collected into two tandem impingers. Samples collected in isopropyl alcohol and o-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride (PFBHA) aqueous solution were applied to GC-MS for chemical analysis. Samples collected in LHC-9 cell culture media were applied for cell proliferation and cytotoxicity evaluation in human epithelial lung cells (BEAS-2B). Our study has shown that these viscosity enhancers can decompose and be oxidized during vaping. Furthermore, the cytotoxicity of the vaping products from these viscosity enhancers will be linked to the corresponding chemical compositions. The results of this study will inform the general public of potential vaping-related health risks.

PL 2443 Chronic Use of Electronic and Tobacco Cigarettes Alters Oxidized Lipids in Healthy Young Adults

R. Gupta, Y. Lin, K. Luna, A. Logue, K. Haptonstall, R. Moheimani, Y. Choroomi, K. Nguyen, E. Tran, A. Yoon, Y. Zhu, K. Faull, H. Middlekauff, and J. Araujo. *University of California Los Angeles, Los Angeles, CA.*
Sponsor: O. Hankinson

Electronic cigarettes (EC) have gained unprecedented popularity in recent years especially among the youth with over 3.6 million users in the US. Recent published case reports have detailed range of severe pulmonary illnesses associated with increased oxidative stress and/or inflammation among EC users. Here, we aimed to determine whether chronic EC use leads to changes in antioxidant defense and/or lipid peroxidation in plasma as compared to chronic tobacco cigarette (TC) smokers. We enrolled EC users (n=32), TC smokers (n=29) and control non-smokers (n=45), with mean ages of 28, 27.4 and 27.5 years, respectively. Plasma levels of oxidized fatty acid metabolites were assessed by liquid chromatography-mass spectrometry. Paraoxonase-1 (PON-1) enzymatic activity and total antioxidant capacity (TAC) were also evaluated in the plasma. Plasma levels of arachidonic acid (AA) and linoleic acid (LA) were significantly higher in TC smokers as compared with EC users ($p<0.01$). On the other hand, the levels of oxidized LA metabolites (9-hydroxyoctadecadienoic acid (9-HODE) + 13-HODE) in EC users (5.05 ± 0.41 ng/ml) and TC smokers (4.43 ± 0.43 ng/ml) were markedly lower ($p<0.01$) as compared to controls (9.85 ± 1.06 ng/ml). Surprisingly, a significant increase ($p<0.001$)

was observed in plasma total antioxidant capacity in TC smokers (1.62 ± 0.07 mM Trolox) when compared to controls (1.37 ± 0.03 mM Trolox) with a similar trend in EC users (1.47 ± 0.03 mM Trolox) when compared to controls (p=0.14), with no differences in either PON-1 or arylesterase activities. In conclusion, chronic use of either EC or TC smoking over a year leads to reduced plasma levels of oxidized fatty acid metabolites (9-HODEs and 13-HODEs) in healthy young adults, likely due to homeostatic compensatory anti-oxidant responses triggered by EC and TC pro-oxidant effects.

PL 2444 Prenatal E-cig Aerosol Exposure Leads to Sex-Dependent Abnormal Extracellular Matrix (ECM) Remodeling and Myogenesis in Offspring Mice

Q. Wang[1], I. K. Sundar[1], J. L. Blum[2], J. R. Ratner[2], J. H. Lucas[1], T. Chuang[3], Y. Wang[3], J. Liu[3], V. K. Rehan[3], J. T. Zelikoff[2], and I. Rahman[1]. *[1]University of Rochester Medical Center, Rochester, NY; [2]New York University School of Medicine, New York, NY; and [3]David Geffen School of Medicine at UCLA, Torrance, CA.*

E-cig vaping is a serious concern, especially since many pregnant woman who smoke consider it safe. However, little is known about health risks of prenatal exposure to unflavored e-cig aerosols later in life. The goal of this toxicological study is to determine the effects of prenatal exposure of mice to e-cig aerosols on lung development, particularly on ECM remodeling and myogenesis. Pregnant CD-1 mice were exposed to unflavored e-cig aerosols, with or without nicotine; at 6-wk-of-age, male and female offspring were examined. Lung tissue was histologically-analyzed and total RNA and protein were isolated for quantification of lipogenesis/myogenesis and ECM remodeling biomarkers. Compared with sex- and age-matched air control offspring, female mice exposed prenatally to e-cig aerosols (with or without nicotine) demonstrated increased protein levels of the myogenic proteins: fibronectin, LEF-1, and E-cadherin, whereas males exposed prenatally to e-cig aerosols with nicotine had decreased E-cadherin, but increased PPARγ protein levels. Pertinent lipogenesis/myogenesis lung mRNAs (*ADRP*, *CNN1* and *ACTA2*) were also dysregulated in a sex-dependent manner. Interestingly, ECM regulator PAI-1 was significantly increased in females exposed prenatally to e-cig aerosols with nicotine, whereas it was up-regulated in males following exposure to e-cig aerosols with or without nicotine. MMP9, a downstream target of PAI-1, was down-regulated in both sexes, while MMP2 and TIMP1 were increased only in females exposed to e-cig aerosols with or without nicotine. No differences in lung histology were observed between treatment groups. Our data show that mice exposed prenatally to unflavored e-cig aerosols could be predisposed to developing pulmonary disease later in life in a sex-dependent, but nicotine-independent manner. These findings suggest that e-cig use during pregnancy is not safe and could increase the offspring's propensity for interstitial lung diseases later in life. *NIH 1R01HL135613; NIH HL127237; TRDRP 27IP-005; NIH P30 ES000260.*

PL 2445 Short-Term JUUL and Third-Generation E-cig Aerosol Exposure Dysregulates Biotransformation and Inflammation-Related Genes in Murine Macrophages Exposed at the Air-Liquid Interface

R. I. Pinkston[1,2], E. Hossain[1], M. Selig[1], A. Penn[1], and A. Noel[1]. *[1]Louisiana State University, Baton Rouge, LA; and [2]Southern University and A&M College, Baton Rouge, LA.*

Electronic nicotine delivery systems (ENDS), including electronic-cigarettes (e-cigs) and JUUL-like devices, are now considered the most commonly used form of tobacco products among youth in the United States. The prevalence of ENDS usage is currently 2.1 million among middle and high school students, fueling concerns over the adverse health effects related to ENDS use. Emerging evidence suggests that ENDS aerosols affect local immune function of key protective cells, including alveolar macrophages, the lungs' first line of defense against inhaled xenobiotics. The aim of the present study was to evaluate the *in vitro* toxicity and gene expression of two popular JUUL and e-cig flavors (crème brûlée and mango) using an *in vitro* physiologically-relevant exposure model. JUUL and e-cig aerosols were generated using a peristaltic pump or a third-generation e-cig device. Applying standard vaping topography profiles, murine macrophages (RAW 264.7) were exposed to JUUL or e-cig aerosols at the air-liquid interface (ALI) for 60 minutes. Filtered-air was used as a control. Cell viability, cytotoxicity and membrane damage, nitric oxide (NO) production, and gene expression were assessed. Although crème brûlée and mango-flavored JUUL and e-cig aerosol exposures did not affect cell viability or LDH activity, JUUL and e-cig aerosols in both flavors resulted in ≥ 50% reduction in NO production compared to air controls. This was supported by the downregulation of *iNos*, a key gene that plays a role in macrophage inflammatory responses. Moreover, crème brûlée-flavored aerosols from both devices upregulated the expression of α_7*nAChR, Cyp1a1*, *AhR*, *Tgf-β* and *Mmp12* genes, while down-regulating *Ifn-γ* and *Il-6*. Exposure to mango-flavored aerosols from both devices upregulated the expression of α_7*nAChR,* while down-regulating *Il-6 and Cyp1b1*. Only e-cig mango exposures resulted in up-regulation of *Cyp1a1* and down-regulation of *AhR*, while JUUL only downregulated *Tgf-β*. These results suggest that flavored e-liquids, when aerosolized through e-cigs or JUUL devices, may adversely affect immune and respiratory health through alteration of key inflammatory molecules and associated genes. Moreover, all flavors may not be equal in toxicity, as flavors composed of a mixture of constituents, like crème brûlée, may be more detrimental to macrophages than other flavors, e.g. mango. Our future studies intend to investigate the underlying mechanisms associated with these effects using *in vitro* and *in vivo* models.

PL 2446 Impact of E-cigarette Flavoring Agents on Activity of CYP2A6, the Primary Nicotine-Metabolizing Enzyme

B. R. Winters[1], T. Kochar[1], P. W. Clapp[1], I. Jaspers[1], and M. C. Madden[2]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

Flavorings in e-cigarette liquids (e-liquids) are a primary driver of e-cigarette use among teens. While recent studies have investigated pulmonary toxicities associated with exposure to flavoring agents in e-cigarettes, little research has been conducted on the impact of flavoring agents on the pharmacokinetics of nicotine, the primary addictive compound of e-cigarettes. Utilizing recombinant microsomal CYP2A6, the enzyme primarily responsible for the metabolism of nicotine, we screened 3 e-liquids - Strawberry Poptart (SP), Apple Watermelon (AW), and Flamethrower (FT) - at concentrations ranging from 0.000031% to 0.125% (v/v), for CYP2A6 activity inhibition. CYP2A6 activity was determined by measuring the formation of the fluorescent metabolite of 3-cyano-7-hydroxycoumarin, a substrate of CYP2A6. Incubation with FT and SP strongly inhibited CYP2A6 at concentrations as low as 0.00038% and 0.0058%, respectively. AW exhibited negligible CYP2A6 inhibition. Mass spectrometry was conducted to identify concentrations of flavoring agents in flavored e-cigarette liquids that inhibited CYP2A6. Recombinant microsomal CYP2A6 was subsequently exposed to flavoring agents at concentrations ranging from 0.03 μM to 500 μM. Of the flavoring agents tested, cinnamaldehyde and benzaldehyde were found to be the most potent inhibitors of microsomal CYP2A6, with identified IC_{50} values of 1.1 μM and 3.0 μM, respectively. To confirm our findings in a cell-based system, we transduced BEAS-2B cells to overexpress CYP2A6 and subsequently exposed them to e-liquids and flavoring agents in the presence of coumarin, a CYP2A6 probe substrate. Exposure to SP, FT, and aromatic aldehydes utilized as flavoring agents significantly reduced the metabolism of coumarin by CYP2A6 at concentrations consistent with what was observed using recombinant microsomal CYP2A6. In summary, these data indicate that some flavoring agents in e-cigarettes have the capacity to inhibit CYP2A6 activity, the enzyme responsible for catabolizing nicotine. This may increase serum concentrations of nicotine and have implications for the risks associated with e-cigarette use. *This abstract may not reflect official US EPA policy.*

PL 2447 E-cigarette Vapor Decreases Bone Marrow Hematopoietic Stem and Progenitor Cells

G. Ramanathan, B. Craver, R. J. Arechavala, D. Herman, H. Yeng Lai, S. Renusch, M. T. Kleinman, and A. G. Fleischman. *University of California Irvine, Irvine, CA.*

Environmental exposure to fine particulate matter (PM) is associated with increased circulating endothelial progenitor cells. Electronic nicotine delivery system (ENDS) or E-cigarette use has increased exponentially in recent years and while a few studies indicate inflammatory and pro-oxidant effects of vaping in the respiratory system, there is limited evidence of vaping effects on the hematopoietic system. Since e-cigarette usage generates fine and ultra-fine PM, we hypothesize that chronic e-cigarette smoke exposure can alter hematopoietic stem and progenitor cell (HSPC) frequency and function via chronic inflammation. Female C57BL/6J mice were exposed via nose-only inhalation to ENDS-vapor containing nicotine for 2 months. At euthanasia, bone marrow was collected and cells stained with HSPC-specific antibodies for flow cytometry. Data was analyzed using FlowJo software. After 2 months of ENDS-exposure, we observed a decrease in hematopoietic stem and progenitor cells (HSPCs). Specifically, the lineage negative, c-Kit positive and Sca-1 positive (LKS) population was significantly reduced in the ENDS-exposed group with concomitant reduction in common myeloid progenitor (CMP) and granulocyte-monocyte progenitor (GMP) populations. There was also a

slight decrease in the frequency (p=0.065) and absolute (p=0.051) numbers of long-term HSCs. Interestingly, this reduction did not lead to changes in peripheral blood cell counts nor spleen weight. We also determined the effect of systemic LPS administration post-exposure on the proliferation of HSCs and observed no significant differences between ENDS and air exposed groups. Our study provides important evidence of changes in bone marrow HSPC populations following chronic E-cigarette exposure that can eventually lead to myelosuppression. Incidentally, combustible cigarette smoke exposure has also been shown to decrease HSPC numbers and it is striking that E-cigarette vapor exerts similar effects, although it is possible that these effects are nicotine-dependent. Future work includes determining HSC reconstitution in mice transplanted with bone marrow from the ENDS-exposure group.

PL 2448 Acute Exposure to E-cigarette Aerosols Alters Cardiac Conduction and Autonomic Balance and Induces Arrhythmia in Mice

A. P. Carll, M. D. Miles, E. H. Combs, N. Talebi, J. Zurita, and D. J. Conklin. *University of Louisville, Louisville, KY.*

E-cigarette (e-cig) use has rapidly increased, especially among youth and amidst assumptions that e-cigs are safer than smoking. Vaping has been linked to adverse cardiopulmonary effects, but the full extent of effects remains unknown. Several constituents in e-cigs may increase the risk for adverse cardiopulmonary outcomes partly by disturbing cardiac electrophysiology and autonomic nervous system (ANS) regulation. E-cig aerosols will differentially induce pro-arrhythmic changes in cardiac conduction and autonomic balance in mice depending on the presence of nicotine and flavors. Electrocardiograms (ECGs) were collected by telemetry in 5 healthy male mice (C57BL/6) exposed for 6 hours to clean air or various e-cig aerosols (9-minute puff sessions every 18 minutes) from JUUL e-liquids (Virginia [VA] Tobacco, Mango, or Menthol at ≈5% nicotine benzoate), or a nicotine-free mixture of propylene glycol and vegetable glycerin solvents (PG:VG, 30:70 ratio). ECG morphology, heart rate variability (HRV), and arrhythmias were analyzed by mixed models with $P < 0.05$ (vs. Air) for all reported effects. All e-cig aerosols increased ventricular arrhythmias throughout exposure, with PG:VG inducing the greatest effects. PG:VG also markedly increased advanced supraventricular block arrhythmias and uniquely decreased heart rate. In contrast, aerosols from nicotine-containing flavored e-liquids increased heart rate and decreased HRV, suggesting increased sympathetic modulation. E-cig aerosols from PG:VG and VA Tobacco prolonged QTc interval, suggesting arrhythmogenic impairments in repolarization regardless of nicotine. Mango and Menthol accelerated atrial (P duration) and atrioventricular (PR interval) conduction, whereas VA Tobacco accelerated atrial conduction without commensurate atrioventricular changes. E-cigs may increase risk for cardiac arrhythmia through e-liquid solvents, which when thermally aerosolized generate toxic aldehydes and particulates. Nicotine and flavor chemicals may modify the cardiac and autonomic impacts of e-cigs. Further studies are needed to determine how e-cig aerosols induce cardiac arrhythmia and whether these effects translate to cardiac morbidity and mortality in humans.

S 2450 Immunosuppressive and Anti-inflammatory Activity of Cannabis and Cannabinoids: Adverse or Therapeutic?

N. Kaminski. *Michigan State University, East Lansing, MI.*

Cannabis is currently the most widely used illicit drug in the US, with an estimated 35 million regular users, or people using cannabis more than twice a month. In addition, medicinal cannabis and cannabinoid-based therapeutics have been gaining prominence, with 33 states, four (out of five) permanently inhabited US territories, and the District of Columbia having legalized medical marijuana as of January 2019. Cannabinoids are a family of more than 60 structurally related compounds initially identified in *Cannabis sativa*. Certain cannabinoids, including the primary psychotropic congener Δ^9-tetrachydrocannabinol, are widely established as possessing immune modulating activity. Over four decades of investigation have revealed that virtually every immune cell type responds to modulation by cannabinoids. The biological activity of cannabinoids is mediated primarily, but not exclusively, through two G-protein coupled receptors termed *cannabinoid receptors* (CB1 and CB2). CB1 is expressed primarily in the CNS but can be found in most peripheral tissues, including immunocompetent cells. CB2 is found primarily in the periphery, with the exception of microglial cells, and is expressed most notably by immune cells. The identification and cloning of CB1 and CB2 led to the discovery of endogenous cannabinoids and the endocannabinoid system, which appears to influence a diversity of physiological processes, including immune responses. The widespread recreational use of cannabis (legal in 11 states and DC) has raised concerns for adverse effects. By contrast, cannabinoid receptors, and in particular CB2, represent potential therapeutic targets. The goal of this session is to discuss both the potential adverse as well as the therapeutic aspects associated with cannabinoid-mediated immune modulation in specific contextual settings based on experiments performed in animal and human model systems. The Symposium will begin with an introduction to cannabis and cannabinoids, followed by presentations that address the role of cannabinoid receptors in NK cell and innate lymphoid type 2 (ILC2) cell responses to an airway allergen; the effect of cannabinoids on the gut microbiome and downstream immunological consequences; the ability of cannabidiol, a nonpsychotropic cannabinoid that was recently US Food and Drug Administration approved for epilepsy, to inhibit immune responses in the periphery to attenuate autoimmune disease; and cannabinoid-mediated suppression of immune responses implicated in HIV-associated neuroinflammation. After this session, attendees will have a better understanding of the underlying biology of immune modulation by cannabinoids with respect to both adverse as well as potential therapeutic applications.

S 2451 History of Cannabis Use and Introduction to Cannabinoids

A. Hayes. *University of South Florida, Temple Terrace, FL.*

Cannabis is, and will remain, in the news for the foreseeable future. The term cannabis refers mainly to the marijuana plant, *Cannabis sativa*. Cannabinoids are structurally similar plant-derived chemicals in cannabis that possess similar actions to endogenous cannabinoids, termed *endocannabinoids*. Plant-derived cannabinoids and endocannabinoids exhibit activity, in part, via cannabinoid receptors, CB1 and CB2. While expression of both receptors is ubiquitous, CB1 is highly expressed in the central nervous system and CB2 is highly expressed in immune cells. The two best-characterized plant cannabinoids are Δ9-tetrahydrocannabinol (THC) and cannabidiol (CBD). THC is the major psychotropic compound in marijuana, while CBD does not produce a high, which is likely due to the fact that THC exhibits affinity for the CB1 receptor while CBD does not. A similar pattern has emerged for CB2: THC possesses affinity for CB2 and some of the immune effects of THC are mediated by CB2, while CBD does not exhibit high affinity for CB2. In fact, identification of the receptor(s) mediating the immune effects of CBD remains elusive. Despite their distinct pharmacology, THC and CBD exhibit anti-inflammatory and immune suppressive effects. It also is clear that endocannabinoids must possess immune modulatory activity, as CB1 and/or CB2 regulate immune function. Whether the immune suppression by cannabinoids should be considered adverse or therapeutic will be focus of this Symposium.

S 2452 CB2 Receptors Impact the Development of Allergic Airway Inflammation

Z. Jaffar. *University of Montana, Missoula, MT.* Sponsor: N. Kaminski

In allergic asthma, inhalation of environmental allergens such as the house dust mite (HDM) effectively activates both innate and adaptive immunity in the lung. Endogenously generated cannabinoids acting via CB2 receptors play important roles in both homeostatic and inflammatory processes. Our studies revealed that CB2-deficient (CB2-/-) mice had increased numbers of pulmonary natural killer cells (NK cells) that were inversely associated with the number of group 2 innate lymphoid cells (ILC2s) compared with C57BL/6 wild-type animals. Remarkably, CB2-/- mice were markedly less responsive to HDM allergen inhalation than wild-type counterparts since the knockout mice failed to develop many of the cardinal features of asthma. Notably, this included diminished levels of airway hyperreactivity, mucus production, eosinophilic inflammation, and CD4+ lymphocyte infiltration, as well as depressed levels of type 2 cytokines. This phenomenon was corroborated when wild-type mice were treated with a CB2-specific antagonist that caused a pronounced inhibition of HDM-induced airway inflammation and mucus secretion. NK cells were responsible for the attenuated inflammatory responses because depletion of NK cells *in vivo* in CB2-/- mice restored both the HDM-induced allergic inflammation and ILC2 numbers in the lungs. Collectively, these data demonstrate a role for CB2 receptors in the development of allergic airway inflammatory responses by regulating the number and properties of NK cells resident in the lungs.

S 2453 Cannabinoid-Induced Changes in Gut Microbiota and Suppression of Inflammation

M. Nagarkatti. *University of South Carolina, Columbia, SC.*

Exposure to Staphylococcal enterotoxin B (SEB) triggers cytokine storm, acute inflammatory lung injury (ALI), food poisoning, toxic shock syndrome, and often death. Because cannabinoids act as potent anti-inflammatory agents,

we tested the effect of Δ9-tetrahydrocannabinol (THC) on SEB-mediated ALI. Additionally, we tested if the anti-inflammatory effects of THC result from alterations in the microbiota in the gut and in the lungs. SEB administration in mice caused ALI and 100% mortality, while all THC-treated mice survived following suppression of inflammation in the lungs by inducing Tregs and myeloid-derived suppressor cells. We noted significant microbial dysbiosis following SEB treatment in the lungs, specifically with an increase in abundance of various taxa belonging to Proteobacteria, whereas THC-treated SEB-exposed mice showed a reversal in this class. Furthermore, the SEB+THC treated mice also exhibited an increase in the butyrate-producing *Ruminococcus gnavus*. Interestingly, similar changes in *Ruminococcus gnavus* also were observed in the colon in SEB+THC treated group, thereby suggesting a critical role for gut-lung axis in health and disease. We also found that the beneficial butyrate levels were significantly higher in the colonic flush of THC-treated mice that were exposed to SEB when compared with controls. In addition to THC, we found that endocannabinoids were also able to protect mice from SEB-mediated ALI, which also was associated with changes in microbiota. Together, our studies demonstrate that cannabinoids attenuate cytokine storm induced by super antigens such as SEB, through regulation of microbiota and their metabolites, which suppress inflammation through gut-lung axis.

S 2454 Cannabidiol Suppresses IFNγ Production and Neuroinflammation in the EAE Model

B. Kaplan. *Mississippi State University, Mississippi State, MS.*

Cannabidiol (CBD) is a plant-derived cannabinoid similar in structure to the psychoactive cannabinoid, Δ9-tetrahydrocannabinol (THC), although CBD does not produce a high. Despite their differences in psychotropic effects, both THC and CBD are immune suppressive. We utilized the experimental autoimmune encephalomyelitis (EAE) model of multiple sclerosis to determine effects and mechanisms by which CBD suppresses immune function. EAE disease was initiated on day 0 followed by five days of dosing with CBD by oral gavage. CBD significantly reduced disease severity at day 18. T cell responses in the spleen, lymph nodes, spinal cord, and cerebellum were assessed at day 3, 10, and 18 following disease initiation. Although it has been shown that CBD can induce T regulatory cells (Tregs) *in vitro*, we did not detect a significant increase in Tregs any time, at least in spleen and lymph nodes. However, IFN-γ production was significantly inhibited by CBD in the spleen at day 10, which preceded robust suppression of inflammation in the spinal cord and cerebellum at day 18. Together, these data demonstrate that CBD is effective in attenuating autoimmune disease and suggests that inhibition of immune responses in the periphery early might contribute to later attenuation of inflammation in the central nervous system as part of the mechanism for disease attenuation.

S 2455 Cannabinoids Suppress Immune Responses Implicated in HIV-Associated Neuroinflammation

N. Kaminski. *Michigan State University, East Lansing, MI.*

An estimated 37 million people worldwide are infected with human immunodeficiency virus (HIV). Combined antiretroviral therapy has turned HIV into a chronic infection with significantly longer life expectancy. New health issues have surfaced as HIV patients live longer. Specifically, 50% of HIV-infected (HIV+) individuals exhibit neurocognitive impairment, termed *HIV-associated neurocognitive disorders* (HAND). A key event leading to HAND is persistent low-level chronic neuroinflammation resulting in neuronal damage. A major contributor to HIV-induced neuroinflammation is activated monocytes, which are significantly elevated in patients with HIV-associated dementia. Activated, $CD16^+$ monocytes are infected by HIV in the periphery and migrate across the blood-brain barrier (BBB) to release HIV virions and neurotoxic and proinflammatory factors. Before entering the CNS, resting ($CD16^-$) monocytes transition into $CD16^+$ through poorly understood mechanisms including elevated interferon alpha (IFNα). Interestingly, cannabis, which has constituents (e.g., Δ^9-tetrahydrocannabinol (THC)) possessing immune suppressive and anti-inflammatory activity, is widely used (approximately 25%-37%) by HIV patients. Beneficial versus deleterious effects of cannabinoid therapy in HIV patients remains unknown. Our results show that THC suppresses IFNα-mediated $CD16^-$ to $CD16^+$ monocyte transition as well as IL-7 receptor upregulation on $CD8^+$ T cells. Moreover, HIV+ marijuana-users (MJ+) have fewer circulating $CD16^+$ monocytes compared with HIV+MJ-. In addition, monocytes and $CD8^+$ T cells, when cocultured with astrocytes significantly drive the secretion of astrocyte-derived inflammatory mediators, IL-6 and IP-10, a response suppressed by THC. Collectively these results suggesting that marijuana use may be protective against HAND.

S 2456 Resolution of Inflammation in Chemical Toxicity/Tissue Injury: What's Emerging?

K. Gowdy. *East Carolina University, Greenville, NC.*

Inflammation is a rapid and dynamic protective response to injury or infection. It involves a sequential accumulation of phagocytic neutrophils and macrophages derived from blood and bone marrow precursors at sites of injury/infection. The goal of the inflammatory response is to rid the body of pathogens, foreign materials, dead and dying cells, and debris and to restore normal tissue structure and function. Complete resolution of the inflammatory response and return to homeostasis are essential for restoring healthy tissues. Increasing evidence suggests that resolution is an active process that involves the downregulation of inflammatory cell recruitment and activation and the upregulation of cellular processes that drive tissue restoration. Recruitment of inflammatory cells and production of mediators have been implicated in the toxicity of diverse xenobiotics, whereas few have considered the alterations in the resolution process. In a number of experimental models, the pathogenic response to xenobiotics is a consequence of an impaired resolution of inflammation. Additionally, therapeutics that promote the resolution of inflammation response may limit xenobiotic-induced tissue injury and the development of chronic disease. The goal of this Symposium is to present new and emerging information on processes that regulate the resolution of inflammation and the how toxicant exposure alters these pathways. The first three speakers will focus on inflammatory macrophages as key cellular mediators of xenobiotic-induced pulmonary injury and the role of lipid mediators in regulating their ability to downregulate inflammation and initiate tissue resolution. The first talk will cover how xenobiotic exposure impairs macrophage clearance of apoptotic cells, termed *efferocytosis*, and its restoration by specialized pro-resolving mediators (SPMs), while the second talk will present on the role of lipid related transcription factors (FXR, PPARg) and downstream lipid transport genes (CD36, ApoE, ABCA1) as regulators of macrophage anti-inflammatory/wound repair activity in lung injury. The third talk will specifically focus on oxidized lipids and nitric oxide as regulators of necro-inflammatory cell death pathways in macrophages, including ferroptosis during inflammatory resolution. The next two talks will present the latest experimental and clinical approaches that are being tested for preventing and resolving toxicant-induced inflammation and injury in the lung; these include endogenous epoxyfatty acids, SPMs, and nitro-fatty acids. From this Symposium, the audience will gain knowledge about tools and technologies for assessing inflammation resolution, translational potential of intervention strategies, and research gaps and needs.

S 2457 Evolving Concepts in Inflammation Resolution and Future Opportunities

S. Naddadur. *NIEHS, Research Triangle Park, NC.*

This presentation will focus on the molecular mechanisms known to restore tissue homeostasis. There are critical knowledge gaps in our understanding of how toxicants/chemicals alter these processes that need to be investigated to improve the efficacy of clinical interventions.

S 2458 Mechanisms Mediating Perturbations in Alveolar Macrophage Efferocytosis Following Exposure to Toxicants

K. Gowdy. *East Carolina University, Greenville, NC.*

The lung is constantly exposed to inhaled toxicants, including air particulates and oxidant gases that trigger pulmonary inflammation. These insults can compromise gas exchange and induce irreversible tissue injury. Alveolar macrophages, which constitute approximately 95% of the immune cells found in murine and human lungs at homeostasis, are critical in regulating pulmonary inflammation after environmental insults. While it is well established that alveolar macrophages play an essential role in host defense by eliminating pathogens via phagocytosis, recently it has been shown that they also promote tissue homeostasis through efferocytosis, a process whereby macrophages engulf and eliminate apoptotic cells. Efferocytosis also produces anti-inflammatory mediators, such as IL-10, TGF-ß, and PGE2. This is essential to the resolution of pulmonary inflammation, the prevention of secondary necrosis, and the restoration of tissue homeostasis. A number of studies have linked impaired efferocytosis with chronic lung diseases, including asthma, chronic obstructive pulmonary disease, and idiopathic pulmonary fibrosis. Exposure to inhaled toxicants can specifically increase alveolar macrophage release of proinflammatory lipid mediators; however, whether toxicants alter the efferocytotic response of alveolar macrophages is unknown. Therefore, identifying the consequences of exposure to inhaled toxicants on efferocytosis and the molecular mechanism underlying potential defects will provide

key information related to how toxicants modulate the resolution of inflammation. This presentation will highlight the effects of inhaled toxicants on alveolar macrophage efferocytosis. Currently, an avenue of research that we are pursuing is investigating pulmonary lipid metabolism after ozone exposure, with emphasis on the production of specialized pro-resolving lipid mediators. Our data indicate that ozone exposure suppresses the pulmonary production of specialized pro-resolving lipid mediators, leading to decreased alveolar macrophage efferocytosis. These data, together with studies by other laboratories, link immune cell function with lipid metabolism to provide mechanistic insights for potential therapeutic interventions.

S 2459 Macrophage Phenotype and Inflammation in Lung Injury and Resolution: Role of Lipid Metabolism

D. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Macrophages play a key role in both the initiation of inflammatory responses and the resolution of inflammation and tissue repair. These diverse activities have been attributed to proinflammatory M1 macrophages and anti-inflammatory/wound repair M2 macrophages, which sequentially appear in injured tissues. Key to effective tissue repair is a balance in the activities of M1 and M2 macrophage subpopulations. Thus, whereas overactivation of M1 macrophages or underactivation of M2 macrophages can lead to exacerbation of tissue injury, excessive activation of M2 macrophages can result in chronic inflammation and fibrosis. We have been investigating the role of macrophages in lung injury induced by inhaled toxicants. In previous studies, we showed that both M1 and M2 macrophage subpopulations accumulate in the lung following exposure to pulmonary toxicants such as ozone, particulates, and mustard vesicants. We speculate that toxicant-induced lung injury and disease pathogenesis is due to a failure of M2 macrophages to suppress proinflammatory responses of M1 macrophages. RNA-seq analysis revealed that nuclear transcription factors involved in lipid handling, including PPARγ, LXR, and FXR, are downregulated in the lung after pulmonary toxicant exposure. This is associated with prolonged inflammatory activity of M1 macrophages and reduced anti-inflammatory activity of M2 macrophages. PPARγ agonists induced M2 macrophage activation and reduced lung inflammation and oxidative stress induced by pulmonary toxicants. Conversely, mice deficient in FXR exhibited exacerbated proinflammatory macrophage activity and prolonged oxidative stress. Taken together, these data indicate that lipid handling and metabolism are key to regulating macrophage activation and the resolution of inflammation following lung injury.

S 2460 Regulation of Macrophage Programmed Death in Inflammation by Redox Lipid Signaling

V. Kagan. *University of Pittsburgh, Pittsburgh, PA.* Sponsor: K. Gowdy

Signaling by macrophages orchestrates, to a large extent, the transition from proinflammatory responses to successful resolution of inflammation. Among these, the potent regulators of such signals are orderly dying apoptotic cells using oxidized phospholipids, phosphatidylethanol-amine, and cardiolipin, for this purpose. In contrast, chaotic signaling by necrotic materials enhances and perpetuates inflammation. Recent discoveries of necrotic cell death programs, particularly necroptosis, pyroptosis, and ferroptosis, point to their necro-inflammatory effects, thus emphasizing the important role of the type of cell death program in regulation of inflammation. Ferroptosis, the latest addition to the list of regulated necrosis, occurs due to the loss of control over three homeostatic mechanisms regulating iron, lipid peroxidation, and thiols. By applying redox lipidomics, we discovered that 15-lipoxygenase (15-LOX) complexed with phosphatidyl-ethanolamine binding protein 1 (PEBP1) catalyzes the generation of pro-ferroptotic signals, 15-hydroperoxy-eicosatetraenoyl-phosphatidylethanolamine (15-HpETE-PE), hence modulates the ferroptotic endurance. We further established that this pro-ferroptotic signaling is essential for the execution of the ferroptotic program not only by mammalian cells, but by prokaryotes, particularly bacterial pathogens (*P. aeruginosa*) as a "theft-ferroptosis" mechanism to manipulate the host inflammatory responses. Analysis of cell death programs in macrophages revealed that their characteristic phenotypic features define their susceptibility or resistance to ferroptosis. We discovered that iNOS/NO· is the major regulator of macrophage ferroptotic pathways and established the underlying molecular mechanisms. These new concepts of cell death-type propagated necro-inflammation versus non-necrotic apoptosis-driven resolution of inflammation will be discussed in the context of the essential lipid redox signaling.

S 2461 Endogenous Epoxyfatty Acids Prevent and Resolve Inflammation by Stabilizing Mitochondria and Reducing Pathological Endoplasmic Reticulum Stress

C. Morisseau. *University of California Davis, Davis, CA.* Sponsor: K. Gowdy

Lung inflammation is involved in a variety of pulmonary diseases, as well as following exposure to dust, environmental chemicals, and potential chemical warfare agents. The arachidonic acid cascade has long been known to play a role in pulmonary inflammation through two predominantly inflammatory branches driven by cyclooxygenase and lipoxygenase enzymes. Therapeutically, many drugs that reduce pulmonary inflammation either block the formation of inflammatory products from the cyclooxygenase and lipoxygenase branches of the arachidonic acid cascade or by blocking the action of these products. However, there is a third branch to the cascade known as the cytochrome P450 cascade, which is predominantly, but not exclusively, anti-inflammatory. Within this cascade, cytochrome P450 enzymes produce epoxides of polyunsaturated fatty acids, which act as powerful chemical mediators to stabilize against mitochondrial dysfunction, thus reducing reactive oxygen species and endoplasmic reticulum stress leading to inflammation and fibrosis. These epoxyfatty acid (EpFA) chemical mediators are largely degraded by an enzyme known as the soluble epoxide hydrolase (sEH), which works near the diffusion controlled limit to convert the EpFA to the corresponding 1,2-diols, which are either inactive or, in some cases, proinflammatory. Thus, inhibiting sEH increases inflammation resolving EpFA, which mitigates some pulmonary disorders. The sEH inhibitors in many cases are more active in animals with an ω-3 enhanced and an ω-6 depleted diet. They also synergize with FLAP inhibitors in asthma models. The sEH inhibitors have been effective in a variety of animal models of pulmonary inflammation, including asthma, COPD, and idiopathic pulmonary fibrosis, suggesting that sEH inhibitors, EpFA, or their mimics could be therapeutic agents. This is being explored in several human trials with COPD as a target.

S 2462 The Road from Bench to Bedside: the Clinical Development of the Nitro Fatty Acid CXA-10

D. Jorkasky. *Complexa, Berwyn, PA.* Sponsor: K. Gowdy

The evolution of an endogenous mediator with promising signaling actions into a regulatory approved pharmaceutical product requires extensive preclinical and clinical development. CXA-10 is the synthetic pure regioisomer, 10-nitro-octadec-9-enoic acid, of endogenous nitrated oleic acid (NO2 -OA), a prototypical molecule of a class of endogenously generated mediators called nitrated fatty acids (NO2 -FA). *In vitro* observations and *in vivo* animal models have demonstrated their significant cytoprotective effects through anti-inflammatory, immunomodulatory, and pro-metabolic signaling responses, which have pharmacological potential in human inflammatory diseases. To support human development, preclinical characterization of CXA-10 included the determination of its absorption, distribution, metabolism, and excretion; safety evaluation at doses greatly exceeding pharmacological activity; and development of validated assays for measurement of CXA-10 and its key metabolites. Dose/exposure response ranges of pharmacological activity were constructed to facilitate translation of CXA-10's pharmacokinetic/pharmacodynamic results into humans. Both IV and oral CXA-10 formulations were developed and utilized in phase 1 studies in lean and obese healthy volunteers and subjects with impaired kidney function. The mechanisms of NO2 -FA signaling mediated by CXA-10 observed in preclinical studies (heat shock response [HSR] and Nrf2 activation and NF-κB inhibition) have been translated at predicted dose/exposures in humans. Measurement of gene expression in peripheral blood mononuclear cells and urinary exosomes derived from the kidney demonstrated Nrf2 and HSR activation after a single dose, and significant inhibition of inflammatory mediators MCP-1, leptin, and IL-6 was demonstrated after multiple days of once daily oral dosing. The pro-metabolic effects of CXA-10 were observed by significant reductions in serum triglyceride and cholesterol levels. CXA-10's actions on Nrf2, which affects metabolic transporters, also were confirmed in a drug-drug interaction study. Overall, despite CXA-10's unique chemical pedigree as a reversible covalent electrophilic fatty acid with pluripotent pharmacological activity, human phase 1 studies have demonstrated the safety, tolerability, and predicted pharmacological actions of CXA-10 with once-a-day dosing.

2463 Single-Cell Technologies: A Potentially Transformative Tool for Toxicology

S. Bhattacharya. *Michigan State University, East Lansing, MI.*

Single cell genomics and epigenomics have been among the breakthrough biological technologies of the last few years. These methods provide detailed views of living systems at unprecedented resolution and bypass the problems associated with averaging over heterogeneous cellular responses in bulk assays. Some spectacular successes of single cell RNA sequencing (scRNA-seq) include cell-by-cell reconstruction of transcriptomic atlases of xenopus and zebrafish embryos, along with ambitious undertakings like the Human Cell Atlas to map the transcriptomes of all cell types in the human body. This timely and topical Symposium will provide an overview of the capacities and limitations of current single cell technologies and describe cutting-edge applications of single cell methods in detecting perturbations in cellular state in health and disease, including identification of rare and altered cell types. The presenters will explore the role of single cell transcriptomic profiling in revealing phenotypic heterogeneity among breast cancer stem cells, mapping alterations in the developmental trajectory of early germ cells subject to environmental insult, discovery of a novel subpopulation of alveolar macrophages in an animal model of asbestos-induced pulmonary fibrosis, and identification of an altered effector CD8 T lymphocyte population in smokers. Overall, the presentations in this Symposium will introduce the field of single cell 'omics and provide a snapshot of the first generation of applications of these novel technologies in toxicology.

2464 Dissecting Complex Systems with Multidimensional Single Cell Data

G. Zheng. *Arsenal Biosciences, South San Francisco, CA.* Sponsor: S. Bhattacharya

Biological systems are complex, with many individual components. Discriminating the subunits and their relationships is critical to elucidating biological systems and gaining mechanistic insights from genotypes to phenotypes. In the last few years, advances in single cell technologies have made it possible to study intercellular relationships among complex tissues at unprecedented scale, resolution, and precision. These advances include the ability to query the genome, transcriptome, epigenome, and proteome in a large number of cells at single cell resolution and the ability to perturb the genome and epigenome of every single cell. This presentation will describe single cell technologies in each area and the expanding number of available experimental platforms, along with key examples of applications that have already advanced our understanding of biology. In particular, the power of profiling gene expression and a panel of cell surface proteins from the same cells, and recent efforts to use this technology to discover T cell receptor and antigen interaction at scale, will be discussed. In addition, a case study of single cell epigenetic profiling of intratumoral T cells from solid tumor biopsies will be presented. The presentation will close with a discussion of trends in single cell 'omics research over the next few years.

2465 Single Cell Profiling to Characterize Breast Stem Cell Heterogeneity in Development and Cancer

J. A. Colacino. *University of Michigan, Ann Arbor, MI.*

Emerging epidemiological evidence points to the number of stem cells in a tissue as being a key determinant of risk of multiple cancers, including breast cancer. Breast cancers also are driven and sustained by a stem-like population of cells. Breast cancer stem cells transit between multiple phenotypic states, from mesenchymal-like to epithelial-like states. Stem cell heterogeneity in the normal human breast is not well understood but could be an important predictor of cancer risk. To better understand this heterogeneity, we profiled normal reduction mammoplasty tissues by flow cytometry for two known markers of breast stem cells, ALDH+ and CD44+/CD24-. RNA-seq of sorted ALDH+ cells revealed an epithelial phenotype, reflected by expression of CDH1, EPCAM, and KRT8. CD44+/CD24- had a mesenchymal expression pattern, reflected by high VIM, CDH2, and ZEB2 expression. Isolated ALDH+ normal breast stem cells were profiled for single cell gene expression using the Fluidigm C1 and Biomark systems. Unbiased hierarchical clustering revealed that the ALDH+ single cells clustered in three classes, an epithelial-like, a mesenchymal-like, and a hybrid epithelial/mesenchymal (E/M) phenotype. Hybrid E/M cells also expressed high levels of genes associated with poor prognosis in triple negative breast cancer samples, including CD146, KRT7, and NOTCH3. Additionally, we used drop-seq for single cell RNA-seq on normal mammary epithelial cells grown in conditional reprogramming (CR) conditions. These cells were enriched in hybrid E/M cells, relative to mammary epithelial cells, which were not grown in CR. Aligning the CR cells to publicly available single cell RNA-seq data generated by sampling mouse mammary gland at multiple time points through the life course shows that hybrid E/M cells preferentially map to the *in utero* mammary gland. Thus, the hybrid E/M state reflects an *in utero* stem cell state, with gene expression patterns activated in aggressive breast cancers. Ongoing work is using single cell profiling of breast epithelial cells from African American women and European American women to test the hypothesis that the increased risk of triple negative breast cancer in African American women is linked to an expansion of hybrid E/M stem cells and testing whether toxicant exposures can cause expansion of this rare cell population.

2466 Understanding Environmental Impact on Germ Cell Differentiation Trajectories Using scRNA-Seq

P. Allard. *University of California Los Angeles, Los Angeles, CA.*

While the intricate steps of germ cell development have long been hypothesized to provide unique windows of sensitivity to environmental insults, little is known of the effect of chemical exposure on the epigenome of germ cells and of the mechanisms of inheritance of these effects. This gap is particularly significant as embryonic germ cells undergo an extensive remodeling of their chromatin, which includes genome-wide demethylation and the establishment of a complex pattern of histone modifications. The failure to properly regulate these histone marks leads to spurious repetitive element expression, germ cell death, and infertility. Here, we use *in vitro* generated mouse and human germ cells termed *Primordial Germ Cell-Like Cells* (PGCLCs) to conclusively show that their epigenetic remodeling period constitutes a period of high sensitivity to environmental exposure. To this aim, we exposed their precursors, epiblast-like cells (EpiLCs) as well as PGCLCs for various lengths of time to (1) known chemical inhibitors of specific histone marks, and (2) a model environmental chemical: BPA. We examined the impact of these exposures on survival/viability as well as the levels of repressive histone marks such as H3K9me3 and H3K27me3. By using targeted chemical inhibitors, we show that the tight regulation of both repressive histone marks, H3K9me3 and H3K27me3, is essential for survival of differentiating PGCLCs. We also show that low BPA concentrations (1 and 10 uM) disproportionately affect PGCLCs survival but not EpiLCs. These effects correlate with a marked decrease of both repressive marks, H3K9me3 and H3K27me3. Finally, by using scRNA-seq, we show that exposure of human PGCLCs to low BPA levels doses alters the developmental trajectory of PGCLCs and affects precursors of PGCLCs disproportionately compared with PGCLCs themselves. We expect this research to provide a much-needed examination of the pathways implicated in the sensitivity of early germ cells to environmental insults and at the root of infertility.

2467 Single Cell Transcriptomics Identifies Key Cellular Players in an Animal Model of Asbestos-Induced Pulmonary Fibrosis

N. Joshi. *Northwestern University, Chicago, IL.*

Occupational and indoor exposure to asbestos can lead to development of pulmonary fibrosis years after exposure, leading to significant morbidity and mortality. Asbestos fibers can lodge within and persist in the bronchoalveolar duct junctions and small airways of humans and mice, respectively. Ontologically distinct populations of macrophages can contribute to asbestos-induced lung fibrosis. Using a comprehensive combination of unbiased single cell transcriptomic profiling (scRNA-seq), genetic lineage tracing, flow cytometry, and *in situ* RNA hybridization, we tested the hypothesis that monocyte-derived alveolar macrophages are key drivers of asbestos-induced pulmonary fibrosis. C57Bl6 mice were exposed to TiO2 (control) or asbestos fibers intratracheally. Lungs were harvested to capture the early stages of pulmonary fibrosis, and scRNA-seq libraries were prepared from cell suspensions using the 10X Chromium platform. Profiling 24,060 cells identified 24 known cellular populations represented in all experimental conditions. All populations exhibited transcriptional changes during the development of fibrosis. Importantly, the emergence of a new, distinct subpopulation of alveolar macrophages was observed in asbestos-exposed animals. This subpopulation was characterized by an immature phenotype and elevated expression of genes known to be causally associated with fibrosis, such as Mmp12, Retnla, Chia1, and Pdgfa (involved in fibroblast proliferation). Furthermore, these cells expressed Itgam and Cx3cr1, suggesting a monocyte origin. Remarkably, this new subpopulation was represented only by cells from asbestos-exposed mice and was absent in control conditions. Flow cytometry, lineage-tracing analyses, and immunohistochemistry confirmed this subpopulation to be monocyte-derived alveolar macrophages. Immunofluorescent microscopy confirmed that Pdgfa-expressing cells were specifically recruited to the areas of fibrosis and were located in the proximity of Pdgfra-expressing fibroblasts.

Cre/lox-mediated genetic deletion of this population by targeting Casp8 prevented the development of pulmonary fibrosis. Collectively, these studies are the first to show a causal association between asbestos-induced epithelial lung injury, localized recruitment of monocyte-derived alveolar macrophages, and subsequent development of spatially restricted lung fibrosis.

2468 Single Cell RNA Sequencing Reveals Altered Effector CD8 T Lymphocytes in Smokers

S. N. Martos. *NIEHS, Research Triangle Park, NC.*

As a risk factor for human diseases, the global disease burden attributed to tobacco smoke exposure remains substantial. In addition to DNA damage, smoking alters the epigenome and transcriptome of human blood leukocytes. Interpretation of bulk genomic approaches is limited because changes could indicate altered distribution of cell (sub)populations or changes in expression within (sub)populations. To characterize smoking-related gene expression changes in primary immune cells, we performed single cell RNA sequencing (scRNA-seq) on >45,000 human peripheral blood mononuclear cells (PBMCs) from smokers (n = 4) and nonsmokers (n = 4). Transcriptomes revealed an altered subpopulation of Natural Killer (NK)-like T lymphocytes in smokers, which expressed elevated levels of FCGR3A/CD16 compared with other CD8 T cell subpopulations. Relatively rare in nonsmokers (median: 1.8%), the transcriptionally unique subset of CD8 T cells comprised 7.3% of PBMCs in smokers. Among CD8 T cells, the increase in NK-like cells (Mann-Whitney p = 0.03) corresponded with a decrease in naïve cells (p = 0.03). Mass cytometry (CyTOF; >1 million cells) of 26 cell surface marker proteins confirmed an increase in CD16+ CD8 T cells in smokers. We did not observe differences in the overall frequencies of CD8 T cells or NKT cells between smokers and nonsmokers by either scRNAseq or mass cytometry. This indicates that smoking is associated with an increased number of CD8 T cells that share characteristics with NK cells, but are not NKT cells. Consistent with an NK-like phenotype, altered effector CD8 T cells had elevated expression of genes reported to be upregulated in T cells reprogrammed to NK-like cells. Compared with other effector CD8 T cells, altered effector CD8 T cells had reduced IL7R and increased IFNG (interferon γ), GZMB (granzyme B), and PRF1 (perforin) expression. In mice, granzyme B and perforin expressing CD8 T cells contribute to the development of atherosclerotic plaques. Our data highlight a potential link between smoking-induced functional changes in human CD8 T cells and atherosclerosis.

2469 Applying Modern Toxicology to Dietary Supplements with Ancient Roots: Botanical Safety in the 21st Century

C. Rider. *NIEHS/NTP, Research Triangle Park, NC.*

Botanical dietary supplements are consumed by millions of people globally, with tens of thousands of products available in the US marketplace. Ensuring the safety of these products is an important public health priority. However, evaluating their safety can be challenging due to the inherent complexity and significant variability in composition and quality, including the possibility of contamination and adulteration. Furthermore, the bioactive constituents in botanicals are often unknown, necessitating toxicological evaluation of the whole mixture. While there have been significant advancements in the development of new approach methodologies (NAMs) for read-across and screening/prioritization of single chemicals, there has been much less attention focused on adapting and evaluating these methods for application to complex mixtures. Botanical dietary supplements offer a unique opportunity for exploring the extension of NAMs to complex mixtures and building confidence in their application to a risk evaluation context. Toward this goal, there are several key areas that require attention. First, it is necessary to understand the current regulatory landscape for botanicals (i.e., What is the historical context and what are the current approaches being used to ensure product safety?). Next, an overarching challenge in evaluating botanicals is their complex chemistry. Therefore, defining the level and nature of non-targeted and targeted chemical analysis necessary for complex mixture characterization is critical. In terms of hazard characterization, identifying the critical endpoints and assays to include for safety evaluation is an important first step. This effort requires identifying likely biological targets of botanical toxicity (e.g., toxicity signals in adverse event reporting and animal studies) and evaluation of fit-for-purpose NAMs. Finally, to build confidence in any NAM-based safety assessment, it is critical to build orthogonal datasets to compare NAM results with toxicity observed in animal models and humans. Research efforts in each of these key areas will be highlighted by speakers with diverse perspectives.

2470 Applying Modern Toxicology to Botanical Dietary Supplements

M. Embry. *HESI, Washington, DC.*

The 1994 Dietary Supplement Health and Education Act provides the statutory basis for regulating the safety of botanical dietary supplements. Historically, regulatory guidance in the United States has maintained a botanical safety framework that relies on history of safe use and traditional animal testing paradigms with virtually no utilization of *in vitro* and *in silico* approaches. Recently, the US Food and Drud Administration's *Predictive Toxicology Roadmap* described the Agency's dedication to fostering the development and evaluation of new and emerging toxicological tools and technologies for incorporation into regulatory review. The Botanical Safety Consortium (BSC) is a newly formed public-private partnership that embodies the spirit of applying predictive toxicological tools to evaluation of botanical dietary supplement safety. The BSC is a collaboration between scientists in industry, government, and academia, formed with the goal of providing a sound scientific basis for integrating existing data with the latest toxicology tools to evaluate botanical safety. Chemical characterization of complex botanical products and identification of fit-for-purpose assays for evaluating genotoxicity, hepatotoxicity, developmental and reproductive toxicity, cardiotoxicity, and repeat-dose systemic toxicity are key areas to be explored by the consortium.

2471 Chemical Analysis: The Foundation of Botanical Safety

J. Kellogg. *Pennsylvania State University, State College, PA.* Sponsor: C. Rider

Chemical characterization is a critical "first step" in the evaluation of botanical dietary supplement safety. Principally, results from botanical dietary supplement testing cannot be interpreted without precise knowledge of the test substance (i.e., identity of the ingredients, authenticity, quality). There are numerous methods that can be used for this purpose, including DNA barcoding and various analytical chemistry methods (e.g., HP-TLC, HPLC, NMR), each with advantages and disadvantages. Regardless of the specific approach employed, the resulting data are typically high-dimensional, requiring chemometric analysis for interpretation. Application of these approaches will be presented using green tea and goldenseal root extract examples. The green tea example will illustrate the decision tree involved in test article selection based on comparison across numerous related products. The goldenseal example focuses on determination of authenticity and identification of adulterated samples.

2472 Developing and Applying *In Vitro* Liver Models to Address Potential Hepatotoxicity of Botanical Dietary Supplements

A. Roe. *Procter & Gamble, Cincinnati, OH.*

The liver has been identified as an important target for potential injury from botanical dietary supplement exposure. Oral administration to relatively high doses (100s to 1000s mg per day) of botanicals predisposes the liver to insult. Furthermore, the Drug-Induced Liver Injury Network (DILIN) has identified bodybuilding supplements as well as other categories of dietary supplements with increasing incidents of liver injury. Examples of botanical products that have been associated with significant liver toxicity include green tea extract, OxyElite Pro, and Hydroxycut. However, due to the complex chemistry of botanicals, it has been difficult to identify the botanical ingredient or specific constituent associated with observed liver toxicity. The liver has been an area of innovation for development of *in vitro* and *in silico* tools and technologies for evaluating toxicity due to its critical role in drug metabolism and, relatedly, safety testing. Fortunately, holistic liver models that express sufficient baseline functionality for uptake and efflux transporters, metabolizing enzymes, and the regulatory pathways for both exist for the liver. In fact, these types of liver models have been shown to be very useful in studying complex botanical mixtures. Examples of the application of sandwich-cultured human hepatocytes to predict clinically relevant botanical-drug clearance interactions associated with *Schisandra spp*., St. John's wort, and *Boswellia serrata* will be discussed.

W 2473 Systems Toxicology Approaches to Evaluate Botanical Safety

J. Dever. *Amway Nutrilite, Grand Rapids, MI.*

Developing *in vitro* models that incorporate interactions between organ systems and reflect the complexity of biological systems is required to move beyond animal testing. The goals of systems toxicology work in safety evaluation of botanicals are twofold: (1) to build models that allow for higher-throughput assessment of botanicals in complex biological systems, and (2) to generate data allowing for translation from *in vitro* systems to human and animal model contexts (i.e., *in vitro* to *in vivo* extrapolation; IVIVE). Toward the first goal, model systems that have the capacity to recapitulate flow between cell-based organ models are currently under development. Initial testing with botanical dietary supplements will be presented. Regarding the second goal, examples of predicting *in vivo* concentrations based on *in vitro* data will be discussed.

W 2474 Challenges and Approaches for Using Animal and Human Data to Evaluate *In Vitro* Systems in Botanical Safety Assessment

C. Rider. *NIEHS/NTP, Research Triangle Park, NC.*

Building confidence in new approach methodologies (e.g., *in vitro* and alternative approaches) requires the development of case studies that include orthogonal data from traditional sources (i.e., animal toxicity studies, epidemiological studies, and adverse event reports) to define their potential application and limitations. The National Toxicology Program (NTP) has evaluated the toxicity and carcinogenicity of multiple widely used botanical dietary supplements (e.g., goldenseal root powder, kava kava, green tea extract) in mice and rats. Studies have ranged from chronic and comprehensive evaluation of toxicity for hazard identification to targeted studies aimed at better understanding dose-response for a known toxicity (e.g., cardiotoxicity of ma huang with and without caffeine). A key question is how to use this body of animal research combined with human data from epidemiological studies and adverse event reporting to evaluate the utility of *in vitro* systems in a botanical safety assessment context. Challenges include accounting for discordant data, extrapolating across species, and identifying the level of mechanistic data required to support conclusions. Case studies for botanical dietary supplements (e.g., *Ginkgo biloba* extract, green tea extract) that include both animal and human data will be compared with available *in vitro* data to illustrate the challenges and opportunities moving forward.

W 2475 Automation and Machine Learning Techniques to Leverage Resources When Conducting a Systematic Review

V. Walker. *NIEHS/NTP, Research Triangle Park, NC.*

Systematic review is a comprehensive, objective, and transparent multistep process to identify, screen, and synthesize primary scientific literature for reaching evidence-based hazard conclusions on specific research questions. Across the field of toxicology, efforts to apply systematic review methods are gaining momentum, highlighted by regulatory requirements that have been instituted globally to conduct systematic review in support of safety assessments of chemicals and foods (e.g., the US Environmental Protection Agency [US EPA] is required to use systematic review methods under the Toxic Substances Control Act [TSCA]). The National Toxicology Program (NTP), US EPA Integrated Risk Information System (IRIS), and European Food Safety Authority (EFSA) have all implemented systematic review methods in the conduct of either hazard assessments or risk assessments. As highlighted by the systematic review exposure summit in April of 2019, there are efforts to take advantage of the increased transparency and rigor of systematic review methods and apply these techniques to other disciplines of toxicology. However, the principal barrier to greater adoption and innovation of systematic review methods is the level of effort required in an area of fast-paced research and publication. Conducting a systematic review is time-consuming and resource intensive. Effort depends on the size of the evidence base, but on average, systematic reviews can take more than 1,000 hours to complete and can cost over $100,000 USD. This cost varies according to the number of questions being addressed and the amount of literature to evaluate. Further, by the time a systematic review is published, those data can be outdated, and thus perhaps not useful for rapid decision-making. Many of the steps of the systematic review process have the potential to utilize automated or semiautomated approaches; in fact, considerable progress has been made and additional work is underway to automate steps in the review process. Advances in natural language processing, text mining, and machine learning have produced new algorithms that assist with screening and significantly reduce the manual screening burden of large systematic reviews. Automation advances in the SR process require the skills and knowledge of a variety of experts, such as information specialists, developers, software engineers, statisticians, artificial intelligence experts, and researchers from various disciplines who conduct SRs. Given the increasing volume of published studies, automation and semiautomation of labor-intensive steps in the review process have great potential to improve the speed of systematic review and reduce the workload and resources required without compromising the rigor and transparency that are critical to the method. In this Workshop, speakers will introduce the concept of automation or semiautomation in the various steps of the systematic review process and highlight their utility and limitations in reducing the time and resources required to conduct a SR. The session will begin with an overview of basic systematic review principles and a brief description of why systematic review is valuable and impactful to environmental health risk assessments. In addition, a brief introduction to the methods involved in the process and discussion of various steps that are resource or time intensive will be presented. After the introduction, presentations will focus on the individual tasks of screening, data extraction, and risk of bias in the systematic review process and introduce current thoughts and approaches to developing and implementing automated or semiautomated tools to aid in the systematic review process. The final presentation will address the importance of generating training sets to develop gold standard corpora and performance benchmarks for future methods development and evaluation. Collectively, this Workshop will demonstrate current progress and challenges in development and implementation of automation and semiautomated tools and approaches for the labor-intensive tasks of the systematic review process. The Workshop will conclude with a panel discussion where the speakers, who represent industry, academia, and government, will discuss how current advancements and challenges can shape the future development of automation tools to support the systematic review process and impact the time, cost, and resource burden of conducting systematic reviews that support decision-making in environmental toxicology risk assessment and hazard identification.

W 2476 Brief Overview of Systematic Review Methodology and Identification of the Labor-Intensive Tasks Suitable for Automation Approaches

V. Walker. *NIEHS/NTP, Research Triangle Park, NC.*

Systematic review is rapidly becoming the gold standard for addressing environmental health questions. Across the field of toxicology, efforts to apply systematic review methods are gaining momentum, highlighted by regulatory requirements that have been instituted globally to conduct systematic review in support of safety assessments of chemicals and foods. NTP, US EPA IRIS, and EFSA have all implemented systematic review methods in the conduct of either hazard assessments or risk assessments. The systematic review process involves the objective and transparent method of collecting and synthesizing data for reaching hazard conclusions on specific research questions. This overview will provide a brief introduction to systematic review methodology and the impact of this approach to inform decision-making and will highlight steps in the process for which automation approaches could potentially be implemented to potentially reduce the cost and time necessary to conduct systematic reviews of environmental health questions.

W 2477 SWIFT-Active Screener: Accelerated Document Screening through Active Learning and Integrated Recall Estimation

R. Shah. *Sciome LLC, Durham, NC.*

In the screening phase of systematic review, researchers use detailed inclusion/exclusion criteria to decide whether each article in a set of candidate citations is relevant to the research question under consideration. A typical review may require screening thousands or tens of thousands of articles in this manner and require hundreds of person hours of labor. Here, we introduce SWIFT-Active Screener, a web-based, collaborative systematic review software application designed to reduce the overall screening burden required during this resource-intensive phase of the review process. Active Screener uses empirically validated statistical models designed to save screeners time and effort by automatically prioritizing articles as they are reviewed, using user feedback to push the most relevant articles to the top of the list. Meanwhile, a separate statistical model estimates the number of relevant articles remaining in the unscreened document list. Together, the combination of the two models allows users to find relevant documents sooner and provides them with accurate feedback about their progress. We evaluated the Active Screener document prioritization and recall estimation models using 26 systematic review datasets that were previously curated manually by reviewers. The results demonstrate that using Active Screener can result in significant time savings

compared with traditional screening and that the savings are increased for larger project sizes. For example, in document sets with 5,000 or more documents, the average WSS95 obtained is 61%. Furthermore, the recall estimator we have proposed provides a useful, conservative estimate of the percentage of relevant documents identified during the screening process. The software is currently available in the form of a multi-user, collaborative, online web application and has been used successfully to reduce the effort required to screen articles for systematic reviews conducted at a variety of organizations, including NIEHS, US EPA, USDA, TEDX, and EBTC. These early adopters have provided us with an abundance of useful data and user feedback, and we have identified several areas where we can continue to improve our methods and software. Several new features have been planned for the software, and it will be developed, improved, and maintained for the foreseeable future.

W 2478 Semiautomated Data Extraction to Reduce Extraction Time While Maintaining Quality and Reproducibility

Z. Lu. *NIH, Bethesda, MD.* Sponsor: V. Walker

Manually extracting relevant data from included studies is a critical yet rate-limiting step in conducting systematic reviews. Hence, facilitating this laborious and time-consuming step by automated approaches holds great potential to reduce the overall time required to complete a systematic review. In this presentation, an overview of recent developments in natural language processing (NLP) techniques (e.g., deep learning-based approaches) in biomedical concept recognition and information extraction will be presented, with a focus on data elements that are commonly sought in conducting systematic reviews. In addition, state-of-the-art NLP tools and current challenges and future opportunities in putting such tools into action will be discussed.

W 2479 Semiautomated Approaches to Assess Risk of Bias (Study Quality)

J. Liao. *University of Edinburgh, Edinburgh, United Kingdom.* Sponsor: V. Walker

Certain aspects of study design are associated with different estimates of biological effects, and this is important when assessing the credibility of research claims. Considering risks of bias in the systematic review process allows more sophisticated insights to the credibility of reported findings, both at individual (study) and topic (literature) levels. However, ascertaining risks of bias can be both time-consuming and subjective, and—if the ambitions of living systematic reviews are to be realized—tools to automate this process are required. These tools fall into two broad categories. In the first, a given string is identified (Dictionary approach), perhaps considering neighboring strings or other text features (Regular Expressions). In the second, machine-learning algorithms such as convoluted neural networks are trained on labeled learning manuscript sets. While this approach has shown value in ascertaining risks of bias in reports of clinical trials, its use in laboratory biomedical research is less well developed. Challenges include the size of the training datasets required, the risks of propagation of human error into machine performance, the lack of transparency in algorithm decision-making, and the need to convert manuscripts to simple text files. A RegEx for selected risks of bias is enabled on the free-to-use Systematic Review Facility (app.syrf.org.uk), and we are updating this for use in institutional research improvement activities. The early performance of our Convoluted Neural Network approaches that achieved by our RegEx.

W 2480 If You Can't Measure It, You Can't Improve It: On the Importance of Benchmark Datasets

A. Nowak. *Evidence Prime, Kraków, Poland.* Sponsor: V. Walker

One of the hurdles to adoption of systematic review automation tools is lack of good-quality datasets for the individual tasks (such as screening or data extraction). Such datasets are required both for measuring improvements (introduced by new research) and comparing strong and weak points of various systems to select the best tool for the job. They need to be large enough to produce sufficient precision of estimates. They also need to represent diverse use cases, in which systems are used in the wild. Moreover, their quality and collection methods need to reflect methodologies employed by prospective users. Satisfying all these requirements comes at significant cost, so it is in the best interest of the whole automation community to make these datasets reusable and shareable. As is the case in the other machine-learning research areas, benchmarks need to be established, preferably with public leaderboards (e.g., the EBM-NLP project from Northeastern University). This would enable objective comparison of work coming from different groups and contribute to more rapid advances in the field. The work required for creation of shared datasets, such as harmonizing data formats, also could pay off by bringing the community closer to achieving interoperability among the tools. A big investment toward construction of the datasets is building and maintaining the annotation tools. This cost could be shared among the groups by collaboration on the tools and releasing them on open-source licenses. This in turn would enable organizations to create their own application-specific benchmarks and evaluations of the available solutions.

W 2481 *In Vitro* Microphysiological Systems: Developing Tools to Evaluate Immunotoxicity of Drug Candidates

N. Marshall. *GlaxoSmithKline plc, Collegeville, PA.*

There is a crucial need for new technologies that can reliably predict drug safety and efficacy in humans in preclinical studies. Advances in bioengineering, material sciences, microfabrication, and microfluidics technologies have enabled the development of microphysiological systems that mimic the functional units of an organ. These systems recreate the specialized multicellular architectures, tissue-tissue interfaces, physicochemical microenvironments, and vascular perfusion necessary to *recA*pitulate organ-level physiology *in vitro* and have emerged as key tools that permit the study of human physiology. The more recent development of biomimetic immune organs-on-chips, or systems incorporating immune components, increases physiological relevance of these models to drug development and can allow for bidirectional assessment of human immune cell and tissue interactions in a controllable microenvironment. An integrated immune competent microphysiological platform could further enhance our understanding of disease etiology and fill the critical need for improved preclinical model systems to predict efficacy, safety, bioavailability, and toxicity outcomes for candidate compounds. This session will highlight recent advances in system-on-chips models that predict immune-driven toxicities.

W 2482 Human Bone Marrow Dysfunction Recapitulated *In Vitro* Using Organ Chip Technology

D. Chou. *Wyss Institute for Biologically Inspired Engineering at Harvard University, Boston, MA.* Sponsor: N. Marshall

Understanding human bone marrow (BM) pathophysiology in the context of myelotoxic stress induced by drugs, radiation, or genetic mutations is of critical importance in clinical medicine. However, study of these dynamic cellular responses is hampered by the inaccessibility of living BM *in vivo*. Here, we describe a vascularized human Bone Marrow-on-a-Chip (BM Chip) microfluidic culture device for modeling bone marrow function and disease states. The BM Chip is composed of a fluidic channel filled with a fibrin gel in which patient-derived CD34+ cells and bone marrow-derived stromal cells (BMSCs) are co-cultured, which is separated by a porous membrane from a parallel fluidic channel lined by human vascular endothelium. When perfused with culture medium through the vascular channel, the BM Chip maintains human CD34+ cells and supports differentiation and maturation of multiple blood cell lineages over one month in culture. Moreover, it recapitulates human myeloerythroid injury responses to drugs and gamma radiation exposure, as well as key hematopoietic abnormalities found in patients with the genetic disorder Shwachman-Diamond syndrome (SDS). These data establish the BM Chip as a new human *in vitro* model with broad potential utility for studies of BM dysfunction.

W 2483 A Foreign Body Response-on-a-Chip Platform

A. Khademhosseini. *University of California Los Angeles, Los Angeles, CA.* Sponsor: N. Marshall

Understanding the foreign body response (FBR) and designing strategies to modulate such a response represent a grand challenge for implant devices and biomaterials. Here, the development of a microfluidic platform is reported (i.e., the FBR-on-a-chip [FBROC]) for modeling the cascade of events during immune cell response to implants. The platform models the native implant microenvironment where the implants are interfaced directly with surrounding tissues, as well as vasculature with circulating immune cells. The study demonstrates that the release of cytokines such as monocyte chemoattractant protein 1 (MCP-1) from the extracellular matrix (ECM)-like hydrogels in the bottom tissue chamber induces trans-endothelial migration of circulating monocytes in the vascular channel toward the hydrogels, thus mimicking

implant-induced inflammation. Data using patient-derived peripheral blood mononuclear cells further reveal inter-patient differences in FBR, highlighting the potential of this platform for monitoring FBR in a personalized manner. The prototype FBROC platform provides an enabling strategy to interrogate FBR on various implants, including biomaterials and engineered tissue constructs, in a physiologically relevant and individual-specific manner.

W 2484 Application of Immunocompetent Microphysiological Systems in Drug Development

R. Horland. *TissUse GmbH, Berlin, Germany.* Sponsor: N. Marshall

Microphysiological systems enabling long-term co-culture of various human organ equivalents have become increasingly useful for preclinical systemic drug testing. Until now, these systems lacked integration of systemic immunocompetence and therefore didn't generate human immune responses. This hampers their use for the evaluation of vaccines, adjuvants, and stem, somatic, and immune cell therapies as well as modern wound-healing materials, implants, and the investigation of mechanisms of organ rejection. Here, we provide examples of successful development of immunocompetent microphysiological systems. This includes the generation and long-term cultivation of human organoid lymphatic tissues in a Multi-Organ-Chip platform using a chip-compliant hydrogel matrix. Employing the model at a larger scale, it already enables long-term and repeated drug exposure to induce and monitor both cellular and humoral immune responses. Cellular immunity is monitored by cytokine release patterns, while humoral immunity is detected by B cell activation, plasma cell formation, and antibody secretion profiles. Moreover, cellular composition and micro-organoid formation are analyzed by flow cytometry, histology, and *in situ* imaging. Another example is a skin allograft-on-a-chip model. Here allogenic PBMC and skin were co-cultured in a Multi-Organ-Chip system. PBMCs could be tracked in the skin over nine days while first signs of rejection could be detected by increased levels of IFN-gamma, IL-2, and IL-17A. Furthermore, the model may also be adapted to investigate pathogenic mechanisms in chronic inflammatory diseases (e.g., psioriasis).

W 2485 *In Vitro* Microphysiological Systems: Advancing Regulatory Science through Innovation

S. Fitzpatrick. *US FDA, College Park, MD.*

Novel methods such as *in vitro* microphysiological systems or organs-on-a-chip—microfluidic biomimetic devices that aspire to emulate the biology of human tissues, organs, and circulation *in vitro*—are enabling a global paradigm shift in regulatory science. Organ-on-a-chip devices are designed as accurate models of the structure and function of human organs, such as the lungs, liver, and heart. Once developed and integrated, researchers and regulators can use these models to predict whether a candidate drug, vaccine, or biologic agent is safe or toxic in humans in a faster and more effective way than current animal methods. Beyond use in drug research, organ-on-a-chip models will be used as test systems for development of non-pharma treatment approaches, like radiotherapy or hyperthermia for cancer, but also to develop new cosmetics or food additives and for toxicology analysis of environmental contaminants.

W 2486 Sex, Lungs, and Air Pollution

M. Rebuli. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

The National Institutes of Health (NIH) recently mandated that sex be considered a biologic variable in animal and clinical research. Recent focus on sex-dependent biologic effects in toxicology has translated into new discoveries of sex differences in pulmonary responses to respiratory toxicant exposures, such as tobacco and wildfire smoke, ozone, and ambient air pollution. As the effects span multiple models, it suggests common mechanisms that should be highlighted and considered when evaluating respiratory toxicant exposure. This session will explore recent innovative research on sex-dependent pulmonary effects of air pollution. The first speaker will introduce the biology behind the development of respiratory sex differences and its importance for regulatory and safety considerations. Differences in susceptibility to disease, morbidity, and mortality related to respiratory sex differences will be described. For example, asthma prevalence rates are higher in boys than in girls, but this pattern reverses at the onset of puberty, and reverses again following the onset of menopause. The speaker will also review sex differences in nonclinical respiratory toxicology research models and how they contribute to regulatory decisions regarding human safety and risk assessment. The next talk will discuss the impact of *in utero* secondhand smoke (SHS) exposure on the development of cancers later in life and their sex dependence. Though it is well established that SHS exposure contributes to lung disease-related deaths, the onset and progression demonstrates sex specificity. This speaker will illuminate possible mechanisms, including genetic or hormonal influences, for these sex-specific responses using a rodent model of SHS exposure and urethane-induced tumorigenesis. Overall, SHS exposure *in utero* promotes metastasis in females through matrix remodeling, while promoting large tumors in males. The third speaker will describe sex-specific patterns of inflammation and airway hyperresponsiveness (AHR) in ozone exposure that impair lung innate immunity. The findings suggest that fluctuations of circulating hormone levels affect ozone-induced inflammatory responses. In this study, male and female mice underwent gonadectomy and hormone replacement prior to ozone exposure. After exposure, male mice displayed higher AHR than controls, while in females, AHR was reduced, both of which were ameliorated by hormone replacement. Together, these results indicate that sex hormones can modulate ozone-induced inflammation and AHR in adult mice. The fourth speaker will discuss how wood and biomass smoke impacts respiratory and immune function in primates across the life span. Wildfire events are a growing public health concern with the potential to increase cardiac and respiratory disease burden. However, little is known about the long-term effects of acute wildfire smoke inhalation. The speaker will report on recent research on the health of ambient wildfire smoke-exposed primates. Sex-specific responses in lung and immune function throughout the primate life span were observed. At infancy, females showed reduced lung compliance, which persisted into adulthood. These findings suggest that exposure age and sex enhance vulnerability to long-term health outcomes following exposure to wildfire smoke.The fifth speaker will describe how *in utero* exposure to ambient air pollutants in combination with prenatal stress can induce sex-specific respiratory outcomes in epidemiologic studies. Using epidemiological data, the speaker will describe how prenatal ambient pollution exposure and stress can sex-specifically modify children's respiratory outcomes. The speaker also will identify critical windows of developmental exposure, which result in adverse respiratory outcomes. This highlights that in humans, similar to other model systems, there are sex-specific windows of vulnerability and adverse outcomes of exposure to respiratory toxicants. Finally, there will be a scheduled panel discussion on how sex-specific findings in respiratory toxicant exposures influence funding, risk and safety assessments, and standard setting. This discussion will help define best practices for inclusion of sex as a biological variable in toxicity testing from cell culture to epidemiology. Presenters and Chairs who are from industry and academia, MDs and PhDs, junior and senior investigators, diverse in sex, race, and ethnicity, from across the US and Canada, and studying a variety of model systems will provide diverse perspectives on this issue. In summary, this Workshop will provide an overview of some of the sex-specific responses to respiratory toxicants and potential mechanisms elucidated from multiple models and a variety of respiratory toxicants.

W 2487 Influence of Sex and Sex Hormones on Lung Function and Disease: Research, Risk, and Regulatory Insights

J. W. Card. *Intertek Scientific & Regulatory Consultancy, Mississauga, ON, Canada.*

The roles of sex and sex hormones in lung function and disease are complex and not completely understood. In humans, sex hormones appear to exert regulatory effects on lung development before and during the neonatal period, with anatomical and functional differences between the sexes observed through to adulthood. Sex differences also exist in the prevalence of asthma, chronic obstructive pulmonary disease, pulmonary fibrosis, and other lung conditions. Delineating the underlying contribution of sex (and, by association, sex hormones) to these diseases is complicated by the inherent difficulties associated with identifying the roles of specific factors from epidemiologic data. As a result, the potential contribution of sex hormones to sex disparities in numerous toxicities and diseases of the lung has been evaluated by various research groups using animal models under more controlled conditions, with results reported in the published scientific literature. In mice, sex differences have been reported in baseline lung function parameters and in the airway response to cholinergic stimulation. Moreover, other studies have documented sex differences and sex hormone-mediated influences in mouse models of lipopolysaccharide-induced inflammation, allergic lung inflammation, pulmonary fibrosis, tobacco smoke-induced injury, ozone-induced inflammation, and others. These investigations have confirmed the need to consider sex in the design and evaluation of animal models of lung toxicities and diseases. This is consistent with expectations for high-quality studies that are used for health risk evaluations, such as the derivation of inhalation occupational exposure limits, and with regulatory expectations for toxicology studies conducted to support drug development programs. Continued

study of the impact of sex and sex hormones will serve to strengthen the understanding of exposure risks and of potential strategies to address lung toxicities and diseases that may have a sex-specific component.

2488 Murine *In Utero* Secondhand Smoke Exposure Promotes Urethane-Induced Lung Tumors in Males and Metastases in Females via Extracellular Matrix-Remodeling

A. Noël, and A. Penn. *Louisiana State University, Baton Rouge, LA.*

Recently, it has been shown that lung cancer incidence is higher among young women than young men—a phenomenon that was not completely explained by differences in sex-specific smoking behaviors. Additionally, while secondhand smoke (SHS) exposure is a risk factor for lung cancer, it is unclear whether there is an association between *in utero* SHS exposure and lung cancer. We previously identified that *in utero* exposure to SHS caused, in adult mice, upregulation of miR-155-5p, miR-21-3p, and miR-18a-5p and downregulation of 16 tumor suppressor genes. This suggests that *in utero* SHS exposure may increase the susceptibility in adulthood to lung cancer development. This presentation will outline investigations of how *in utero* SHS exposure promotes the development of urethane-induced carcinomas, intrapulmonary metastases/emboli at 58 weeks of age, in both male and female mice. Pregnant Balb/c mice were exposed gestationally to 10 mg/m3 of SHS or filtered air. In adulthood, offspring were treated with intraperitoneal injections of urethane (1 g/kg) or saline. At 58 weeks of age, mice were sacrificed, and tumors were analyzed for number, volume, histopathological classification, and gene expression. SHS-exposed males showed increased numbers of tumors and tumor volume compared with control males. SHS males differentially expressed genes were part of functional clusters associated with non-small cell lung cancer, tumor suppressors, and ras signaling pathway. This suggests that the increased numbers of tumors in SHS males may be associated with increased risk of cancer progression. In females, SHS-exposed animals had an increased number of tumors, tumor volume, number of intrapulmonary metastases/emboli, and the percentage of lymphocytes in BALF, compared with female controls. In addition, SHS-exposed females showed dysregulated cancer-related gene expression associated with increased risk of metastasis. In this study, we demonstrate that *in utero* SHS exposures promote large tumors through dysregulation of tumor suppressor and ras signaling genes in male, while promoting metastasis through matrix remodeling in female mice. This is consistent with previous reports that demonstrated that estrogen plays a role in proliferation and can influence metastasis without affecting tumor growth.

2489 The Role of Gonadal Hormones in Sex-Specific Lung Inflammatory Response to Ozone

P. Silveyra. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Ozone exposure contributes to impairment of lung innate immunity. Emerging evidence suggests that lung diseases affect men and women disproportionately and that fluctuations of circulating hormone levels can affect inflammatory responses. Here, we hypothesized that 17ß-estradiol regulates inflammation and airway hyperresponsiveness (AHR) triggered by ozone exposure. We performed gonadectomy and hormone replacement (17ß- estradiol, 2 weeks) in C57BL/6J male and female mice, and exposed animals to 1 ppm of ozone or filtered air for 3 hours. We compared lung function parameters, expression of cytokines/chemokines in lung tissue, and lipocalin-2 levels in bronchoalveolar lavage fluid (BALF). We found significant changes in respiratory parameters and gene expression in males and females after ozone exposure. These were affected by gonadectomy and 17ß-estradiol treatment in a sex-specific manner. Gonadectomized male mice displayed higher AHR than controls (sham) exposed to ozone, and hormone treatment ameliorated this response. In females, ovariectomy reduced ozone-induced AHR, which was restored by 17ß-estradiol treatment. Ozone exposure increased lipocalin-2 levels in both females and males, and these were reduced in gonadectomized mice. Treatment with 17ß-estradiol restored lipocalin-2 in females but lowered it in males. Gonadectomy affected expression of inflammatory genes induced by ozone exposure in both males and females; expression of IL-6 and MIP-3 was strongly dependent on 17ß-estradiol levels in females. Together, these results indicate that sex hormones modulate ozone-induced inflammation and AHR. Future studies examining diseases associated with air pollution exposure should consider the patient's sex and hormonal status.

2490 Sex-Dependent Health Impacts of California Wildfire $PM_{2.5}$ across the Life Span

L. A. Miller. *University of California Davis School of Veterinary Medicine, Davis, CA.*

Climate change has contributed to an increased incidence of wildfire events due to dry weather and overgrowth of vegetation. Prescribed burns and wildfires are now recognized by the US Environmental Protection Agency as significant sources of air pollution in the United States. Acute wildfire smoke exposure is associated with increased respiratory morbidity, including asthma symptoms and medication use, obstructive airways disease exacerbations, and hospitalization. Wildfire events are a growing national public health concern and have the potential for increased burden of disease; however, there is little known about the long-term health outcomes of acute wood/biomass smoke inhalation. To address this knowledge gap, we noninvasively and progressively monitored the health status of an outdoor colony of California National Primate Research Center rhesus monkeys over 10 years following exposure to ambient smoke from the Trinity and Humboldt County wildfires in 2008, with the rationale that nonhuman primates may serve as an animal surrogate for pediatric populations. At three years of age, adolescent rhesus monkeys that were exposed as infants displayed significant attenuation of responsiveness to microbial ligands in peripheral blood *ex vivo* in a sex-dependent manner, suggesting a persistent immune effect of air pollutants. Exposed adolescent animals also demonstrated significant alterations in lung function parameters, including reduced compliance in female monkeys. In a follow-up study at eight years of age, adult female monkeys continued to show evidence of immune dysregulation in peripheral blood after infant exposure. Using high-resolution computerized tomography to image the female adult monkey chest wall, we determined that early-life exposure to wildfire smoke significantly correlated with changes in lung volume, physiologic capacity, and lung remodeling in adulthood relative to unexposed age-matched counterparts. Ongoing studies following the recent Butte County wildfires in 2018 will monitor the health impacts of ambient smoke exposure on a cohort of pregnant and infant rhesus monkeys at the center. Collectively, our findings in a colony of nonhuman primates suggest that age of exposure and sex contribute toward vulnerability to long-term health outcomes following acute exposure to wildfire smoke.

2491 Disentangling Effects of *In Utero* Exposure to Ambient Air Pollutants, Prenatal Stress, and Fetal Sex on Respiratory Outcomes in Epidemiologic Studies

R. J. Wright. *Icahn School of Medicine at Mount Sinai, New York, NY.*
Sponsor: M. Rebuli

The influence of outdoor air pollution on respiratory health starts *in utero*. Fetal lung growth and structural development occurs in stages; thus, effects on postnatal respiratory disorders may differ based on both exposure dose and timing of exposure. Moreover, the impact of prenatal ambient pollution exposure upon children's respiratory outcomes may be modified by infant sex as well as exposure to other toxins such as psychosocial stress. Our group has implemented innovative data-driven methods to identify sensitive windows for effects of prenatal exposure to ambient pollutants (fine particulate matter, nitrates, and their mixtures) on children's asthma development in an urban pregnancy cohort, which also allows for examining effect modification by infant sex and other exposures. These windows correspond to specific developmental processes that may be altered by environmental insults and likely vary depending on the mechanisms of the chemical exposures that may impact specific aspects of development. Methods that lead to a better understanding of how these windows of vulnerability differ by infant sex can lead to new insights into underlying mechanisms programming differential risk based on sex.

2492 Protecting Public Health and the Environment during Wildfire Recovery

S. DuTeaux. *California Department of Pesticide Regulation, Sacramento, CA.*

California is the only state that mandates cleanup activities following wildfires and assists impacted homeowners via a comprehensive remediation program. In most states, property owners deal with the destruction left in the wake of a wildfire largely on their own. These uncoordinated recovery activities have led to questionable and often hazardous ways of dealing with debris and ash, and can result in a legacy of contamination for affected communities. California emergency response and environmental protection

agencies joined forces in 2007 to develop a coordinated approach to remediating properties impacted by wildfires, which includes expedited removal of immediate hazards, asbestos abatement, and fire ash and debris removal. This unique and public health-protective approach supports communities in safely rebuilding. This session will outline the principles underpinning the California model; describe the steps involved in removing contaminants and clearing properties; present results from ash, air, soil, and water sampling in the aftermath of the fires; and discuss how public health, occupational health, and the environment are protected along the way. The presentations in this session will be given by State of California employees who were deployed under the Governor's Declaration of Emergency to work on wildfire recovery in Northern and Southern California following the November 2018 Camp and Woolsey wildfires and who will be drawing from their "boots on the ground" experience.

2493 Overview: Why a Recovery Program after Wildfires with Urban Interface is Critical to Protecting Public Health and the Environment

M. Santillano. *California Environmental Protection Agency, Sacramento, CA.* Sponsor: S. DuTeaux

On November 8, 2018, multiple wildfires broke out in California. The Camp Fire was the deadliest and most destructive wildfire in California history to date. The fire started in the small community of Pulga in Butte County, in Northern California. Exhibiting extreme fire behavior and gale force winds, the Camp Fire ripped through the communities of Concow and parts of Magalia and virtually decimated the town of Paradise. In total, 19,000 structures on almost 14,000 properties were lost. The fire claimed the lives of 85 victims. After the fire was contained, an estimated 240 square miles of forested and populated areas were destroyed. The Camp Fire started around 6:30 am on November 8. A mere eight hours later, under the same dry conditions and severe winds, the Woolsey Fire broke out in Southern California. The fire started on the Santa Susanna Field Laboratory property, an industrial research and development complex operated by Boeing near the boundary of Los Angeles and Ventura counties. When it was contained, the Woolsey Fire left in its wake over 1,600 destroyed structures, three fatalities, and the evacuation of close to 300,000 people. How do communities recover from such devastation? This session will provide an overview of how California environmental and emergency management leaders developed a model for the safe cleanup of fire ash and debris, and how this model has been used to successfully recover from wildfires with urban interface in California since 2007. The session will go into detail about how the cleanup process is accomplished. It also will review the contaminants monitored and how they are detected in air, ash, soil, and water samples. The session presenters hope to show how California's consolidated recovery efforts can be a model for wildfire cleanup in other states.

2494 Fire Ash and Debris Removal: Phases I and II of Wildfire Recovery

L. Chumney. *California Environmental Protection Agency, Sacramento, CA.* Sponsor: S. Iyer

When a typical home burns, all the contents can be destroyed, including major appliances, electronics, furniture, and cars. During this process, numerous hazardous substances can be released into the environment. These can include flame retardants, plasticizers, home and garden pesticides, lead and other metals, asbestos, and highly toxic combustion by-products. Cleaning up thousands of properties can be overwhelming for affected communities. The State of California's consolidated wildfire debris removal program paves the way for communities to start rebuilding after a devastating natural disaster by expediting the safe removal of fire ash and debris in a stepwise manner. The first and most important action that follows a California wildfire is the declaration of a local public health emergency. This establishes the government's authority to enter private property to abate immediately hazardous conditions without property owner permission. This action initiates Phase I of the wildfire recovery process by allowing hazardous materials teams to remove bulk hazardous materials, such as partially burned pesticide and paint containers, unexploded propane tanks, and unspent munitions. Once these immediate hazards are removed, the next phase of debris removal can commence. Phase II consists of a series of coordinated steps, including site assessment, asbestos abatement, metal and concrete segregation, ash and debris removal, and soil confirmation sampling and clearance. This second phase requires homeowner permission, since the immediate threats have been removed, and is usually coordinated between state agencies and the county environmental health department. This presentation will discuss the implementation of Phase I and II wildfire recovery efforts for the recent California wildfires. Specific sensitivities when working in impacted communities also will be discussed.

2495 What Is in the Ash and How Do We Keep It from Getting in the Air?

S. DuTeaux. *California Department of Pesticide Regulation, Sacramento, CA.*

One of the biggest concerns for communities in the aftermath of a wildfire is exposure to the contaminants in ash. As repopulation begins, residents may find themselves surrounded by decimated properties, twisted and melted metal, and piles of ash. It is understandable that they would be concerned about what is in the ash and what they are breathing. Recovery efforts for California wildfires include strict dust mitigation efforts and community and site-specific air monitoring and sampling designed to detect if any ash from debris removal activities becomes airborne. Comprehensive ash sampling was conducted following major wildfires in California in 2003, 2007, and 2015. For wildfires with urban interface, the ash typically contains elevated concentrations of several metals, with arsenic, cadmium, copper, lead, nickel, and zinc usually found in the highest levels. Polycyclic aromatic hydrocarbons (PAHs) have been sampled following previous fires but were found mainly in concentrations below residential California Human Health Screening Levels (established by the California Environmental Protection Agency) and Preliminary Remediation Goals (established by the US Environemtnal Protection Agency). Comprehensive ash sampling is being conducted for the Camp Fire. With results pending, the screening levels for airborne contaminants were based on what was known from previous ash analysis. Air sampling was conducted for asbestos and the heavy metals listed in Title 22 of the California Code of Regulations, Section 66261.24 ["Environmental Health Standards for the Management of Hazardous Waste"]. Air quality also was monitored for particulate matter (both $PM_{2.5}$ and PM_{10}) using the National Ambient Air Quality Standards and the values in the Wildfire Smoke Guide as screening levels. This presentation will cover the latest ash characterization data and the major contaminants of concern found in the Paradise area. Details will be shared on how sampling times, durations, locations, and screening levels were chosen for the different air monitoring and sampling approaches, as well as data on the airborne excursions (metals, asbestos, and PM), and if those detections were associated with debris removal activities. This presentation also will cover special air quality activities required around repopulated areas and public outreach on air quality data.

2496 Fire Ash and Debris Removal: Quantitation of Success via Confirmation Soil Sampling

S. Iyer. *California Environmental Protection Agency, Oakland, CA.*

California's consolidated debris removal program for areas impacted by wildfires uses soil testing results to evaluate site cleanup. The approach of comparing soil contaminant levels to health-based or other standards is integral to assessing sites with hazardous materials spills, decommissioned military bases, and Superfund sites to determine if they are safe enough for rebuilding or repurposing. California state environmental officials created and implemented a methodology tailored for the unique contamination that can result from wildfires with urban interface, based on the characterization of hazardous constituents found in burn debris and ash from previous fires. Soil samples collected following debris removal from an impacted property are tested for the metals specified under Title 22, California Code of Regulations, Section 66261.24. These include antimony, arsenic, barium, beryllium, cadmium, chromium, cobalt, copper, lead, mercury, molybdenum, nickel, selenium, silver, thallium, vanadium, and zinc. The soil samples are analyzed with US Environmental Protection Agency Method 6020. The number of soil samples collected per cleared parcel depends on the size of the original ash footprint; typically, at least one sample is collected for every 100 square feet. California develops project-specific cleanup goals for each metal, based on state or federal health-based standards, or background soil concentrations. Background soil samples are collected from the vicinity of the wildfire, excluding the ash-impacted areas, and are used to establish local metal concentrations. Establishing these background levels is critical for meeting the debris removal program's goal of removing ash and debris related to the recent wildfire incident. If initial soil testing results from cleared parcels fail to meet the project cleanup goals, additional soil is scraped from the parcel, and confirmation soil testing is repeated. Once the soil samples meet the cleanup goals, erosion control measures are installed, and the property is ready for rebuilding. This presentation will explain the soil sampling protocol and will review available soil data from recent California wildfires.

2497 Water, Water Everywhere: Efforts to Protect Drinking Water and Sensitive Aquatic Species

B. Stanton. *California Environmental Protection Agency, Sacramento, CA.* Sponsor: S. Iyer

Years ago, wildfires across the western United States generally occurred during the hot and dry months of summer and early fall. The reality for western states is that there is no longer a "wildfire season." Wildfires have ignited in California in November, December, and even January. The Camp wildfire occurred in November 2018 and was fully contained just prior to the start of a record rainy season, making it very difficult to clear debris because of the wet conditions. This resulted in consecutive months where fire ash and debris sat untouched. The inevitable question was whether any contamination migrated off-site from thousands of destroyed properties, and if there were any impacts to drinking water and aquatic life. Erosion control efforts are critical in many areas in California following wildfires because so much of the population receives its drinking water from surface water sources and because of impacts to critical species, such as winter run Chinook salmon. In the Paradise area, results from surface water analysis conducted from January to April 2019 showed levels of certain contaminants exceeding water quality standards for drinking water in areas impacted by the Camp Fire. Preliminary laboratory analyses found concentrations of aluminum, antimony, arsenic, cadmium, lead, and selenium exceeding Primary Maximum Contaminant Levels (MCLs) at most monitoring stations. PAH concentrations also were elevated but did not exceed the MCL. Such contamination could potentially impact repopulated areas that use untreated surface water or private wells for drinking water. Contaminants in fire ash also could potentially impact aquatic species if ash enters the watershed. This presentation will cover the efforts to protect water from contamination following wildfires with urban interface, additional considerations for seasonal waterways, and the measured impact to surface water from the fires.

2498 Using the Key Characteristics of Carcinogens to Organize Mechanistic Data for Acetaminophen

M. Sun, S. Elmore, K. Ricker, C. Hsieh, F. Tsai, K. Li, and M. S. Sandy. *California EPA, Sacramento, CA.*

Acetaminophen (paracetamol) is one of the most widely used medications for pain relief and fever reduction. Many new studies have been published since 1999, when it was evaluated by IARC and classified as a Group 3 carcinogen. We recently evaluated the evidence of carcinogenicity for acetaminophen by reviewing data from relevant human, animal, and mechanistic studies. Here we present our approach to the evaluation of mechanistic data, which identified and organized data according to the 10 key characteristics (KCs) of carcinogens (Smith et al., EHP 124:713, 2016, IARC 2019). As such, our review included data on metabolism, genotoxicity, DNA repair, epigenetic alterations, oxidative stress, immune and inflammatory responses, receptor-mediated effects and cell proliferation. Our review and analysis found that the available mechanistic data on acetaminophen provide support for four KCs, specifically, KC 1, 2, 3, and 5. Regarding KC 1, acetaminophen can be metabolized to form electrophilic compounds such as *N*-acetyl-*p*-benzoquinone imine and *p*-benzoquinone, and free radicals such as the *p*-aminophenoxy radical. Regarding KC 2, there is evidence that acetaminophen and several of its metabolites are genotoxic, e.g., inducing chromosomal and DNA damage, including at doses that fall within the therapeutic range. Regarding KC 3, acetaminophen and/or its metabolites have been observed to alter DNA repair via inhibition of ribonucleotide reductase and decreased 8-oxoguanine DNA glycosylase activity, and are associated with genomic instability as measured by increases in γ-H2AX, a marker of double-strand breaks, and by inhibiting DNA topoisomerase IIα. Regarding KC 5, there is evidence that acetaminophen induces oxidative stress, based on data from *in vivo* and *in vitro* studies conducted in humans and animals, even at sub-toxic doses. Results of omics studies also indicate the induction of oxidative stress. This work demonstrates how the KCs of carcinogens can facilitate the organization of complex mechanistic data that are pertinent to carcinogenesis, and thus provide insights on the potential mechanisms of action for acetaminophen.

2499 Loss of SWI/SNF Chromatin Remodeling Activates NRF2 Signaling in Non-small Cell Lung Carcinoma

V. Nguyen[1], S. Song[2], T. Shranck[1], N. Hayes[1], M. B. Major[1], and B. Weissman[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]Oncology Center, ZhuJiang Hospital of Southern Medical University, Guangzhou, China.* Sponsor: R. Fry

The NF-E2-related factor 2 (NFE2L2) transcription factor, also known as NRF2, induces expression of cytoprotective genes upon cellular exposure to oxidative stress. Next-generation sequencing studies of lung cancer have shown a significant number of activating mutations within the NRF2 signaling pathway. Mutations in components of the SWI/SNF chromatin-remodeling complex, a general regulator of transcription employing either SMARCA4/BRG1 or SMARCA2/BRM as the catalytic subunit, also frequently occur in lung cancers. Here, we show that loss of SWI/SNF complex function activated a subset of NRF2-mediated transcriptional targets. Using a series of isogenic NSCLC lines with reduced or depleted BRG1 and/or BRM expression, we observed significantly increased expression and protein levels of the NRF2-target genes HMOX1 and GSTM4. Expression of the NRF2 target genes NQO1 and GCLM modestly increased following BRM reduction but were not affected by BRG1 suppression. High-throughput RNA sequencing of BRG1-proficient and -deficient cell lines confirmed these changes in KEAP1-NRF2 target gene expression as well as identified novel targets of the SWI/SNF complex. Importantly, low BRG1 expression levels in primary human NSCLC correlated with increased NRF2-target gene expression. Our data demonstrate that loss of BRG1 or BRM in lung cancer results in activation of the NRF2/KEAP1 pathway and increased expression of a subset of its downstream targets. Therefore, we provide an additional molecular explanation for why patients harboring BRG1 or BRM mutations show a poor prognosis. Our results also potentially link mutations in SWI/SNF complex components, that occur in >20% of human cancers, with exposure to environmental toxicants. Additionally, a better understanding of these mechanism may yield novel insights into the design of targeted treatment modalities for human lung cancers.

2500 Use of the 10 Key Characteristics of Carcinogens and Evidence Integration in National Toxicology Program (NTP) Cancer Hazard Assessments

G. Jahnke[1], A. Wang[1], S. Atwood[2], P. Schwingl[2], S. Mehta[1], S. Garner[2], and R. Lunn[1]. *[1]NIEHS, Research Triangle Park, NC; and [2]Integrated Laboratory Systems Inc., Research Triangle Park, NC.*

NTP conducts literature-based cancer hazard evaluations, usually to review substances for listing in the Report on Carcinogens (RoC). Following guidelines in the RoC Handbook, these assessments use systematic review methods and integrate evidence from human, experimental animal, and mechanistic studies. Recognizing the increasing importance of mechanistic data in hazard assessments and the challenges in identifying informative studies from a large and diverse literature base, the NTP has adopted a structured approach using the 10 key characteristics of carcinogens (KCs) to search, organize, and review mechanistic information. Here we describe the use of the KCs in several NTP cancer hazard assessments: antimony trioxide, haloacetic acids (HAAs), night shift work (NSW), and light at night (LAN). In each assessment, we searched PubMed, Scopus, and Web of Science using terms targeting each KC. Mechanistic data evidence maps were developed by screening and tagging the literature by KCs and other relevant data (e.g., toxicokinetics and biological effects other than KCs) using an online content-management system. For NSW and LAN, studies of circadian disruption were also tagged by KCs. The next steps were to evaluate the studies, synthesize the evidence across KCs, and integrate the evidence with other data relevant to cancer. For each assessment, the evidence indicated that exposure to the substance (or exposure scenario) was associated with several specific KCs. For some KCs, there were too few studies to assess the strength of the evidence, thus, evidence mapping by KCs may help to identify data gaps. For assessments that did not have human cancer data (antimony and HAAs), the KCs informed biological plausibility. In the HAA assessment, consistent trends in toxicokinetics and KCs were related to the halogen substitution patterns across the 13 HAAs. These trends were used in read-across approaches that supported listing 2 HAAs that did not have animal cancer data. A primary strength of the NSW and LAN evaluations was that the database included some cancer studies that also evaluated KCs or other mechanistic effects and provided evidence of a direct contribution to cancer. In all recent NTP cancer hazard assessments, the 10 KCs provided an effective framework for identifying, organizing, and integrating mechanistic data with human and animal cancer data and other relevant information.

2501 Role of Endothelial RhoA-ROCK Pathway in Cancer Metastasis

M. S. Sajib, F. T. Zahra, J. H. Park, P. E. Tullar, S. K. Srivastava, U. Bickel, and C. M. Mikelis. *Texas Tech University Health Sciences Center, Amarillo, TX.*

Metastasis, the cause of over 90% of cancer-related deaths, is the principal complication during cancer therapy. An important step in the metastatic process is the migration of the cancer cells through the endothelial lining of vasculature during intravasation and extravasation. The molecular mechanisms underlying trans-endothelial migration, is poorly understood. It has been shown that endothelial RhoA-Rho kinase (ROCK) pathway is involved in vascular permeability. Here, we investigated the role of endothelial RhoA-ROCK pathway *in trans*-endothelial migration and cancer metastasis. *In vitro*, we used a quantifiable, highly reproducible, transwell-based, two-cell co-culture model of trans-endothelial migration, where fluorescently-labeled cancer cells transmigrate through an endothelial layer. Both human primary and immortalized endothelial cells, were used and a wide range of human and murine cancer cells were tested. Endothelial RhoA-ROCK pathway was blocked by pharmacological inhibitors or siRNA. The number of cancer cells migrating through the endothelial monolayer was quantified and compared to the controls. To measure endothelial RhoA activation, RhoA pull-down assay was performed with cancer cell supernatant. *In vivo*, endothelial-specific *RhoA* knockout mice were used in experimental metastasis models, where syngeneic murine cancer cell lines B16-F10, LLC-LL3 and E0771 were administered, using both intravenous and intracardiac model. The number of metastatic lung nodules was quantified from the excised lungs. Fasudil, a clinically relevant inhibitor of the RhoA-ROCK pathway was used. A variety of different cancer cell lines of both murine and human origin were able to potently activate endothelial RhoA. *In vitro*, treatment of endothelial cells with either Rho inhibitor, C3 toxin or siRNA for RhoA decreased the trans-endothelial migration of all the cancer cells tested. Similar results were observed when Rho kinase (ROCK) was inhibited using Fasudil or Y-27632. *In vivo*, we observed decreased number of metastatic foci in endothelial-specific RhoA-deficient mice compared to the littermate controls for all the cancer cells tested. Treatment with Fasudil, significantly decreased the metastatic colonization of both human and murine cancer cells. Collectively, our findings highlight the role of endothelial RhoA-ROCK signaling in cancer cell trans-endothelial migration and metastasis. Blockade of this pathway showed a better outcome in cancer metastasis, highlighting the potential of Fasudil as an anti-metastatic drug candidate.

2502 High-Fat Diet Unmasks Tumorigenic Potential of Transient Vinyl Chloride Exposure at Sub-OSHA-Level Concentrations

A. Kumar[1], R. D. Schnegelberger[1], S. P. Monga[1], G. E. Arteel[1], L. Chen[2], B. Wahlang[2], M. C. Cave[2], and J. I. Beier[1]. *[1]University of Pittsburgh, Pittsburgh, PA; and [2]University of Louisville, Louisville, KY.*

Vinyl chloride (VC) monomer is volatile organic compound used in the industry to produce polyvinyl chloride (PVC). At high exposure levels VC causes hepatic angiosarcoma and toxicant associated steatohepatitis. However, we have recently shown that lower exposure levels (i.e., < OSHA exposure limits), which do not directly damage the liver, enhance injury caused by high fat diet (HFD). Although these lower exposure levels are currently considered 'safe', it is unknown if the long-term impact of transient low-concentration VC enhances the risk for the development of liver cancer. This is especially a concern given the fact that fatty liver disease is in and of itself a risk factor for the development of liver cancer. To evaluate the long-term effect of VC exposure C57Bl/6J mice were fed HFD, or low-fat control diet (LFD) for 1 year. During the first 12 weeks of feeding, mice were also exposed to VC in inhalation chambers at concentrations below the current OSHA limit (<1 ppm) or room air for 6 hours/day, 5 days/week. The remaining 9 months of feeding, mice were not exposed to VC. Plasma and liver samples were collected for histology and determination of liver damage. As expected, chronic LFD feeding did not cause hepatic injury in the presence or absence of VC. VC did, however, significantly enhance hepatic steatosis in the LFD group. Feeding HFD for 1 year caused significant hepatic injury, including steatohepatitis and moderate fibrosis, which was exacerbated by VC. Specifically, HFD increased indices of oxidative stress (4-HNE) and of fibrosis (Sirius Red, fibrin) which were significantly increased by VC exposure. Additionally, HFD feeding induced the formation of some, mostly benign tumors. In the HFD+VC group the number of tumors was significantly increased. Tumors in the HFD+VC group ranged from moderately to poorly differentiated HCC with clear basophilic cytoplasm, moderate to high nuclear atypia and tumor cells were without steatosis. Importantly, mice in this group also had an increase in CD31, and potential endothelium-derived tumors, which may be resembling VC-induced hemangiosarcoma seen in humans. Our data indicate that VC sensitizes the liver to other stressors (e.g., HFD) resulting in enhanced tumorigenesis. These data raise concerns about potential interaction between VC exposure and HFD diet (Western diet). Further it also emphasizes that current OSHA safety restriction may be insufficient to account for other factors that can influence hepatotoxicity.

2503 Novel Mechanism of Liver Carcinogenesis Mediated by Peroxisome Proliferator-Activated Receptor-α (PPARα)

X. Zhu[1], Q. Liu[1], P. B. Smith[1], A. D. Patterson[1], A. K. Sharma[2], S. Amin[2], F. J. Gonzalez[3], and J. M. Peters[1]. *[1]Pennsylvania State University, State College, PA; [2]Pennsylvania State University, Hershey, PA; and [3]National Cancer Institute, Bethesda, MD.*

Chronic administration of PPARα agonists causes hepatocarcinogenesis in rodents through a mechanism mediated by PPARα. A large body of evidence indicates that the hepatocarcinogenic effect of PPARα agonists is rodent-specific and humans are refractory to this. Administration of the potent human PPARα agonist GW7647 for up to 18 months caused nearly 100% incidence of hepatocarcinogenesis in wild-type mice. This effect was diminished in *Ppara*-null and humanized *PPARα* (h*PPARα*) mice but a low incidence of hepatocarcinogenesis was observed in these mice, independent of treatment. The mechanism by which *Ppara*-null and h*PPARα* mice spontaneously develop liver cancer was examined in the present study. Metabolomic analyses revealed that hepatic fatty acids increased in *Ppara*-null and h*PPARα* mice, independent of GW7647 treatment and this effect was not observed in wild-type mice. Moreover, *Ppara*-null and h*PPARα* mice had higher hepatic levels of unsaturated fatty acids including polyunsaturated fatty acids (PUFA). GC-MS detected an increase in PUFAs including linoleic acid in the liver of *Ppara*-null and h*PPARα* mice, independent of ligand activation of PPARα by GW7647. Since linoleic acid can selectively cause $CD4^+$ T lymphocytes loss and promote hepatocarcinogenesis, it is of interest to note that $CD4^+$ T lymphocytes were decreased in *Ppara*-null and h*PPARα* mice compared to wild-type mice. Additionally, serum IFN-γ and TNF-α, which are essential for $CD4^+$ T cell-dependent immune surveillance, were significantly decreased in *Ppara*-null and h*PPARα* mice compared to the control. Hepatic 8-oxo-dG DNA adducts exhibited an age-dependent increase in all genotypes. These studies suggest that genetic silencing of mouse PPARα causes increased hepatic linoleic acid in *Ppara*-null and h*PPARα* mice. This change is associated with reduced hepatic level of $CD4^+$ T cells that is associated with decreased levels of serum IFN-γ and TNF-α, two biomarkers of $CD4^+$ T cell activity. Combined, this suggests that liver tumors found in *Ppara*-null and h*PPARα* mice are due to reduced immune surveillance leading to age-related hepatic cancer. Since there are no known null mutations for PPARα in nature, and this mechanism is not related to ligand activation of PPARα, it must be considered when assessing the phenotype of *Ppara*-null and h*PPARα* mice.

2504 Role of Novel HDAC Inhibitors in Castration Resistant Prostate Cancers

Z. Rana[1], J. Tyndall[1], M. Hanif[2], and R. Rosengren[1]. *[1]University of Otago, Dunedin, New Zealand; and [2]University of Auckland, Auckland, New Zealand.*

Castration resistant prostate cancer is the second most common cause of death from cancers in men. Overexpression of histone deacetylases (HDACs) 1 and 2 is linked to poor prognosis in prostate cancer, making HDACs an enticing target. However, clinical trials using HDAC inhibitors have failed owing to toxicity in patients, poor pharmacokinetic profile and evolution of resistance. Therefore, *N*1-hydroxy-*N*^{8}-(4-(pyridine-2-carbothioamido)phenyl)octanediamide 1 and [chlorido(η^5-pentamethylcyclopentadienyl)(*N*1-hydroxy-*N*^{8}-(4-(pyridine-2-carbothioamido-κ^2*N,S*)phenyl)octanediamide)rhodium(III)] chloride 2 were synthesized and tested in comparison with the clinically used HDAC inhibitor, suberoylanilide hydroxamic acid (SAHA). HDAC inhibition, acetylation induction, cytotoxicity and anti-angiogenic potential were assessed in androgen receptor (AR)-positive LnCAP, AR-negative Du145 and PC3 prostate cancer cell lines and normal prostate cells PNT1A6. HDAC inhibition assays revealed that equipotent inhibition was observed for SAHA, 1 and 2. Docking studies using 4LXZ (SAHA co-crystallized with HDAC2) revealed that 1 coordinates via sulfur and nitrogen with the zinc ion, whereas one pose also revealed that it coordinates to the zinc ion via the hydroxamate group. Acetylation of histone variant-3 was also induced in response to 1 and 2 in PC3, Du145 and PNT1A6 cells. As determined by sulforhodamine B assays, 1 and 2 had EC_{50} values of 2.37 and 3.06 μM, 1.81 and 7.21 μM, 5.41 and 9.38μM, 2.81 and 3.24μM in PC3, Du145, PNT1A6 and LnCAP cells respectively. Of note, 1 and 2 were less cytotoxic towards PNT1A6 with EC_{50} values of 5.41 and 9.38 μM respectively than SAHA (EC_{50}= 1.96 μM). Anti-angiogenic roles were explored using Western blotting of VEGFR-2 and VEGF-A in PC3 cells; 1 and 2 reduced their expression, in contrast, SAHA increased the levels of VEGFR2. Tube formation assays using HUVEC cells revealed a significant reduction of

24.14% and 27.4% of total segment length per field in response to 1 and 2 as compared to control. Both 1 and 2 inhibit HDACs, induce acetylation, possess anti-angiogenic activity and are cytotoxic against prostate cancer cells. Thus, examination of pharmacokinetic and toxicity profile of these drugs in *in vivo* models is warranted.

2505 Chronic Arsenic Exposure Increases Metastatic Potential of Lung Cancer Cells via Transcriptional Regulation of SOX9 by NRF2

C. J. Schmidlin, and D. D. Zhang. *University of Arizona, Tucson, AZ.*

Chronic arsenic exposure continues to be a worldwide health concern because of its prevalence and contribution to disease, specifically tumorigenesis and, as recently evidenced, metastasis. Non-small cell lung cancer (NSCLC) patients that develop a metastatic lesion have a 5-year survival rate of 6%, as compared to 60% in localized tumors; however, the exact mechanism for what causes NSCLC cells to metastasize is unknown. One proposed contributor is nuclear factor (erythroid-derived 2)-like 2 (NRF2), a transcription factor with known oncogenic properties that is induced by arsenic toxicity. Under basal conditions, a Ring-Box 1-Cullin-3 (RBX1-CUL3) E3 ubiquitin ligase complex maintains low NRF2 expression via constant ubiquitylation and degradation; however, alterations to Kelch-like ECH-associated protein 1 (KEAP1), a substrate adaptor protein of the RBX1-CUL3 complex that binds NRF2, either by cysteine oxidation, mutation, or p62-dependent sequestration, allows NRF2 to translocate into the nucleus, bind to antioxidant response elements (ARE), and promote transcription of its target genes. Here, we demonstrate that chronic arsenic exposure causes malignant transformation of normal immortalized lung epithelial cells (BEAS-2B) and aids in invasion and migration via NRF2-dependent upregulation of SRY-box 9 (SOX9): a transcription factor linked with metastasis. Upon analysis of the *Sox9* gene, we confirmed the presence of a functional ARE sequence in its promoter region, suggesting that NRF2 is responsible for controlling SOX9 expression. To verify, we demonstrated that pharmacological induction or inhibition of NRF2 increased or decreased SOX9 expression, respectively. Additionally, we showed that mutation of the ARE sequence upstream of the *Sox9* gene prevented NRF2 binding, thus blocking transcription of SOX9. As increased proliferation is linked with tumorigenesis, we utilized NSCLC cells (H1299) to demonstrate that heightened activation of NRF2 via knockout of KEAP1 contributes to proliferation; while, inhibition of NRF2 or direct knockdown of SOX9 reduced proliferation in both a wild type and constitutively active NRF2 setting. To further elucidate the role of NRF2 in metastasis, we also showed that loss of NRF2 or SOX9 slowed the ability of cancer cells to migrate and invade. Overall, this evidence suggests that NRF2 control of SOX9 expression can contribute to the metastatic potential of both environmentally and genetically driven lung tumors.

2506 Role of AhR Ligands in miR-132-Mediated Modulation of HMBG1 in Inducing Th17/T Regulatory Cell Differentiation in Delayed Type Hypersensitivity

O. A. Abdulla, M. Nagarkatti, and P. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

The aryl hydrocarbon receptor (AhR) is known to have an impact on immunomodulation. Recent data has shown that TCDD, an exogenous AhR ligand, induces T regulatory cells (Tregs), while FICZ, an endogenous AhR ligand, induces Th17 cells. miR-132 has been involved in autoimmune encephalomyelitis. The aim of this present study is to investigate the effects of TCDD and FICZ on T cell differentiation in delayed type hypersensitivity (DTH) by using miR-132 KO mice. Treatment of C57BL/6 mice with TCDD attenuated DTH responses to methylated bovine serum albumin and induced Tregs. In contrast, treating DTH mice with FICZ induced pro-inflammatory Th17 cells. Analysis of microRNA (miR) profiles from draining lymph nodes showed differential regulation between TCDD and FICZ groups. Specifically, miR-132, which was overexpressed in TCDD group, led to downregulation of the gene target, high mobility group box 1 (HMGB1). Downregulation of these gene targets led to an increase in Treg differentiation. In contrast, FICZ treatment caused a downregulation of miR-132, which leads to an upregulation of HMGB1. Treatment of miR-132 KO mice with TCDD or FICZ in DTH to validate this pathway showed that TCDD failed to suppress the immune response by increase in the footpad thickness and increase in the absolute number of cells in the draining LN. Furthermore, Foxp3 was significantly reduced due to increase in the HMGB1. On the other hand, FICZ treatment of miR-132 KO mice showed same results as the wildtype mice by increasing Th17 cells. In summary, miR-132 KO mice showed that TCDD and FICZ have divergent effects on miR-132 in a DTH model, and both ligands differentially regulate miR-132, which targets HMGB1 affecting key components involved in Th17 and Treg development. *Supported by NIH grants P01AT003961, P20GM103641, R01ES030144, R01AI129788 and R01AI123947.*

2507 Physiologic Expression of AhR Regulates Resident Tissue Macrophages in the Small Intestine and Alters Susceptibility to Type 1 Diabetes

A. Ehrlich[1], J. Pennington[2], H. Kahalehili[1], and N. Kerkvliet[2]. [1]*University of California Davis, Davis, CA; and* [2]*Oregon State University, Corvallis, OR.*

Susceptibility to type 1 diabetes (T1D) is influenced by both genetic and environmental factors. Identification of these environmental contributors has become increasingly urgent as a result of the steady rise in young children diagnosed with T1D over the past twenty years. Two environmental factors that have been associated with altered T1D risk are the diet and alterations in the intestinal microbiome. Metabolites derived from the diet and microbiome have been shown to activate the aryl hydrocarbon receptor (AhR), a ligand activated transcription factor that regulates the immune response. We therefore hypothesized that diet- and microbial- derived metabolites may influence the autoimmune response and subsequent susceptibility to type 1 diabetes. To test this hypothesis, we generated AhR knockout mice on the nonobese diabetic (NOD) background and examined the intestinal immune response and development of type 1 diabetes. Female AhR knockout mice had had reduced insulits at 12 weeks of age, and a decreased incidence and onset of overt diabetes in comparison to their wild type littermates. A similar trend was observed in AhR knockout and wildtype male mice. To determine whether physiologic expression of AhR was altering the immune response, we analyzed CD4+ T cell subsets in Peyer's patches, and the lamina propria and intraepithelial layer of the small intestine. While there were no significant changes in the percentage of Th17 cells at any tissue site, there was an increase in IL10R+Foxp3+ Tregs in the LPLs of AhR knockout mice. While analyzing intestinal CD4+ T cell populations, we also discovered a new population of resident-like macrophages in the small intestine lamina propria. These cells are negatively regulated by AhR, have a very strong positive correlation to lamina propria Tregs, and correlate with protection against insulitis in NOD mice. To identify the potential source of AhR ligands that regulate these resident-like macrophages, mice were fed an AhR ligand-deficient diet. These cells were not further regulated by dietary ligands, and therefore, it is likely that the AhR ligands originates from the intestinal microbiome. Future studies are planned to determine how AhR regulates the expression of lamina propria resident macrophages and to uncover their immunoregulatory function duringT1D pathogenesis.

2508 Validated Immunophenotyping Panels for the Assessment of Immunotoxicity in Nonhuman Primate, Humanized Mouse, Canine, and Rat Toxicology Studies

D. L. Clark, R. Pal, J. Schaubhut, L. Brown, and J. J. Stewart. *Flow Site Contract Laboratory. LLC, Bothell, WA.*

Understanding how cells respond to drugs and other external stimuli is an important part of the drug development process. Because of the clinical success of the immune checkpoint inhibitors, the number of immune-modulating drugs in development has increased dramatically in the past 10 years. This includes drugs that are designed intentionally to be immune-activating, or immunosuppressive. In addition to expected effects, drugs can have unexpected and off-target toxicities on the immune and hematologic systems. Thus, monitoring immune cells is an important part of hazard identification and risk assessment in any well designed Toxicology study. Immunophenotyping is used to identify immune cell subsets based on antigens expressed on the cell surface, and can also include cytoplasmic and nuclear antigens. Specific antigens are identified using antibodies tagged with fluorescent dyes. Antibodies are used in combination, called a panel, to phenotype cells. Immune cells are most commonly analyzed from peripheral blood, but can also be analyzed from single cell suspensions prepared from the lymphoid organs (bone marrow, spleen, lymph node) using flow cytometry. Immunophenotyping relies heavily upon CD, or cluster of differentiation, markers on the cell surface. There are currently almost 400 CD markers, overseen by the International Workshop and Conference on Human Leukocyte Differentiation Antigens (HLDAs). Non-clinical species commonly used for immunotoxicology studies include the non-human primate (NHP) for protein therapeutics, and rat and canine for small molecules. Cross-reactivity of antibodies to the CD markers of non-clinical species must be known in order to design immunophenotyping panels. Typically, rodent and canine antibodies are made to species-specific antigens, so cross-reactivity is not an issue. However, NHP antibodies are made to human CD antigens, so their cross-reactivity must be confirmed

(www.nhpreagents.org). Humanized mice are an invaluable tool for studying the human immune system, *in vivo* (and there are no issues with the cross reactivity of antibodies), and are increasingly used as an alternative to the NHP in toxicology testing. FCSL has developed and validated flow cytometry Immunophenotyping panels for monitoring the immune cells of four non-clinical species: NHP, canine, rat and humanized mice, for use on GLP and non-GLP studies.

2509 Differential Effects of the AhR on Immunoglobulin Expression in a Human B Cell Line

M. Bhakta, C. Allex-Buckner, C. Sulentic, and K. Burra. *Wright State University, Dayton, OH.*

Inhibition of antibody expression and secretion by the environmental contaminant 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) is well established in animal models. This inhibition is mediated by the aryl hydrocarbon receptor (AhR). However, the effect of TCDD on human B cells is less clear. Therefore, the objective of this study was to evaluate the effects of TCDD on Ig expression, via ELISA analysis and real-time PCR, in a human B-cell line (CL-01). CL-01 cells were originally generated from a Burkitt lymphoma patient. These cells can be stimulated by CD40L and IL-4 to secrete Ig and undergo class switch recombination. TCDD significantly inhibited IgG secretion but had no effect on IgM secretion. TCDD also altered Ig heavy chain (*IGH*) transcription, producing a significant decrease in γ1-4 transcripts and an increase in α1 and α2 transcripts. Co-treatment with an AhR antagonist not only reversed the effects of TCDD but also enhanced stimulation-induced γ1-4 expression and IgG secretion, perhaps due to the presence of endogenous AhR ligands in the media. These results support a role of the AhR in regulating human *IGH* expression.

2510 *In Vitro* Assay System to Assess Alterations of Thymocyte Development by Environmental Toxicant Exposures

V. Sanchez, and C. Broussard. *University of La Verne, La Verne, CA.*

Endocrine disrupting chemicals (EDCs) are widespread and are in many common household items. These are chemicals that interfere with the body's endocrine system and can cause developmental, reproductive, neurological, and immunological effects by mimicking and/or interfering with the activity of hormones. Exposure to these chemicals may cause autoimmune diseases and have long-lasting effects. Previous research has shown that exposure to EDCs, such as Diethylstilbestrol (DES) and 2,2-bis(p-hydroxyphenyl)-1,1,1-trichloroethane (HPTE; the primary metabolite of the pesticide methoxychlor), decreases cell viability and alters development of gestational day 16-18 C57BL/6 primary embryonic thymocytes during *in vitro* differentiation (Leung-Gurung et al., 2018). Effects were seen in the double positive population of developing thymocytes, the population of immature thymocytes that differentiates into mature CD4+ helper T-cells or mature CD8+ killer T-cells. Investigating effects on embryonic thymocyte differentiation in primary cells is cost- and labor-intensive. Until now, no cell line had been identified that could be used as a suitable replacement for primary cells in the differentiation assay to investigate the impacts of environmental toxicants on thymocyte development. In this study we explored using a double positive thymic lymphoma cell line, VL3-3M2. VL3-3M2 cells were cultured with and without CD2 and TCR antibodies (used to signal the cells to differentiate) and treated with 50pM, 50nM, and 50uM of DES or HPTE for 24 hours. The results from the VL3-3M2 cell line show similar effects as seen in primary embryonic thymocytes, including changes in cell viability and cell surface markers. This work establishes a new assay system for exploration of the alteration of thymocyte development by environmental toxicant exposure.

2511 Constructing and Challenging a Gastrointestinal Co-culture Model for Immunotoxicity

L. R. Steele, S. H. Pradhan, D. Carrasco, and C. M. Sayes. *Baylor University, Waco, TX.*

In the field of nanotoxicology there is increasing interest in determining the immunological responses in the gut after ingestion of advanced materials used in the food and drug industry. To probe for oral exposure toxicities, a cell-based reproducible model for the gut is severely needed. To create a more comprehensive gastrointestinal *in vitro* model, three human cancerous cell types were co-cultured: HT29-MTX (intestinal mucous-producing goblet cells), Caco-2 (colon epithelial cells), and Raji B (lymphocytes). When Raji B and Caco-2 cells were co-cultured, a subpopulation of the Caco-2 epithelial cells transformed into endocytic, immune-supporting Microfold cells ("M cells"). The intestinal epithelial barrier model produced by this co-culturing method contained a "true" epithelial cell (Caco-2), a goblet cell (HT29-MTX), and two types of immunological cells (Raji B and differentiated M cells). This culture method allows for more robust immunotoxicological analyses. Furthermore, the combination of M cells and HT29-MTX cells is known to play an important role in endocytosis-mediated transepithelial absorption of particle like materials, thus allowing for a more comprehensive analysis of the naturally-polarized intestinal barrier nanomaterial uptake. Cellular communication and metabolic activity experiments, including cell viability, gastrointestinal barrier integrity, oxidative stress, and proinflammatory response markers, were used to characterize the model. After completion of baseline characterization, simulated cellulose digestate and undigested cellulose were used to challenge the model, and the model was also exposed to a positive control to induce toxicity. In comparison to monocultures of the three cell lines, the triculture has increased sensitivity to exposure and thus allows for a more realistic challenge-response analysis. This co-culture model and model challenge provides a foundation for reproducible future oral exposure toxicity analyses without the need for animal models.

2512 Historical Immunophenotyping Data in Preclinical Species

C. Dumont, G. Desilets, and M. Piché. *Charles River, Senneville, QC, Canada.*

Flow cytometry allows multiparametric analysis of thousands of particles per second and helps to adequately identify or functionally characterize complex cell populations of interest. It is a tool often used in basic research, discovery, preclinical and clinical trials. During the preclinical phase for the development of new drugs, flow cytometry has routinely been used for assessing the immunotoxic effects of a candidate drug by evaluating the immunophenotype of various cell populations in whole blood, lymphoid tissues, or other matrices. Despite the fact that immunophenotyping data is being generated by multiple different laboratories, combined database presentation and comparison of preclinical immunophenotyping data in various animals, strains and tissues/whole blood has been limited. The objective of this study was to compile relevant preclinical immunophenotyping data from monkeys (cynomolgus, rhesus), dogs (beagle), rats (Sprague-Dawley, Wistar, Fisher) and mice (various strains), from different matrices. The database from a single site was extracted from control data generated from over fifteen years of work. The specie, strain, age, cell population and sample type were grouped to provide a representation of expected lymphocyte population distribution profiles.

2513 Checkpoint Inhibitors Induce Immune-Mediated Liver Injury in Mice

S. Arat[1], H. Llewellyn[2], J. Wen[2], J. Gao[2], M. Martin[1], and C. Ji[2]. *[1]Pfizer Inc., Groton, CT; and [2]Pfizer Inc., La Jolla, CA.*

Inhibition of immune checkpoints (e.g. cytotoxic T-lymphocyte-associated protein 4 (CTLA-4); programmed cell death 1 (PD-1) and indoleamine 2,3-dioxygenase 1 (IDO1)) has demonstrated antitumor efficacy, especially in various combinations, in preclinical models and humans across several types of cancers, despite of immune-related adverse events. We developed a novel mouse model to elucidate the immune mechanisms of one of the more commonly seen adverse events, hepatitis, in the setting of combinatorial checkpoint blockade. PD-1-/- mice (C57BL/6) were treated with anti-CTLA4 (clone 9D9 mouse IgG2b, 300 µg/dose) intravenously weekly. Epacadostat (600 mg/kg) or vehicle control was administered twice a day by oral gavage. Each treatment group has 4 mice. Necropsy was performed after 2 weeks. CD45+ enriched liver cells (Miltenyi) were processed with the 10X genomics platform for single cell RNA sequencing. T cell receptor (TCR) and B cell receptor (BCR) repertoire profiling was performed in conjunction with gene expression. Single cell transcriptomics revealed that (1) the liver injury due to immune checkpoint inhibitors (ICIs) is associated with a population of CD8 T cells that express activation and exhaustion markers; and (2) ICI combination treatment decreased T cell clonality, indicating a broadening of the immune repertoire. This model could be of significant value to the greater scientific community in that it can provide mechanistic insight into immune-mediated liver toxicity associated with various drug combinations. It may provide circular guidance and support for clinical anti-cancer drug combination regimens that contain ICIs.

2514 Cannabinoid Receptor 2 Activation Exerts Anti-Inflammatory Effects on Primary Human CD8+ T Cells

J. R. Marty, J. Zhou, A. Bach, J. Henriquez, R. B. Crawford, and N. E. Kaminski. *Michigan State University, East Lansing, MI.*

Combined antiretroviral therapy (cART) has altered the prognosis of HIV from a fatally progressive disease to a manageable chronic disease. However, an increase in neural inflammation is found to be associated with aging HIV infected individuals. The inflammation contributes to the etiology of HIV associated neurocognitive disorder (HAND) of which there are specific diagnoses with varying severity. While the underlying mechanism of HAND is still largely unknown, immune cells such as $CD8^+$ T cells have been observed to cross the blood brain barrier and produce pro-inflammatory cytokines, which may induce neuronal cell injury. Tetrahydrocannabidiol (THC) has been previously shown by our laboratory to reduce immune cell activation and production of pro-inflammatory cytokines. Therefore, due to the preferential expression of cannabinoid receptor (CB) 2 on lymphocytes, we hypothesize that activation of CB 2 by THC could reduce the activation and pro-inflammatory responses by human $CD8^+$ T cells, which will be confirmed by treatment with JWH-015, a selective CB2 agonist. Therefore, in the current studies, naïve human peripheral blood $CD8^+$ T cells from healthy subjects were activated by anti-CD3/anti-CD28 and treated with THC or JWH-015 followed by restimulation with PMA/Io after a six day incubation. A decrease in $CD8^+$ T cell activation marker expression, CD25 and CD107a, as well as inhibition of pro-inflammatory cytokine production, IFN-γ, were observed in cells treated with THC. *Supported by NIH R01-DA047180.*

2515 Strain Comparison of Sprague Dawley and Wistar Rats in Immunotoxicology Endpoints

A. M. Repic[1], M. P. Shea[1], A. L. Rowse[2], M. P. Brandt[2], E. Bruder[1], and A. M. Frantz[1]. *[1]Covance Inc., Madison, WI; and [2]Covance Inc., Greenfield, IN.* Sponsor: A. Phadnis-Moghe

The two most commonly used strains of rat, Sprague-Dawley and Wistar, were assayed to determine possible differences between the strains for major immunotoxicology endpoints: immunophenotyping (IPT), T cell dependent antibody response (TDAR) and peripheral blood cytokine detection. For IPT analysis, whole blood from each rat strain was stained with a cocktail of antibodies to assess Total T, Helper T, Cytotoxic T, B, and Natural Killer cells. Results showed small differences between relative percentages of Total T, Helper T, and B. Cytotoxic T and Natural Killer cells did not display significant differences between the two rat strains. TDAR analysis reflects the literature and illustrates there are no significant differences in the KLH IgG and IgM expression during primary or secondary response between strains. Analysis of peripheral cytokines in rat serum and plasma was assessed. Whole blood from 15 animals per sex was used to create three pools of whole blood per strain. The whole blood pools were stimulated with mitogens to generate cytokine positive plasma, which was spiked into naïve serum or plasma to generate cytokine positive sample. Overall the cytokine expression between the strains was similar. In summary, the strain comparison for these major endpoints is interpreted to indicate that the two strains of rat perform similarly for immunotoxicology monitoring in standard preclinical safety assessment studies.

2516 Understanding Appropriate Use of Cytokine Release Assay Formats as Related to Therapeutic Agent Mechanism of Action

A. L. Rowse[1], C. Cooper[2], P. Cherukuri[1], J. R. Munday[2], E. Troksa[1], and A. M. Frantz[3]. *[1]Covance Inc., Greenfield, IN; [2]Covance Laboratories Limited, Harrogate, United Kingdom; and [3]Covance Inc., Madison, WI.* Sponsor: A. Phadnis-Moghe

Following adverse (cytokine storm) events associated with administration of TGN 1412 (anti-CD28 superagonist) in healthy individuals, *in vitro* cytokine release assays (CRAs) are now routinely used as risk assessments to understand potential hazards associated with therapeutic agents prior to first-in-human (FIH) clinical studies. The challenge in designing CRAs is modeling an *in vitro* assessment that has *in vivo* predictive value and accurately reflects risk of cytokine release syndrome (CRS) within the clinic. Despite an industry-wide focus on CRA optimization over the past decade, there is no consensus on preferred assay formats, likely due to the complexity of understanding mechanism of action (MoA) of therapeutic agents while trying to model *in vivo* conditions within a well-controlled *in vitro* assessment. This investigation aims to provide an understanding of the assay format as it related to the MoA of controls and comparator molecules within multiple assay formats including liquid phase and solid phase (wet coat and dry coat). Specifically, anti-CD3 monoclonal (OKT3), anti-CD28 monoclonal (ANC28.1), anti-CD20 monoclonal, and anti-TNF monoclonal antibodies were chosen for evaluation. Additionally, the use of two different serum-free medias were investigated for use in liquid phase CRAs to determine if robust assessments can be accomplished in the absence of fetal bovine serum (FBS). Use of serum-free media compared to complete media containing FBS impacted cytokine production including background (unstimulated) and isotype control cytokine production. These assessments highlight the importance of understanding biologic conditions modeled by *in vitro* assessments, including the impact of media composition on the health and status of immune cells. Additionally, this assessment of serum-free media underscores the importance of evaluating cytokine data as a function of both concentration and fold change (over background or isotype control values). Overall, this poster will focus on the importance of selecting appropriate assay format as related to MoA of therapeutic agents, assay conditions and data presentation and interpretation to provide insight into improving predictability of CRAs.

2517 T Cell-Dependent Antibody Response in Monkey and Rat: Establishing the "Normal Range" in Immune Response for the Assessment of Immunotoxicity

Z. Faraahi, A. Shaw, J. Munday, K. Hunjan, R. Chris, C. Fielding, and T. Watson. *Covance Laboratories Limited, Harrogate, United Kingdom.* Sponsor: A. Phadnis-Moghe

Increased expectations from regulatory agencies call for additional immunotoxicity tests as part of repeat-dose toxicity studies recommended for the improved prediction potential of adverse effects on the immune system. Evaluation of T-cell-dependent antibody response (TDAR) provides an overall measure of host immune function and requires the active participation of T-lymphocytes, B-lymphocytes, and macrophages/Dendritic cells. Assessment of anti- keyhole limpet hemocyanin (KLH) is fast becoming an industry standard for TDAR assessment. However, there are numerous concerns around the application of TDAR tests, specifically concerning KLH-TDAR assessment, including high animal to animal variability, a lack of an established normal range of the immune response and ambiguity of the level of inhibition of the TDAR to be considered toxicologically imperative. As such, there is an immediate need to evaluate these issues. The objective of this study was to establish a consensus on the implications of these factors on using the KLH-TDAR results in hazard/risk identification, and to establish standard criteria in rodent and non-human primate (NHP) *in vivo* models for immunotoxicants classification. To establish a standard 'normal range', the serum levels of anti-KLH and IgM antibodies titres in naïve Rat and Cynomolgus Monkey were assessed using a validated enzyme-linked immunosorbent assay (ELISA) method following dosing with 300 µg/kg KLH. Animals were administered KLH at the start of the study to induce an initial immune response and given a consecutive dose approximately 2 weeks later to enable a secondary immune response. Blood samples were obtained prior to KLH administration and subsequently throughout the study to monitor anti-KLH response. Response to KLH was calculated using the Area Under the Curve (AUC). Next, correlations between KLH response, key pro-inflammatory cytokine levels (IL-2, IL-6, IL-8, TNFα IFNγ and IL-10) and the number of circulating lymphocytes (CD3+, CD4+, CD8+ and CD14+) were assessed to further develop the 'normal' TDAR model. Taken together, the results from the present study will assist in a more accurate means to classifying changes outside of a 'normal' humoral immune response. The addition of a set range of immune parameters, including cytokines levels and lymphocytes counts will help better define set criteria for KLH-TDAR response in rodent and NHP *in vivo* models commonly used in Immunotoxicology.

2518 Upregulation of ROS Detoxification Genes Protects against Lipopolysaccharide Toxicity: Role of NFkappaB

H. Ahmed[1], D. Pitts[1], C. Griffith[1], J. A. Rifaie[1], S. Belperain[1], A. Dunphy[1], H. Zhu[2], R. Y. Li[2], and Z. Jia[1]. *[1]University of North Carolina at Greensboro, Greensboro, NC; and [2]Campbell University School of Osteopathic Medicine, Buies Creek, NC.*

Dysregulated response by the body towards an infection leads to tissue and organ damage is known as sepsis. Currently, approximately 18 million people worldwide are affected by this deadly disease annually. However, the mechanism underlying this illness remain not been fully defined. Lipopolysaccharide (LPS), also known as endotoxin, is commonly used in controlled experiments to trigger the symptoms of sepsis. This study was undertaken to determine whether the LPS-induced inflammatory injury could be ameliorated via the

endogenous upregulation of antioxidant defense. CDDO-Im, a novel triterpenoid compound, was used to upregulate endogenous antioxidant defenses. *In vivo* mice trials indicated that pro-inflammatory cytokine levels of TNF-alpha, IL-6, and IL-1β in hepatic tissue were significantly decreased as a result of CDDO-Im treatment in LPS-induced mice. Also, LPS-induced increase in expression of pro-inflammatory cytokine levels is reduced by CDDO-IM in macrophages differentiated from ML-1 monocytes. Additionally, CDDO-IM has been shown to protect against LPS-induced cytotoxicity in macrophage. Interesting, NF-kB transcriptional activity was also noted to decrease upon treatment with CDDO-IM in macrophages. This data demonstrated that the endogenous upregulation of a multitude of antioxidants by CDDO-Im attenuated LPS-induced inflammation and injury. This study may contribute to the advancement of our understanding of treating life-threatening inflammatory diseases such as sepsis.

PS 2519 The Involvement of Lymphocyte-Specific Protein Tyrosine Kinase (LCK) in the Aryl Hydrocarbon Receptor (AhR)-Mediated Suppression of the IgM Response in Human CD5$^+$ Innate-Like B Cells

J. Zhou, L. Blevins, R. Crawford, and N. E. Kaminski. *Michigan State University, East Lansing, MI.*

LCK is a well-characterized tyrosine kinase critical for cell activation and proliferation. The function of LCK has been extensively investigated in T cells; however, little is known about the role of LCK in B cells. Studies have demonstrated that CD5$^+$ Innate-like B cells (ILBs), a subpopulation of mature B cells, highly express LCK. Previous studies from our laboratory also demonstrated the involvement of LCK in the suppression of the IgM response to AhR activation by 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) in total human B cells. These observations suggested that different subsets of B cells expressed different levels of LCK and had differential sensitivity toward AhR activation. Therefore, we hypothesized that the AhR-mediated suppression of the IgM response involved an increase in LCK activity in CD5$^+$ ILB. In the current studies, we investigated the role of LCK in the context of AhR-mediated suppression of the IgM response by CD5$^+$ ILBs. We demonstrated that AhR activation resulted in a significant increase in LCK, which correlated with significant suppression of the IgM response in CD5$^+$ ILBs. In addition, LCK inhibitor treatment prevented the AhR-mediated suppression of the IgM response in CD5$^+$ ILBs. Furthermore, treatment with an AhR antagonist also prevented the increase of LCK in CD5$^+$ ILBs following AhR activation. Collectively, these data demonstrated a critical role by LCK in the suppression of IgM responses in CD5$^+$ ILBs. *Support by P42 ES00491.*

PS 2520 AhR Activation Enhances Influenza A Virus Gene Expression in Dendritic Cells

D. Castro-Meléndez, A. M. Franchini, and B. Lawrence. *University of Rochester, Rochester, NY.*

Influenza A viruses (IAV) cause severe disease in humans and are a significant public health problem. Epidemiology studies have shown that human exposure to dioxins and PCBs exacerbate influenza and other respiratory diseases. These compounds bind the aryl hydrocarbon receptor (AhR), and by activating the AhR they hinder effective host response to infection by negatively regulating the ability of dendritic cells (DCs) to prime naive CD8+ T cells. Thus, AhR activation reduces the generation of cytotoxic T cells (CTLs), which are critical for controlling viral infections. Yet, how environmental AhR ligands regulate antiviral defenses in DCs is not fully understood. Recently, transcriptomic analysis of DCs isolated from the lungs of IAV infected mice revealed that AhR activation changed expression of several gene families associated with viral uptake and processing. For example, AhR activation significantly decreased expression of *Cd209a* and *Clec9a*, which encode receptors that detect and bind carbohydrate antigens, influence DC phagocytic activity, and antigen processing pathways. The present study tests the hypothesis that AhR-driven decreased expression of *Cd209a* and *Clec9a* enhances susceptibility of DCs to direct viral infection. To test this, we used *in vitro* derived bone marrow derived DCs (BMDCs) from C57BL/6 mice. Cells were exposed to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) to active the AhR, and subsequently infected with IAV. Alterations in viral and endogenous gene expression were measured using qRT-PCR. Influenza virus nucleoprotein (NP), non-structural protein 1 (NS1), and matrix genes were significantly higher in TCDD treated BMDCs compared to vehicle controls. In addition, BMDCs treated with TCDD have significantly increased expression of known AhR target genes *Cyp1a1* and *Cyp1b1*, which indicates sensitivity to AhR activation. These data are further evidence that the AhR is a multifaceted regulator of the immune system, and understanding the effects of its activation will give us further insight into how environmental exposures modify anti-viral immune responses.

PS 2521 Immunologic Assessment of Cannabidiol (CBD) in Human Peripheral Blood Mononuclear Cells (PBMC)

R. B. Crawford, T. Bach, M. D. Rizzo, S. Sermet, L. K. Blevins, J. Zhou, D. M. Isha Olive Khan, and N. E. Kaminski. *Michigan State University, East Lansing, MI.*

Cannabidiol (CBD), first discovered in 1940, is one of 113 structurally related cannabinoids in the *Cannabis satvia* plant and is a non-psychotropic phytocannabinoid due to its low binding affinity to cannabinoid receptor (CB1). Recently CBD has garnered much attention for its medicinal properties in the treatment of certain types of epilepsy and as an anti-inflammatory agent. Due to its purported anti-inflammatory properties CBD is being added to skin creams and foods and beverages. The objective of this study was to evaluate pro and/or anti-inflammatory effects by CBD in different cell types present in human PBMC. CBD concentrations extending from 0.001 to 10 μM were added to human PBMC which were then stimulated with either CpG (plasmacytoid dendritic cell (pDC)), LPS (monocytes), anti-CD3/CD28 (CD4 and CD8 cells) or IL-15/21 (NK cells). Phagocytosis, proliferation, activation marker expression and cytokine production were quantified. Out of the 22 unique responses assayed, CBD modulated three responses that were statistically different from their vehicle controls. Interestingly, all three responses were in the monocyte population. Phagocytosis at 10 μM was significantly decreased along with IL-1β and IL-6 production at 10 μM after 24 hours post stimulation with LPS. These studies suggest that CBD preferentially targets certain monocyte-mediated responses while having no effect on the inflammatory responses by pDC or on CD4 or CD8 T cell populations in human PBMC. *Supported in part by GBS Global Biopharma Inc. and Center for Research on Ingredient Safety.*

PS 2522 AhR Controls Expression of the Cell Cycle Regulator Aurora A Kinase in Hematopoietic Stem and Progenitor Cells

A. M. Franchini, K. L. Vaughan, S. Bhattacharya, K. Singh, and B. Lawrence. *University of Rochester, Rochester, NY.*

Hematopoietic stem cells (HSCs) self-renew and give rise to all cells of immune system, ensuring lifelong protection against disease. Recent evidence suggests that the environment-sensing transcription factor aryl hydrocarbon receptor (AhR) is an important regulator of HSCs. For example, AhR levels decline as HSCs exit quiescence and actively differentiate, and global loss of *Ahr* (AhR KO) results in an increased rate of HSC proliferation. Yet, the mechanism by which AhR regulates HSCs is poorly understood. To better delineate this, HSCs and multipotent progenitor cells (MPPs) from wild-type and AhR KO mice were isolated by FACS and transcriptome analysis (RNA-Seq) was performed. The most significant differences were seen when analyzing the transition from HSC to MPP in wild type (WT) compared to AhR KO mice, which revealed 1336 differentially expressed genes (DEGs). These DEGs included lineage specific markers such as *Gata1*, *Itga2b*, and *Spi1* (PU.1). Further analysis of the 640 upstream regulators associated with this altered gene expression profile revealed 19 unique regulators in AhR KO compared to WT. Absence of AhR also altered 24 genes involved in cell cycle progression, including the known AhR target gene *Cdkn1a* (p21). A novel component identified in this transcriptomic analysis was Aurora A kinase (*AurA*), which was increased in AhR KO compared to WT HSC and MPPs. AurA is required for mitotic entry into G2 and cell cycle progression. Also, we identified 3 putative AhR regulatory elements in the upstream regulatory region of *AurkA,* suggesting it may be controlled directly by AhR. Similar to AhR KO mice, conditional deletion of the *Ahr* from hematopoietic cells increased AurA levels in HSCs and MPPs. Also, *in vivo* AhR antagonism using CH-223191 increased levels of AurA in HSCs and MPPs. Induction of HSC cycling using 5-fluorouracil (5-FU) increased AurA levels in HSCs and all MPP subsets; AhR activation altered this effect of 5-FU on AurA levels in HSCs and the MPP subsets. Overall, these data highlight a potential novel mechanism by which AhR controls HSC homeostasis, by tightly constraining mitotic progression via influencing Aurora A kinase. These findings advance our knowledge of external environmental signals act through the AhR to perturb hematopoietic stem and progenitor cell function.

2523 Daily Ascending Dosing to Mitigate Cytokine Release Syndrome Induced by an Anti-GPC3 T Cell Redirecting Antibody in Cynomolgus Monkeys

J. Taketo, M. Sasaki, Y. Iwata, A. Harada, S. Akai, T. Ishiguro, A. Narita, A. Kaneko, and M. Mishima. *Chugai Pharmaceutical Co. Ltd., Shizuoka, Japan.* Sponsor: J. Taketo, Japanese Society of Toxicology

A CD3 bispecific construct is an emerging measure of cancer immunotherapy, but CD3 bispecific constructs have difficulties in management of adverse effects in clinical use. Cytokine release syndrome (CRS), a potentially life-threatening systemic inflammatory response associated with elevated levels of circulating cytokines, is the most common adverse effect associated with the cancer immunotherapy using this type of constructs. A combination of intra-patient/animal dose escalation and treatment with corticosteroid was reported to reduce CRS, which may be the most effective measure to CRS in the current knowledge. However, this mitigation effect is limited with premedication alone, suggesting that the dosage regimen itself might be a more important factor in reducing CRS. The purpose of this study is to examine how effectively a modified dosing regimen can mitigate CRS. An anti-glypican-3 (GPC3) T-cell redirecting antibody, ERY22, can bind to CD3 and GPC3 in both humans and cynomolgus monkeys. In this study, ERY22 was intravenously administrated to cynomolgus monkeys at the doses of 10 (n=2), 100 (n=1), or 1000 μg/kg (n=1) in single dose administration. In ascending dose administration, ERY22 was intravenously administrated to 2 animals with daily ascending of 1, 3, 10, 30, 100, 300, and 1000 μg/kg during Days 1-7, followed by two shots of 1 mg/kg after one week intervals at Days 14 and 21. Toxicological parameters related to CRS were compared after single or ascending dose with intravenous administration of ERY22. The daily ascending dosing up to 1000 μg/kg markedly reduced the peak cytokine levels as well the clinical severity of CRS whereas single dose with 1000 μg/kg induced severe CRS compared with a single dose of 1,000 μg/kg. Peak cytokine levels following the single and ascending doses were 60,095 pg/mL and 1,221 pg/mL for IL-6; 2,219 pg/mL and 42 pg/mL for IL-2; 353 pg/mL and 14 pg/mL for TNF-α; and 123 pg/mL and 16 pg/mL for IFN-γ. The tolerance acquired with daily ascending doses up to 1,000 μg/kg remained effective for the following weekly doses of 1,000 μg/kg. These results can provide useful information to be extrapolated for human, and will support future applications for CD3 bispecific constructs.

2524 Validation of a 14-Color Flow Cytometry Panel for GLP-Compliant Blood Cell Subpopulation Analyses in the Nonhuman Primate

G. Massonnet, M. Fontaine, P. Singh, M. Carrière, and P. Ancian. *Charles River, Evreux, France.*

Due to the lack of both specific guidelines and adapted standardized cellular quality controls (QC), the validation of a GLP-compliant flow cytometry-based method is a challenging process. Following recommendations from literature and white papers, we developed and validated a 14-color panel (CD3, CD4, CD8, CD20, CD14, CD25, CD69, CD335 + CD159a, CD95, CD28, CD27, CD107a, KI67 and FoxP3) for whole blood from nonhuman primates to be used as a decision making tool within nonclinical toxicology studies. A dual platform approach was applied using a hematology analyzer (ADVIA 2120, Siemens) in combination with a three-laser flow cytometer (MQ16, Miltenyi Biotec) in order to express results in relative (%) and absolute (cells/μL of blood) counts as well as in fluorescence intensity units (MFI) for KI67, CD69 and CD107a. The validation parameters assessed were: precision (intra-, inter-assay), sensitivity (LLOQ), stability [before (BP) and after (AP) process and combined (BP+AP)], robustness (inter-analyst variability) and carryover. Due to cross reactivity between humans and nonhuman primates of the different antibodies, ImmunoTrol cells from Beckman Coulter (stabilized human erythrocytes and leukocytes) were characterized (in terms of acceptance range and stability) in order to be further used as a QC for in-study sample analysis. After optimization (including antibody titration, red blood cell lysis, instrument setting and gating strategy definition), validation results showed that intra- and inter-assay precision values (CV%) ranged from 0.4% to 13.9% and from 0.8% to 26.5%, respectively. LLOQs were determined as up to 30 events for rare subsets (among an average of 220 000 lymphocytes acquired). Stability (expressed as bias % from T_0) was ≤20% for 73, 101, 83 and 73 out of the 120 measured parameters at 4hBP, 6hAP, 24hAP and 4hBP+16hAP, respectively (with a maximum of 148.2%, 32.5%, 50.4% and 93.9%, respectively). There was no significant impact on manual subset gating across two different analysts (CV% ranged from 0.5% to 20.3%). There was no significant inter-sample contamination (≤1%). Despite being unsuitable for intra-nuclear markers, reference ranges for extracellular markers and stability period could be defined for Immuno-Trol. This quasi-quantitative flow cytometry method was thus considered as successfully validated for its intended use in nonclinical GLP studies.

2525 An *In Vivo* PBMC Humanized Mouse Model for Determining Checkpoint and Bispecific Antibody Treatment Related Cytokine Release Syndrome

J. JIAO[1], C. Ye[1], L. Yao[1], D. Cai[1], M. Cheng[1], M. Brehm[2], D. Greiner[2], L. Shultz[3], and J. Keck[1]. *[1]The Jackson Laboratory, Sacramento, CA; [2]University of Massachusetts Medical School, Worcester, MA; and [3]The Jackson Laboratory, Bar harbor, ME.* Sponsor: M. Collinge

Although antibody and CAR-T cell therapies have been successfully used for cancer treatment, they can cause significant adverse effects such as cytokine release syndrome (CRS) in patients. The animal models and *in vitro* human PBMC assays presently in use do not reliably predict the occurrence of CRS in patients unfortunately. This significant gap between pre-clinical testing of novel therapeutics and clinical trials suggests that there is a critical need for translational protocols that could predict immune toxicity more accurately. We have developed a sensitive and reproducible humanized mouse model that can rapidly measure cytokine release *in vivo*. NSG mice and derivative strains were engrafted with human PBMCs for 6 days before being treated with various antibodies including bispecifics, checkpoint inhibitors such as pembrolizumab, avelumab, anti-CD28 and anti-CD3 (OKT3). Cytokine levels in the peripheral blood were determined at 6 hours post dose. The cytokine release detected from this model is both donor-dependent and drug-specific for cytokine and toxicity response. NSG mice lacking murine MHC Class I and Class II provides a useful tool to study CRS in the absence of GvHD. This PBMC humanized mouse model was applied to examine cytokine release from novel bispecific antibodies treatment. A dose- dependent cytokine release was detected from a BCMAxCD3 bispecific antibody in PBMC humanized Mice. Significant higher cytokine release was observed in a high-affinity bispecific antibody compared to cytokine release from a low-affinity bispecific antibody, which was correlated to different mice clinical symptoms and to downstream readouts. In summary, we have developed a novel PBMC humanized mouse model that is capable of differentiating human PBMC donors based on response to human antibody *in vivo*. Our newly developed *in vivo* CRS assay may be used to assess *in vivo* safety of various human therapeutic antibodies including immune checkpoint inhibitors and bispecifics with better reliability than an *in vitro* assay. It may also have potentials for the safety assessment of CAR-T therapy in drug development.

2526 Anandamide Impaired Immune Cell Activation, Induced Apoptosis, Inhibited T Cell Proliferation, and Promoted Induction of MDSCs and T Regulatory Cells following Treatment with Staphylococcus Enterotoxin B (SEB)

M. A. Sultan, P. Nagarkatti, and M. Nagarkatti. *University of South Carolina School of Medicine, Columbia, SC.*

Staphylococcus Enterotoxin B (SEB) produced by *Staphylococcus aureus* causes a wide range of diseases including acute lung injury, multiple organ failure and may be fatal. SEB is a superantigen that activates up to 30% T cells by crosslinking the T cell receptor (TCR) to nonpolymorphic region of MHC class II on antigen presenting cells (APC). SEB is a CDC select agent of bioterrorism. Anandamide (AEA), an endogenous cannabinoid, is part of endocannabinoid system (ECs) and binds to CB1 and CB2 receptors. In the current study, splenocytes were pretreated with AEA (20uM) or vehicle (VEH) and SEB 1ug/ml was used to activate the lymphocytes *in vitro*. Flow cytometric analysis showed that there was a significant decrease in the inflammatory cells including activated immune cells based on expression of biomarkers such as CD69 and CD44 to assess activation in SEB+AEA group when compared to SEB+VEH group. VEH-treated control group showed no activation. In addition, CD4+T cells, CD8+ T cells, Vβ8+ T cells and NK-T cells were also decreased in SEB+AEA group compared to SEB+VEH group. Furthermore, flow cytometry data showed an induction of CD11b+Gr1+ Myeloid Derived Suppressor Cells (MDSCs) and T regulatory cells (CD4+FOXP3+). There was also a significant decrease in the proinflammatory cytokines such as IL2 and IL6 as assessed by ELISA. We next examined the role of AEA in SEB-induced T cell proliferation through the ^{3}H-thymidine incorporation assay and found that there was a significant decrease in the proliferation in SEB+VEH compared to SEB+AEA group. Apoptosis assay was performed wherein we found a significant increase in apoptotic cells in SEB+AEA compared to SEB+ VEH group. In addition, we determined the expression of anti-inflammatory genes by RT-PCR

and found that NOS2, Arg1 and FOXP3 were upregulated that correlated with MDSCs and T regulatory cells in SEB+AEA compared to SEB+VEH group. In summary, AEA plays a protective role against SEB by inducing apoptosis in immune cells, inhibiting T cell proliferation, as well as by promoting anti-inflammatory MDSCs and T regulatory cells. *Supported by NIH grants P01AT003961, P20GM103641, R01ES030144, R01AI129788 and R01AI123947.*

2527 *In Vitro* Differentiation and Characterization of Plasmablasts and Plasma Cells from Cynomolgus Macaque CD20+ B Cells

K. C. Tang[1], N. F. Marx[1], T. C. Vandivort[2], C. Wachtel[2], A. Mauseth[2], K. A. Smith[1], R. E. Guzman[1], G. M. Yanochko[1], and J. R. Piccotti[1]. *[1]Celgene Corporation, San Diego, CA; and [2]Charles River, Reno, NV.*

Assessing biomarkers for B cell targeted therapies in nonclinical studies is hampered by low circulating levels of plasma cells, scarcity of cross-reactive reagents for cynomolgus monkeys, and a general lack of understanding of B cell development in nonhuman primates. We identified conditions to differentiate monkey CD20+ B cells into antibody-producing plasma cells (PCs) with a three-phase culture system beginning with an antigen-independent stimulation of CD20+ B cells by CpG (phase 1) (Huggins et al, 2007), followed by plasmablast expansion (phase 2), and ending with the terminal differentiation of short-lived plasma cells (phase 3). We confirmed differentiation with a combination of morphological, flow cytometry, and immunoglobin (Ig) secretion assays. Cytospins were prepared throughout the time course of differentiation and cell morphology was evaluated after May-Grünwald/Giemsa staining and CD138 immunohistochemical labeling. CD138 positive cells with eccentric nuclei and prominent Golgi apparatus, consistent with features of plasmablasts (PBs) and PCs, were detected from cells in culture by the end of Phase 2. A flow cytometry panel for identification of cynomolgus monkey PBs and PCs was developed using peripheral blood and bone marrow with the commonly used human PC marker of CD138, HLA-DR, and the transcription factor IRF4 (Shaw et al, 2017). Monkey PBs were identified as CD138-/IRF4+/HLA-DR^{high}, while PCs were primarily found to be CD138+/IRF4+/HLA-DR$^{neg/low}$. Using this flow cytometry panel, we were able to show a gradual loss of surface marker CD20 and HLA-DR and a gain of CD138 in the differentiating cells, consistent with the phenotype of cells progressing towards a PC fate (Robillard et al, 2014). Supernatants collected for quantitation of IgG by ELISA at the end of each culture phase had increasing amounts of IgG over the course of the experiment, with maximal IgG production at Phase 3. Cell sorting using the markers on the flow panel, evaluation of additional Ig subsets, and assessment of cytokine production by differentiated single cells via ELISPOT is ongoing. Our results indicate that CD20+ B cells isolated from whole blood of cynomolgus macaques can differentiate into PBs and PCs *in vitro* and that the combination of HLA-DR, IRF4, and CD138 are useful in identifying monkey PBs and PCs.

2528 Translational Investigation of the Intrinsic Immunogenicity of Tolvaptan and Metabolites through the Use of *In Vitro* Cell Culture Platforms

S. Hammond[1], A. Gibson[1], K. Jaruthamsophon[1], S. Roth[2], and D. Naisbitt[1]. *[1]University of Liverpool, Liverpool, United Kingdom; and [2]Otsuka America Pharmaceutical Inc., Rockville, MD.*

Tolvaptan DILI has been of interest since the observation of an imbalance in hepatic safety signals between tolvaptan and placebo in the TEMPO 3:4 (NCT00428948) trial. The clinical pattern of such DILI includes a delayed reaction onset and rapid recurrence of injury upon re-challenge, indicating a role of the adaptive immune system in the manifestation of liver injury [1]. Hence, this study assessed the intrinsic immunogenicity of tolvaptan in healthy donors using *in vitro* T-cell culture platforms and evaluated the translational relevance to (ADPKD) subjects enrolled on the TEMPO 3:4 (NCT00428948) trial whom experienced DILI. Peripheral blood mononuclear cells (PBMC) derived from 3 healthy donors were primed to tolvaptan and 2 major metabolites; DM-4103 and DM-4107. T-cell clones (TCC) from healthy donors exhibited differential cross reactivity profiles between antigens depending on the compound originally primed to. A signature core secretory molecule profile for TCC was identified via ELISpot, with IFN-gamma, IL-13, granzyme B and perforin featuring almost universally upon antigen challenge. CD4+ TCC were found to be HLA-DR restricted with allelic dependence identified. Mechanistically, compound-specific TCC activation was dependent on the presence of soluble drug rather than antigen-pulsed APCs and could occur within 4 hours of antigen exposure. DM-4107-responsive TCC were also identified from PBMC of patients that experienced liver injury, and expressed similar phenotypes to those generated from healthy donors. Tolvaptan DILI may be attributable to an adaptive immune attack upon the liver. Data from this study implicates DM-4107 as a major antigenic determinant, which, alongside the possibly altered disposition of this metabolite under ADPKD disease state, and the greater therapeutic dose for this indication, alludes to why tolvaptan DILI is exclusively observed in this therapeutic indication. [1] Watkins PB, Lewis JH, Kaplowitz N, Alpers DH, Blais JD, Smotzer DM, *et al.* (2015). Clinical Pattern of Tolvaptan-Associated Liver Injury in Subjects with Autosomal Dominant Polycystic Kidney Disease: Analysis of Clinical Trials Database. *Drug Safety.* 38**:** 1103-1113.

2529 The Importance of Dose Metrics in Predicting the Incidence of Percutaneous Immediate-Type Hypersensitivity

K. Yokozeki, T. Yuki, A. Ogasawara, A. Katagiri, Y. Takahashi, and H. Sakaguchi. *Safety Science Research Laboratories, Kao Corporation, Tochigi, Japan.* Sponsor: J. Avalos

For the effective assessment of human health risks, appreciating the dose metrics that is correlated with the incidence of toxicity is necessary. Although the incidence of delayed-type hypersensitivity (skin sensitization) is correlated with antigen dose per unit area, the dose metric which correlates with incidence of percutaneous immediate-type hypersensitivity (antigenicity) remains unclear. Several animal tests were conducted to clarify the dose metrics for predicting the incidence of percutaneous immediate-type hypersensitivity. Papain, which causes immediate-type hypersensitivity via percutaneous sensitization in humans, was used to sensitize guinea pigs. Total dose per animal or dose per unit area was adjusted to understand the conditions that contribute to sensitization. We collected sera from sensitized guinea pigs to perform passive cutaneous anaphylaxis (PCA) and ELISA for papain specific IgG1. To elucidate the underlying mechanism that contribute to the dose metrics for immediate-type hypersensitivity, Alexa488-labeled papain was administered to CBA/J mice in varying total doses per animal or doses per unit area. The number of antigen-bearing B cells (Alexa488+/B220+) in the draining lymph nodes was calculated using flow cytometry. ELISA was performed to quantify papain specific IgG1 and IgE levels in the serum of sensitized mice. In guinea pigs, the PCA test revealed that positive PCA reaction rates did not correlate with dose per unit area but with total dose per animal. Papain-specific IgG1 levels also correlated with total dose per animal. In CBA/J mice, the number of antigen-bearing B cells in the draining lymph nodes and papain-specific antibody (IgG1 and IgE) levels correlated with total dose per animal. The current study demonstrated that the incidence of immediate-type hypersensitivity correlates with the amount of total dosage per animal. Although the process by which antigens activate dendritic cells in the skin is important for delayed-type hypersensitivity, the process by which antigens reach draining lymph nodes to activate B cells is important for immediate-type hypersensitivity.

2530 Comparative Analysis of Nonhuman Primate Plasmacytoid Dendritic Cell Immunophenotyping in Tissue

G. Bondarenko, A. Phadnis-Moghe, P. A. Sims, M. Bockenstedt, S. Webster, A. Frantz, and A. K. Sharma. *Covance Inc., Madison, WI.*

Plasmacytoid dendritic cells (pDC) are one of two main groups of DC described in humans. These antigen-presenting cells are derived from bone marrow precursors and play a key role in regulating immunity through activation of T- and B-lymphocytes, NK cells, and cytokine secretion, thus linking the innate and adaptive immune response. pDC are involved in the antiviral immune response, regulate mucosal immunity and the development of central and peripheral tolerance, and associated with immunopathology of autoimmune and inflammatory diseases. While human myeloid DC (mDC) characterized as HLA-DR+CD11c+CD123-, pDC are HLA-DR+CD11c-CD123+. Non-human primate (NHP) pDC exhibit similar morphology and phenotype to their human counterparts. In humans, pDC are distinguished from mDC by the expression of CD123, CD303 (BDCA-2) and CD304, while CD123 is the only specific marker of pDC available for use in NHP models, due to the lack of cross-reactivity and poor sensitivity of some anti-human antibodies. Since NHPs are one of the main models in drug safety assessment, it is important to identify specific antigens for detection of pDC in tissues in pre-clinical toxicology studies. The goal of this study was to design and develop an immunostaining panel that would allow detection of pDC in NHP tissue through cross-platform comparison of immunophenotyping data obtained by flow cytometry with immunohistochemistry (IHC) and immunofluorescence (IF). Bone marrow and peripheral lymphoid tissue (spleen, tonsil) were collected from naïve cynomolgus monkeys (*Macaca fascicularis*). Immunophenotyping of unfixed tissue leukocytes was performed by flow cytometry and IHC and IF were completed on formalin-fixed paraffin-embedded tissue sections from the same animal. Results demonstrated that CD303 can be used as a specific

marker for pDC detection in NHP tissues by IHC and IF. While CD123 is still one of the critical antigens for identifying pDC via flow cytometry, its expression on endothelial cells makes it a less favorable marker for histopathological evaluation using IHC or IF. Data showed a direct correlation of pDC tissue distribution when measured via flow cytometry and IHC. As pDC constitute ≤ 1% of CD45+ lymphocytes in tissues, results indicate lower pDC proportions in spleen and tonsils compared with bone marrow. Taken together, these results provide a valuable approach for using a specific panel of antibodies for pDC immunophenotyping in tissue sections.

PS 2531 Identification of the Dog Orthologue of Human MAS-Related G Protein Coupled Receptor X2 (MRGPRX2) Essential for Drug-Induced Pseudo-Allergic Reactions

E. Hamamura-Yasuno, J. Matsushita, S. Tamai, T. Iguchi, N. Niino, K. Kumagai, Y. Tsuchiya, and K. Mori. *Daiichi Sankyo Company Limited, Tokyo, Japan.*

MAS-related G protein coupled receptor-X2 (MRGPRX2) is a Gi or Gq-coupled receptor expressed in human mast cells and associated with drug-induced pseudo-allergic reactions. Dogs have been reported to be highly susceptible to the drug-induced anaphylactic reactions caused by various agents including fluoroquinolones; however, the distribution and its physiological function of dog MRGPR families including MRGPRX2 remains largely unknown. In the present study, we clarified the distribution of dog MRGPR family genes (X2, D, F, and G) in total of 21 organs/tissues from male dogs (n = 3) including lung and skin by a quantitative PCR method. We also investigated the stimulatory effects of compound 48/80 and several fluoroquinolones (ciprofloxacin [CPFX], gatifloxacin [GFLX], levofloxacin [LVFX], and pazufloxacin [PZFX]) on HEK293 cells transiently transfected dog MRGPR family genes or human MRGPRX2 to identify the physiological function of dog MRGPR family genes by intracellular Ca^{2+} mobilization assay. Amino acid sequence homology of dog MRGPRX2, D, F, or G to human MRGPRX2 was 62, 41, 38, or 32%, respectively. Dog MRGPRX2 and MRGPRG were distributed in the limited organs/tissues including skin and eyelid, whereas MRGPRD and MRGPRF were extensively expressed in almost all organs/tissues examined. Intracellular Ca^{2+} mobilization assay demonstrated that HEK293 cells expressing dog MRGPRX2 or human MRGPRX2, but not dog MRGPRD, MRGPRF and MRGPRG, responded to compound 48/80, CPFX, GFLX, and LVFX. Interestingly, the concentration of compound 48/80 inducing intracellular calcium changes in dog MRGPRX2-expressing cells was comparable to that in human MRGPRX2-expressing cells. In contrast, the concentrations of CPFX, GFLX, and LVFX inducing intracellular calcium changes in dog MRGPRX2-expressing cells were 3- to 27-fold lower than those in human MRGPRX2-expressing cells. The results indicate the functional heterogeneity of dog MRGPRX2 to various histamine releasing agents. PZFX which is known not to induce histamine release in dogs did not change intracellular calcium in dog MRGPRX2- and human MRGPRX2-expressing cells. The present results suggest that dog MRGPRX2 is the functional orthologue of human MRGPRX2 and plays an essential role for drug-induced anaphylactic reactions in dogs.

PS 2532 Host Cell Proteins Induce Inflammation and Immunogenicity as Adjuvants in an Integrated Analysis of *In Vivo* and *In Vitro* Assay Systems

K. Yasuno, E. Hamamura-Yasuno, K. Ishikawa, K. Fujita, D. Nishimiya, M. Soma, M. Imaoka, K. Kai, and K. Mori. *Daiichi Sankyo Company Limited, Tokyo, Japan.*

Host cell proteins (HCPs) are contaminated proteins remaining after purification of biopharmaceuticals. Recent reports revealed clinical implications of HCPs in anti-drug antibody (ADA) development in patients without any inflammatory effects. During preclinical development of an intravitreal biopharmaceutical, we observed ocular inflammation in rabbits which may have been associated with the contamination by HCPs. Therefore, we evaluated the inflammatory effects and immunogenicity of HCPs in an *in vivo* study by intravitreal administration to rabbits and an *in vitro* THP-1 cells assay. *Escherichia coli* HCP antigen concentrate used for the positive control of the *E. coli* Host Cell Protein ELISA Kit was used as HCPs in this study. HCPs at 200 ng/eye with or without the commercial intravitreal biopharmaceutical, ranibizumab at 0.25 mg/eye were administrated intravitreally to rabbits. For *in vitro* examination, differentiated THP-1 cells were stimulated with HCPs at 0.17 to 10.88 μg/mL with or without ranibizumab at 0.2 mg/mL. As a result, co-administration of HCPs and ranibizumab induced ocular inflammation which was characterized histopathologically by mononuclear cell infiltration in the vitreous body, ciliary body, iris, choroid, and perivascular space of the optic disc. Furthermore, ADA was detected in the vitreous fluid by co-administration of HCPs with ranibizumab in rabbits, but not by HCPs alone. The immunostimulatory effects including increases in inflammatory cytokine secretion (IL-1β, IL-8, and MIP-1β) and upregulation of cell surface markers (CD80 and CD54) involved in antigen presentation were also detected in the THP-1 cells assay, and these reactions were enhanced by co-stimulation with ranibizumab. In conclusion, the present study firstly revealed that HCPs induce inflammation and immunogenicity as adjuvants when they are co-treated with biopharmaceuticals in both *in vivo* and *in vitro* systems. This study provides useful data for risk assessment of HCPs and for discussion of local inflammation induced by biopharmaceuticals. Integrated analyses by *in vivo* rabbit models and *in vitro* assay systems using THP-1 cells would be useful to evaluate the immunological risk of HCPs.

PS 2533 Sex Steroid Hormones and Macrophage Phenotype in Nanoparticle-Induced Lung Inflammation

J. L. Ray, and A. Holian. *University of Montana, Missoula, MT.*

Respiratory diseases such as asthma and COPD occur more frequently in women compared to men, yet the mechanisms behind this sex-bias are unknown. Our laboratory has reported that this bias also occurs in a murine model of multi-walled carbon nanotube (MWCNT)-induced lung injury. MWCNT-treated female mice develop greater innate lymphoid cell-independent acute type 2 inflammation including eosinophilia, cytokine expression, and airway hyper-reactivity (AhR) compared to male mice. This increased acute inflammation precedes worse chronic lung pathology with greater epithelial cell hyperplasia and centriacinar MWCNT accumulation in females. Therefore, we hypothesize that sex-steroid hormones, specifically estrogen receptor alpha (ERα) signaling, promotes an exaggerated M2a phenotype in alveolar macrophages (AMs) and subsequent type 2 inflammation in MWCNT-exposed females. Two mouse models were used to test this hypothesis. First, in order to eliminate the majority of sex-steroid hormone production, female C57BL/6 mice were allowed to develop normally and then ovariectomized (OVX) at 8 weeks of age. Second, intact female mice were implanted with osmotic pumps containing an ERα antagonist to specifically block endogenous ERα signaling. OVX and antagonist-treated mice were then exposed to MWCNTs via oropharyngeal aspiration (2 mg/kg body weight) and sacrificed 7 days later. Lung lavage fluid (LLF) was collected for high-sensitivity cytokine measurement and flow cytometry analysis of immune cell recruitment. AMs were isolated from the LLF by adherence and phenotype was determined by 24-hour *ex vivo* culture and measurement of cytokines released. The AM-specific cytokine profile was compared to that of the LLF and used to determine functional AM phenotype and inflammatory signaling. Pulmonary function outcomes were also determined through lung resistance and dynamic compliance measurements. Results from OVX and antagonist-treated mice will be compared to that of normal, intact females; changes in immune cell recruitment, cytokine expression, AM phenotype, and AhR to define the role of sex-steroid hormones in particle-mediated inflammation and the mechanism of female-biases in lung disease.

PS 2534 Ethanol Dysregulates Chondrocyte Differentiation via Different Sources of Reactive Oxygen Species in Chondrocyte ATDC5 Cells

J. Lewis[1], J. Watt[2], and M. Ronis[2]. *[1]University of New Orleans, New Orleans, LA; and [2]Louisiana State University Health Sciences Center, New Orleans, LA.*

Alcohol abuse is a well-known risk factor for osteoporosis. Skeletal toxicity associated with ethanol (EtOH) exposure is characterized by oxidative stress mediated suppression of bone formation, stimulation of bone resorption and dysregulation of chrondrocyte differentiation in the growth plate resulting in shorter osteopenic long bones. EtOH can produce reactive oxygen species (ROS) as the result of several different pathways including CYP2E1, NADPH oxidases (NOX) and secondary to mitochondrial injury. However, endogenous ROS signaling may also play an important role in normal bone cell differentiation. The current study was designed to examine the effects of EtOH (0/25/50 mM) in the presence or absence of the dietary antioxidant and glutathione precursor N-acetylcysteine (NAC) (0.1/1 mM); the mitochondria targeted antioxidants MitoQ and MitoTEMPO (50/500 nM) or the NOX4 inhibitor GKT137831 (0.1/1 μM) on *in vitro* differentiation, cartilage formation and mineralization in the embryonic chondrocytic rat ATCD5 stem cell line. ATCD5 cells were grown to confluence and exposed to chondroblastogenic medium for 12-14 d to assess cartilage formation by Alcian blue staining and aggrecan (Acan) mRNA expression of mRNAs encloding Col2a1 and Col10a1 as indicators of chondrocyte differentiation. EtOH suppressed chondroblastogenesis and cartilage formation dose-dependently ($P<0.05$). However, this process

was unaffected by GKT137831. Moreover, high doses of mitochondrial ROS inhibitors and NAC inhibited this process in the absence of EtOH. In contrast, assessment of mineralization by Alizarin Red staining at 16 d revealed EtOH dose-dependently stimulated this process ($P<0.05$). MitoQ and MitoTEMPO appear to block EtOH effects on mineralization but NAC exacerbated EtOH effects. These data suggest EtOH dysreguates chondroblastogenesis while stimulating mineralization of embryonic chondrocytic cells processes consistent with dysregulation of bone growth plate formation *in vivo*. EtOH effects on chondrocyte differentiation appear ROS independent and endogenous ROS signaling appear to regulate this process. In contrast EtOH-stimulated mitochondrial ROS appears to play a role in stimulation of mineralization. *Supported in part by NIAAA R37 AA018282 (M.J.R.) and NSF grant #1659752.*

2535 Role of NOX4 Expression in Osteoblast-Precursors in the Development of Alcohol-Induced Osteopenia

A. C. Robertson[1], M. L. Osborn[2], J. Watt[3], K. Pedersen[3], and M. J. Ronis[3]. *[1]Meharry Medical College School of Medicine, Nashville, TN; [2]Louisiana State University School of Veterinary Medicine, Baton Rouge, LA; and [3]Louisiana State University Health Sciences Center, New Orleans, LA.*

Alcohol abuse is a well-known risk factor for skeletal toxicity and the development of osteoporosis. Ethanol (EtOH) has been demonstrated to inhibit bone formation and stimulate bone resorption. However, the molecular mechanisms underlying alcohol-induced osteopenia remain the subject of active investigation. Whole-body knockout of NOX4 in mice has demonstrated that reactive oxygen species (ROS) signaling via the NADPH oxidase enzyme NOX4 appears to play a role in regulation of endogenous bone turnover and EtOH actions. To establish whether NOX4 expressed locally in osteoblast precursors mediate these effects, we have generated pre-osteoblast-specific Prx-Cre-Lox NOX4 conditional knockout mice where the enzyme is oblated specifically in osteoblast precursor cells in long bones and exposed male and female Cre-Lox and NOX4 fl/fl mice to a high fat Leiber-DiCarli liquid diet with or without replacement of up to 28% of food calories with EtOH for 90 days. The hypothesis is that ROS produced in these cells by NOX4 play a significant role in the development of alcohol-induced osteopenia. To test this, the effects of EtOH were determined on bone microstructure of tibias and by femur shaft mRNA expression. In the cortical region of the tibia, the Prx-NOX4 Cre-Lox mice had overall decreased bone area ($p = 0.038$). In mice with the EtOH diet, there was a decrease in bone area and cortical thickness ($p < 0.001$ & $p=0.001$, respectively) independent of genotype. Results from femur shaft mRNA confirms that mRNA NOX4 expression is decreased by more than 95% in Prx-NOX4 Cre-Lox mice ($p < 0.001$) while RANKL, which controls bone reabsorption, is not affected by EtOH or NOX4 in this model. These data demonstrate that while the bone microstructure differs between males and females, EtOH and NOX4 independently affect the cortical bone region. *Supported in part by NIH NIAAA R37 AA018282 (MJR) and LSUHSC Department of Genetics.*

2536 Nrf2 and CSE as Critical Molecules in Parallel Pathways for Repression of Xenobiotic-Mediated Electrophilic Stress in Mice

T. Unoki[1], M. Akiyama[2], Y. Shinkai[2], and Y. Kumagai[2]. *[1]National Institute for Minamata Disease, Ministry of the Environment, Minamata, Japan; and [2]University of Tsukuba, Tsukuba, Japan.*

Transcription factor NF-E2-related factor 2 (Nrf2) plays a key role in detoxification of electrophiles via formation of glutathione adducts and subsequent excretion into extracellular spaces. We found that reactive sulfur species, such as cysteine persulfides produced by cystathionine γ-lyase (CSE), capture environmental electrophiles through formation of sulfur adducts. However, contributions of Nrf2 and CSE to the blockage of environmental electrophile-mediated toxicity remain to be evaluated. The aim of this study was to clarify roles that CSE and Nrf2 play in the protection against various environmental electrophiles. We also wished to clarify the molecular basis of the developmental window of toxicity through investigating expression levels of Nrf2, reactive sulfur species-producing enzymes and sulfur nucleophiles during developmental stages of mice. Methods: Wild-type, CSE knockout (KO), Nrf2 KO, Nrf2/CSE double KO (DKO) mice, and their primary hepatocytes were analyzed in this study. Methylmercury (MeHg), Cadmium, 1,4-naphthoquinone, crotonaldehyde, and acrylamide were used. We conducted Western-blotting, real-time PCR, MTT assays, LC-ESI-MS/MS analysis, ALT activity, histopathological analysis, and rotarod test. Primary hepatocytes from DKO mice were significantly more sensitive to the environmental electrophiles than each single KO counterpart. Both Nrf2 and CSE single KO mice were highly susceptible to MeHg and cadmium, and such sensitivity was further exacerbated in the DKO mice. Lower level expressions of CSE and sulfur nucleophiles than those in adult mice were observed in a window of developmental stage. Our mouse model provided new insights into the response to environmental electrophiles; while Nrf2 is recognized as a key transcription factor for detoxification of environmental electrophiles, CSE is crucial factor to repress their toxicity in a parallel mode. In addition, the sensitivity of fetuses to MeHg appears to be, at least in part, associated with the restricted production of reactive sulfur species due to low-level expression of CSE.

2537 Nrf2 Deficiency Ameliorates Thioacetamide-Induced Liver Injury in Mice via Accelerating Degradation of CYP2E1

R. Wu, B. Lou, Y. Hu, H. Wang, J. Fu, J. Pi, and Y. Xu. *China Medical University, Shenyang, China.*

Nrf2 is a master transcription factor in anti-oxidative and anti-electrophilic stress, with controversial reports on its role in chemical toxicity. In the present study, we investigated the role of Nrf2 in thioacetamide (TAA)-induced hepatoxicity and underlying mechanisms. Male *Nrf2*-knockout (*Nrf2*-KO) and *Nrf2*-wild-type (WT) mice were intraperitoneally administrated with TAA subacutely with escalating dosing regimen (30, 100, 200, 300 mg/kg, 5 weeks) or acutely (one injection of lethal dose 50 mg/kg or non-lethal dose 30 mg/kg). In subacute experiment, *Nrf2*-KO mice were resistant to TAA-induced liver fibrosis according to sirrus red staining, collagen deposition and expression of fibrosis markers. *Nrf2*-KO mice showed a higher survival rate than WT mice in response to the lethal dose of TAA. Acute liver injury characterized by histological analysis, and serum levels of alanine aminotransferase and aspartate aminotransferase, was ameliorated in *Nrf2*-KO mice compared with WT mice. Hepatic mRNA levels of *Gclc*, *Nqo1* and *Cyp2a5* were lower, while the content of malondialdehyde was higher in *Nrf2*-KO mice than WT mice after acute or subacute TAA treatment. Proportion of oxidized TAA metabolites in the urine and expression of TAA metabolic marker acetyllysine were significantly lower in *Nrf2*-KO mice than WT mice after acute TAA administration. *Nrf2* deficiency aggravated TAA-induced decrease in hepatic CYP2E1 protein levels. In addition, CYP2E1 protein levels were significantly lower, while the intracellular levels reactive oxygen species were significantly higher, in *Nrf2*-KO primary mouse hepatocytes than WT hepatocytes with TAA treatment (20 mM, within 12 h). Protein degradation of CYP2E1 was accelerated in Nrf2-KO hepatocytes. Our findings suggest that *Nrf2* deficiency prevents from TAA-induced liver injury by abrogating CYP2E1-mediated metabolic bioactivation. Oxidative stress resulting from *Nrf2* deficiency may impair protein stability of CYPTE1. This finding has significant implications in toxicity of chemicals that are bioactivated by CYP2E1.

2538 Imaging-Based Single Cell Dynamics of KEAP1/Nrf2 Pathway Activation Status to Quantify Pro-Oxidant-Induced Cell Fate Decisions

J. P. Schimming, B. ter Braak, and B. van de Water. *Universiteit Leiden, Leiden, Netherlands.*

A common mode of action (MoA) involved in drug induced liver injury (DILI) are the formation of reactive oxygen species and radical metabolites. This is exemplified by drugs causing intrinsic DILI like acetaminophen but is also suspected to occur with drugs causing idiosyncratic DILI. The Nuclear factor erythroid 2-related factor 2 (Nrf2) pathway is essential for the cellular defence against such cell damage by orchestrating the oxidative stress response (OSR), i.e. by activation of glutathione synthesis, the thioredoxin system and sulfiredoxines. We want to better understand the dynamics and amplitude of the Nrf2 pathway activation in drug induced liver injury as it may give insights for the liver toxicity liability of chemicals. Here we present a novel approach that allows the assessment of the interplay between the activation of the Nrf2 pathway and cell fate decisions (adaptive vs adverse response). Thus, we created a dual-color HepG2 fluorescence reporter cell line (Nrf2-GFP and Srxn1-mScarlet) to follow the translocation of the transcription factor Nrf2 to the nucleus and the subsequent activation of the transcriptional response by sulfiredoxin 1 (SRXN1) on a single cell level. Through single cell tracking we followed the cellular response upon the exposure to a set of compounds inducing oxidative stress and radical formation. Furthermore, through the preexposure to the Nrf2 activator Bardoxolone methyl (CDDO-me) and the L-buthionine sulfoximine (BSO), an effective inhibitor of glutathione synthetase, we simulated pre-activated state or inhibited state of the OSR. A siRNA knock allowed the biological simulation of the inhibition and activation of the OSR. The dynamical patterns found in the cells under the various condition allowed to judge when an exposure to a compound becomes critical for a cell and subsequently lead to an adverse outcome if correctly extrapolated to the *in vivo* situation. This detailed characterization of compounds might add great value towards the correct prediction of DILI potential *in vitro* and if integrated with other MoA driven test systems to an alternative to preclinical

safety testing *in vivo*. *This work was part of the EU-ToxRisk project and received funding of the European Union's Horizon 2020 research and innovation program under grant agreement No 681002.*

2539 Glutathione Depletion and Nrf2 Activation Underlie PFOS Toxicity in Human Kidney Cells

E. G. Severance, A. Rastogi, M. J. Young, and A. R. Timme-Laragy. *University of Massachusetts Amherst, Amherst, MA.*

Perfluorooctanesulfonic acid (PFOS), a persistent xenobiotic historically found in firefighting foams and various consumer products, is known to activate Nuclear Factor(erythroid-derived) like factor 2 (Nrf2), a transcription factor that regulates cellular antioxidant defense genes. Nrf2 activation is also hypothesized to be mediated by glutathione (GSH), the predominant cellular redox buffer. We interrogated whether PFOS activates Nrf2 by inducing reactive oxygen species (ROS) or via GSH depletion. We used a DCF assay to quantify ROS levels and a human Nrf2-GFP fusion protein to visualize Nrf2 dynamics in live Human Embryonic Kidney (HEK293T) cells. This noncancerous cell line conserves Nrf2 signaling in human kidney, a known PFOS target organ. Exposure to model prooxidant and ROS 50 μM tert-butyl hydroperoxide (tBOOH) significantly increased ROS levels at 0.25 and 1 hour. Cells exposed to PFOS showed significantly increased ROS production at 24 hours; 3.2, 6.4, and 64 μM PFOS elicited the greatest changes (n=3 independent experiments). A 24 hour pre-exposure to 100 μM N-Acetyl Cysteine, which bolsters cellular GSH levels, rescued these changes; cells showed decreasing trends in ROS levels starting as early as 1 hour at all concentrations of PFOS. Next, we used time lapse fluorescent microscopy to investigate the effects of these redox disruptions on Nrf2 localization. A 20 minute exposure to tBOOH was sufficient to significantly increase nuclear Nrf2 expression whereas 10 μM tBHQ, a quinone that activates Nrf2, did not significantly increase in nuclear Nrf2 until at least 3 hours. At 9 hours following PFOS exposure, 6.4, 32 and 64 μM PFOS induced a 25% increase in nuclear localization of Nrf2. This change was largely due to a 40% increase in *de novo* expression of nuclear Nrf2 (n= 2 replicates). Next, we assessed the viability of PFOS exposed cells using a Trypan Blue Exclusion Assay. All doses of PFOS induced significantly greater cell death than DMSO controls with 32 μM PFOS inducing 25% more cell mortality (n= 2 independent experiments). Our data indicate that multiple doses of PFOS lead to secondary oxidative stress via GSH depletion. These data indicate GSH depletion induces Nrf2 nuclear translocation, a potential mechanism underlying PFOS toxicity. *This work was supported by R01ES025748.*

2540 Administration of a Pharmacologic Iron Chelator Reduces the Development of Cartilage Lesions in a Model of Idiopathic Osteoarthritis

L. H. Burton, L. B. Radakovich, M. F. Afzali, M. A. Campbell, L. A. Culver, A. J. Marolf, and K. S. Santangelo. *Colorado State University, Fort Collins, CO.*

Iron is a mineral required for numerous biological processes. While crucial for sustaining life, iron also has the potential to promote tissue damage by participating in reactions that generate free radicals. Despite this, there are no direct iron excretion mechanisms beyond normal turnover of skin and gastrointestinal epithelial cells. Indeed, iron has been implicated in several aging-associated disorders, including neurodegenerative disorders and some types of cancers. While iron has been characterized in these conditions, its role in age-related/primary osteoarthritis (OA) remains relatively unexplored. As the leading cause of adult disability in the United States, OA causes pain, swelling, and overall decreased mobility of affected joints. Unfortunately, the underlying mechanisms driving disease pathogenesis remain poorly understood, and there are currently no treatments available to slow OA once it has started. We hypothesize that iron accumulation in joint tissues throughout aging may contribute to the development of primary OA. Here, we assess the ability of systemic iron reduction—achieved by administration of the pharmacologic chelator deferoxamine (DFO) - to prevent or delay the onset and/or progression of primary OA in an animal model of the disease. All procedures were approved by the University's Institutional Animal Care and Use Committee. Three-month-old male Dunkin-Hartley guinea pigs were randomly assigned to receive either 46 mg/kg of DFO or vehicle control twice daily (n=8 per group). Animals were subjected to open field behavior monitoring once per month throughout the study, with baseline activity levels collected prior to initiating treatment. The study was terminated when animals were 8-months-old, and hind limbs were collected for structural and gene expression analysis of knee joints. Collectively, our results indicate that decreasing systemic iron levels via pharmacologic iron chelation may prevent cartilage deterioration by beneficially modulating local iron levels within the knee. Gene expression analysis showed that treatment with DFO decreased oxidant damage and apoptosis, which maintained the mobility of these animals relative to control. Results from this study indicate that iron may be involved in OA pathogenesis and that use of a pharmacologic iron chelator could hold potential as an intervention for this disease process.

2541 Metabolome-Wide Association Study (MWAS) of Plasma Cystine in Healthy Aging Men

Y. Go, Z. Jarrell, and D. P. Jones. *Emory University, Atlanta, GA.*

Cystine (CySS) is an oxidized form of cysteine, abundant in plasma and having different distribution in males and females. Plasma CySS is a measure of oxidative stress and increases with age, but the mechanistic basis is unknown. We hypothesized that if environmental exposures causing oxidative stress in men contribute to increased CySS concentrations with age, a metabolome-wide association study of age should reveal environmental chemical associations with CySS. Perform metabolome-wide association study (MWAS) of plasma CySS in healthy aging men to test for association of environmental chemicals with CySS. Methods: Plasma from 70 men (21 to 90 y; mean, 44.9 y) and without known disease (PRE-MED cohort; NCT00336570) was used. Plasma CySS was quantified by HPLC (mean, 69.2 μM). High-resolution metabolomics of plasma was used for relative quantification of environmental chemicals and metabolites. Samples were analyzed by LC-HRMS with +ESI on C18; data were extracted by apLCMS and xMSanalyzer and log-transformed prior to biostatistics and bioinformatics. Metabolome correlations with CySS and age were performed by xMWAS using Spearman correlation ($r > 0.25$, $P < 0.05$). xMSannotator with HMDB and KEGG was used for metabolome annotation and with the Toxin and Toxin-Target DataBase (T3DB) for environmental chemical annotation. The results showed 183 metabolites positively associated with CySS and 360 positively associated with age ($r > 0.25$, $P < 0.05$). Twenty metabolites including phospholipids and fatty acids were positively associated with both CySS and age. Of those associated with CySS, 19 matched environmental chemicals. These include herbicides, pesticides and insecticides. Of metabolites associated with age, 43 matched environmental chemicals. Correlation of a general herbicide including MCPP (methylchlorophenoxypropionate) and asulam with age was relatively high ($r > 0.4$). The results show that environmental chemicals associate with plasma CySS in healthy aging men. The numbers of environmental chemicals associated with age were greater in men than women. The results indicate that cumulative environmental exposures or decline in elimination of environmental chemicals could contribute to increased oxidative stress with age.

2542 Impact of Sex, Age, and Diet on the Cysteine/Cystine and Glutathione/Glutathione Disulfide Plasma Redox Couples in Mice

W. H. Watson[1], J. C. Greenwell[1], Y. Zheng[1], E. Torres-Gonzalez[2], J. Ritzenthaler[2], and J. Roman[2]. *[1]University of Louisville, Louisville, KY; and [2]Thomas Jefferson University, Philadelphia, PA.*

Age, sex and diet are well-established risk factors for several diseases. In humans, each of these variables has been linked to differences in plasma redox potentials (E_h) of the glutathione/glutathione disulfide (GSH/GSSG) and cysteine/cystine (Cys/CySS) redox couples. Mice have been very useful for modeling human disease processes, but it is unknown if age, sex and diet affect redox couples in mice as they do in humans. The purpose of the present study was to examine the effects of these risk factors on plasma redox potentials in C57BL/6J mice. We found that age had no effect on either redox couple in either sex. Plasma E_h Cys/CySS and E_h GSH/GSSG were both more oxidized (more positive) in females than in males. A 24-hour fast negated the sex differences in both redox potentials by oxidizing both redox couples in male mice, while having no effect on E_h Cys/CySS and a smaller effect on E_h GSH/GSSG in female mice. A diet with excess sulfur amino acids reduced the plasma E_h Cys/CySS in females to a level comparable to that seen in male mice. Thus, sex-specific differences in plasma E_h Cys/CySS could be normalized by two different dietary interventions. Some of these findings are consistent with what has been reported for human plasma redox potentials, while others are not. Most strikingly, mice do not exhibit the same age-dependent oxidation of the plasma redox potentials studied. Also, whereas both species have sex differences in E_h Cys/CySS, female humans are more reduced, while female mice are more oxidized than their male counterparts. Care must be taken when designing and interpreting mouse studies to investigate redox regulation in humans.

2543 Metabolome-Wide Association Study (MWAS) of Plasma Cystine in Healthy Aging Women

D. P. Jones[1], Z. Jarrell[1], and Y. G. Go[2]. *[1]Emory University, Atlanta, GA; and [2]Emory University, Lilburn, GA.*

Cystine (CySS) is an oxidized form of cysteine, abundant in plasma and having different distribution in males and females. Plasma CySS is a measure of oxidative stress and increases with age, but the mechanistic basis is unknown. We hypothesized that if environmental exposures causing oxidative stress in women contribute to increased CySS concentrations with age, a metabolome-wide association study of age should reveal environmental chemical associations with CySS. Aim: Perform metabolome-wide association study (MWAS) of plasma CySS in healthy aging women to test for association of environmental chemicals with CySS. Plasma from 65 women (20 to 62 y; mean, 42.6 y) and without known disease (PRE-MED cohort; NCT00336570) was used. Plasma CySS was quantified by HPLC (mean, 68.9 μM). High-resolution metabolomics of plasma was used for relative quantification of environmental chemicals and metabolites. Samples were analyzed by LC-HRMS with +ESI on C18; data were extracted by apLCMS and xMSanalyzer and log-transformed prior to biostatistics and bioinformatics. Metabolome correlations with CySS and age were performed by xMWAS using Spearman correlation ($r > 0.25$, $P < 0.05$). xMSannotator with HMDB and KEGG was used for metabolome annotation and with the Toxin and Toxin-Target DataBase (T3DB) for environmental chemical annotation. The results showed 265 metabolites positively associated with CySS and 285 positively associated with age ($r > 0.25$, $P < 0.05$). Of those associated with CySS, 30 matched environmental chemicals. A relatively high correlation with CySS was observed for phenol compounds (chloro-, nitro-, dinitrophenols) and lactofen ($r > 0.4$). Of metabolites associated with age, 23 matched environmental chemicals. Correlation of benzofuran compounds with age was relatively high ($r > 0.3$). The results show that environmental chemicals associate with plasma CySS in healthy aging women. The results indicate that cumulative environmental exposures or decline in elimination of environmental chemicals could contribute to increased oxidative stress with age.

2544 Rapid and Sensitive Mass Spectrometry Method for Simultaneous Quantification of Intracellular Reduced and Oxidized Glutathione

Q. Wu, R. Xiong, Y. Wang, X. Cao, and M. S. Bryant. *US FDA/NCTR, Jefferson, AR.*

Reduced glutathione (GSH) plays a key role in the protection of cellular components from damage caused by reactive oxygen species. The ratio of GSH to oxidized glutathione (GSSG) is an important marker for oxidative stress. It is a challenge to quantify precisely the concentrations of GSH and GSSG in biological samples because of the artificial oxidation of GSH during sample preparation and the low levels of GSSG. We have developed a sensitive and rapid mass spectrometry method for the simultaneous determination of GSH and GSSG in cultured cells. Free GSH was stabilized by the S-carbamidomethylation with iodoacetamide during sample processing. GSH and GSSG were analyzed using a Waters UPLC System coupled with a Waters ACQUITY QDa mass detector in the positive ion mode (ESI+) with a run time of 3 minutes. The limit of detections for GSH and GSSG were 4.66 and 1.14 ng/ml, respectively. The LC-MS method was validated following FDA Reviewer Guidance Validation of Chromatographic Methods. Linear calibration curves were obtained ranging from 0.625 μg/ml to 40 μg/ml with a R^2 of 0.999 for GSH and 1.25 ng/ml to 40 ng/ml with a R^2 of 0.998 for GSSG. This rapid and sensitive method has been applied successfully to measure the glutathione redox status in human hepatoma HepG2 cells, undifferentiated normal human primary bronchial epithelial cells and a differentiated human air-liquid-interface airway tissue model.

2545 The Long Noncoding RNA MALAT1 Regulates Oxidative Stress: Mechanism and Therapeutic Application for Multiple Diseases

J. Chen, S. Ke, J. J. Cai, J. Welsh, and Y. Tian. *Texas A&M University, College Station, TX.*

The metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) is a long noncoding RNA and its overexpression is associated with the development of many types of malignancy. It is an evolutionarily highly conserved RNA with high level of expression in various tissues and cell types. MALAT1 null mice show no overt phenotype under normal laboratory conditions. However, in transcriptome analysis of MALAT1 null mice we found significant upregulation of nuclear factor-erythroid 2 p45-related factor 2 (Nrf2) regulated antioxidant genes including Nqo1 and Cat with significant reduction in reactive oxygen species (ROS) in hepatocyte and pancreas. We performed lncRNA pulldown assay using biotinylated antisense oligonucleotides against MALAT1 and found MALAT1 interacted with Nrf2, suggesting Nrf2 is transcriptionally regulated by MALAT1. Exposure to excessive ROS has been shown to cause insulin resistance through activation of c-Jun N-terminal kinase (JNK) which leads to inhibition of insulin receptor substrate 1 (IRS-1) and insulin-induced phosphorylation of serine/threonine kinase Akt. We found MALAT1 ablation suppressed JNK activity with concomitant insulin-induced activation of IRS-1 and phosphorylation of Akt suggesting MALAT1 regulated insulin responses. MALAT1 null mice exhibited sensitized insulin-signaling response to glucose/insulin challenges and significantly increased insulin secretion in isolated MALAT1 null islets, suggesting an increased insulin sensitivity. Furthermore, we established two mutually supporting mouse T2DM model, high fat diet (HFD) and *ob/ob* model and investigated the role of MALAT1 in regulating the insulin signaling pathway and pancreatic β cell function in these two T2DM model. Consistent with our previous results, MALAT1 ablation alleviate the obesity-induced T2DM in *ob/ob* mice. With reduced ROS, MALAT1 null mice showed reduced lipopolysaccharide (LPS)-induced cytokines, suppressed NF-kB and NLRP3 inflammasome signaling pathway, alleviated inflammatory response, and in fact, MALAT1 null mice became resistant to septic shock in the LPS and cecum ligated punctuation (CLP)-induced septic shock mouse models. Our results showed that MALAT1 plays a pivotal role in the crosstalk between Nrf2-regulated detoxification pathway and the oxidative stress related diseases including T2D and proinflammatory response, suggesting ROS homeostasis is a point of convergence of the interactions between MALAT1-Nrf2 axis, and this axis could be a therapeutic target for treating insulin resistance, glucose dysregulation, LPS-induced inflammation and others diseases caused by excessive exposure to ROS.

2546 Differential Temporal Effects of Hyperoxia and Vitamin A on Gene Expression Profiling in Lungs of Newborn Rats: Implications for Bronchopulmonary Dysplasia (BPD)

X. I. Couroucli, W. Jiang, K. Lingappan, C. Coarfa, and B. Moorthy. *Baylor College of Medicine, Houston, TX.*

Supplemental oxygen is administered to premature infants having pulmonary insufficiency. However, hyperoxia contributes to the development of BPD in these infants. The molecular mechanisms of abnormal lung development observed in BPD patients are not completely understood. Vitamin A is a promising treatment regimen that might mitigate the negative long-term effects of hyperoxia exposure. In this study, we tested the hypothesis that exposure of newborn rats to hyperoxia for 7 days, followed by normoxia for another 15 days, will lead to differential temporal alterations in gene expression in pathways that are relevant to oxidative stress and abnormal lung development. We also assessed the effect of Vitamin A treatment in this phenomenon. Newborn Fisher 344 rats were exposed to hyperoxia (95%) or room air from postnatal day (PND) 1 to 8, and animals were either sacrificed on PND 8, or were returned to normoxia and were sacrificed at PND 22. Within each rearing condition, half of the pups were assigned to receive daily intraperitoneal (IP) injections from P1-P5 of either 2 mg/kg vitamin A dissolved in corn-oil, or vehicle (corn-oil, 33 mL/kg) alone. Total RNA was isolated from individual animals (n=3), and gene expression profiling was studied using RNA-seq on the Illumina HiSeq 2500 platform. Gene expression data was quantile normalized and analyzed using the DESeq2 software; significance was achieved for $q < 0.2$ and linear fold change exceeding 1.25x. We identified genes that significantly changed and in opposite direction on PND 22, comparing hyperoxia to normoxia group, and hyperoxia plus vitamin A compared to the hyperoxia group, and then determined enriched pathways (hypergeometric test, $q < 0.2$). Several pathways were altered, which included, neuronal, oxidative stress, and cytokine pathways. In addition, angiogenesis and vasculature development pathways were induced by hyperoxia at both PND 7 and PND 22, and suppressed by administration of vitamin A at PND 7. Therefore, we hypothesize that these genes could be potential targets for intervention in BPD patients.

2547 Cerebrovascular and Neurological Impact of Chronic Smoking on Post-Traumatic Brain Injury Outcome and Recovery: An *In Vivo* Study

F. Sivandzade[1], F. Alqahtani[2], A. Sifat[1], and L. Cucullo[1]. *[1]Texas Tech University Health Sciences Center, Amarillo, TX; and [2]King Saud University, Riyadh, Saudi Arabia.*

Traumatic Brain Injury (TBI) is one of the most common causes of cerebrovascular and neurological damage worldwide. To this end tobacco smoking (TS, one of the most addictive habit and a main public health hazards) affects the vascular inflammatory and neurovascular behavioral responses of the endothelium through oxidative stress (OS) stimuli enhancing the risk of various cerebrovascular and neurological disorders. It has been recently suggested that premorbid conditions such as TS leads to exacerbation of TBI and retardation of post TBI recovery. The aim of the present study is to investigate and dissect out the pathophysiological mechanisms underlying the exacerbation of TBI (simulated using a head weight drop model) following chronic TS exposure. For this purpose, male C57BL/6J mice, age range 6-8 weeks were exposed to TS for three weeks. Then, test animals were subjected TBI by head weight drop so that a metal weight (30 g) was inserted into a pre-positioned vertical guide whereas the weight free fell for a distance of 80 cm before reaching the target. Physical activity and weight of the mice were analyzed before, 1 hr, 24 hr and three days after TBI. Finally, mice were sacrificed to collect blood and brains samples for subsequent biochemical and molecular analysis. Western blotting was used to assess the expression of Nrf2 (a key antioxidant transcription factor) as well as tight junction proteins associated with BBB integrity including, ZO-1, Occludin, Claudin-5 from homogenized brain tissues. Levels of NF-kB (a pro-inflammatory transcript factor which antagonizes Nrf2 activity) along with pro-inflammatory cytokines IL-6, IL-10 and TNF-α were measured by ELISA on blood samples. The results revealed that TS promoted significantly increased inflammation and loss of BBB integrity in TBI when compared to TS-Free TBI mice. These were paralleled by significant worsening of weight loss, behavioral, and motor activity and an overall slower post-TBI recovery when compared to TF-free TBI mice. In conclusion TS leads to TBI exacerbation and retardation of pathophysiological recovery after TBI likely promoted by worsening of BBB impairment, and pro-inflammatory vascular activity induced by chronic smoking.

2548 Live Cell Imaging of Oxidative Stress in Human Airway Epithelial Cells Exposed to a Secondary Organic Aerosol

S. O. Masood[1], E. R. Pennington[2], P. A. Bromberg[1], A. Gold[1], Z. Zhang[1], and J. M. Samet[3]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; [2]Oak Ridge Institute for Science and Education, Oak Ridge, TN; and [3]US EPA, Research Triangle Park, NC.*

Isoprene hydroxy hydroperoxide (ISOPOOH) is a major component of secondary organic aerosol (SOA) generated from the reaction of isoprene with atmospheric OH·, a reaction favored as pollution controls decrease levels of NO_x in the atmosphere. Relatively little is known about the contribution of ISOPOOH to the health effects from exposure to air pollutants. Previous studies have shown that ISOPOOH-generated SOA can induce oxidative stress in cultured human airway epithelial cells (HAEC). The objective of this study was to characterize the mechanisms of oxidative stress induced by exposure of HAEC to non-cytotoxic concentrations of ISOPOOH. Our experimental approach relies on live cell imaging of HBECs expressing the genetically encoded fluorogenic sensor roGFP, which reports specifically on changes in the glutathione redox potential (E_{GSH}) in real time. Low micromolar concentrations of ISOPOOH induced glutathione oxidation in HAEC through a mechanism that is independent of the generation of extracellular H_2O_2 but is effectively blocked by overexpression of catalase in HAEC, suggesting intracellular conversion of ISOPOOH to H_2O_2. The effect of ISOPOOH on E_{GSH} is potentiated by supplementation of the cells with selenium, consistent with the role of glutathione peroxidases in transducing the peroxidative tone presented by ISOPOOH to the glutathione pool. Similarly, deprivation of glucose sensitizes the cells to ISOPOOH-induced increases in E_{GSH}, suggesting the involvement of NADPH-dependent glutathione reductase activity in opposing ISOPOOH oxidative stress. These findings show that ISOPOOH is a potent environmental oxidant that likely contributes to the oxidative burden posed by inhalation of SOA. *This abstract does not necessarily reflect US EPA policy.*

2549 Prenatal Exposure to Polycyclic Aromatic Hydrocarbons (PAHs) Augments Neonatal Hyperoxic Lung Injury and Alveolar Simplification and Causes Alterations in the Composition of Gut Microbiome in Mice: Mechanistic Role of Cytochrome P450 (CYP)1A1, 1A2, and 1B1

K. Lingappan, L. Swanson, A. Veith, K. Hoffman, W. Jiang, and B. Moorthy. *Baylor College of Medicine, Houston, TX.*

Pregnant women living in the vicinity of superfund sites and smokers are at higher risk for preterm delivery, in part due to exposure to polycyclic aromatic hydrocarbons (PAHs). Preterm infants often require treatment with supplemental oxygen (hyperoxia) that in turn leads to a chronic lung disease of prematurity called bronchopulmonary dysplasia (BPD). Cytochrome P450 (CYP) enzymes have been implicated in this type of injury. CYP1A1 induction is protective against hyperoxic lung injury while CYP1B1 acts as a pro-oxidant. PAH administration augmented neonatal hyperoxic lung injury in a dose-dependent manner. The central hypothesis of this project is that prenatal administration of PAHs differentially exacerbates lung injury and causes gut dysbiosis in neonatal mice following postnatal hyperoxia, and that this effect is altered in mice lacking the gene for (Cyp)1a1, 1a2, or 1b1. Timed pregnant WT (C57BL/6J), Cyp1a1-null, Cyp1a2-null and Cyp1b1-null mice were treated orally with the vehicle corn oil (CO) or mixture of PAHs BP and BbF (7.5 mg/kg, each) on gestational days 16-19. The newborn mice obtained from these mothers were exposed to hyperoxia or room air for 14 days. On PND 14, the mice were euthanized, and lung injury was assessed by quantification of the radial alveolar count (RAC). Results showed that PAH exposure differentially exacerbates lung injury in WT, Cyp1a1-null, Cyp1a2-null and Cyp1b1-null mice and that hyperoxia caused reduction in RAC across all genotypes. PAH treatment resulted in significant induction of Cyp1a1 gene expression in room air, with suppression of Cyp1a1 expression following hyperoxia. In room air, Cyp1a1-null and Cyp1b1-null mice expressed significantly more TNF compared with WT mice. In hyperoxia, TNF and IL-6 expression were enhanced in all genotypes. 16S rRNA sequencing of gut microbiome samples at the PND14 timepoint revealed difference in Bray-Curtis beta diversity observed between PAH and CO groups in WT mice, and this was not seen in Cyp1a1-null mice, suggesting that Cyp1a-mediated metabolism of PAH plays a role in altering the intestinal microbiome. Future studies could lead to the development of novel strategies against BPD in premature infants exposed maternally to PAHs.

2550 Metabolic Adaptation in Macrophages as Mechanism of Defense against Crystalline Silica Dust

A. Marrocco, K. L. Frawley, L. L. Pearce, J. Peterson, S. J. Mullett,, S. L. Wendell, and L. A. Ortiz. *University of Pittsburgh, Pittsburgh, PA.*

Inhalation of respirable silica leads to silicosis, one of the most common occupational pneumoconiosis worldwide, associated with autoimmune diseases, lung cancer and increased risk of active tuberculosis by up to four-fold. About 2 million workers are at risk in the United States, but no specific therapy is available. Here, we hypothesize that macrophages exposed to silica undergo metabolic reprogramming, characterized by increased glycolysis, impaired Krebs cycle, suppressed mitochondrial oxidative phosphorylation, which leads to a pro-inflammatory phenotype. To test this hypothesis, murine macrophages RAW264.7 were exposed to silica (50 µg/cm2) with or without priming, with lipopolysaccharide (LPS, 1 ng/ml) and metabolic parameters were assessed after silica exposure up to 24 hours. To assess the effect of silica with and without LPS on mitochondrial respiration and changes in central carbon metabolism, we utilized state of the art instrumentation including the Oroboros O2k high-resolution respirometer and liquid chromatography-high resolution mass spectrometry (LC-HRMS). Lactate and lactate dehydrogenase (LDH) released in the supernatant was measured with lactate and LDH assay. ELISA assay was performed to measure pro-inflammatory cytokines, such as interleukin (IL)-1beta and tumor necrosis factor (TNF)-alpha, Western Blot assay to evaluate the hypoxia-inducible factor (HIF)-1α and Caspase 1, RT-PCR analysis to evaluate the gene expression of IL-1beta and TNF alpha. Exposure of cells to a non-toxic concentration of silica augmented the activation of complex II of the electron transport chain, independently from the complex I activity, to a greater extent than LPS-primed cells. In fact, stimulation of silica-exposed cells with succinate (CII activator), with or without pre-stimulation with rotenone (CI inhibitor), increased oxygen flux and reactive oxygen species (H_2O_2) more than LPS-exposed cells. As a result, HIF-1α stabilization, caspase-1 activation, and IL-1β release were significantly elevated in silica-exposed cells. However, LPS primed cells exhibited a higher transcription and release of TNF alpha. Secreted lactate was similar in silica- and LPS-exposed cells; while, the co-exposure increased lactate secretion, LDH, and cell death.

In conclusion, unlike the current opinion, silica alone can induce metabolic changes in RAW macrophages that eventually determine chronic inflammation and silicosis.

2551 Lung Fibroblasts from Idiopathic Pulmonary Fibrosis Patients Produce an Oxidizing Extracellular Redox Potential

Y. Zheng[1], T. J. Burke[1], J. D. Ritzenthaler[2], I. N. Zelko[1], V. van Berkel[1], D. R. Nunley[3], A. J. Halayko[4], J. Roman[2], and W. H. Watson[1]. *[1]University of Louisville, Louisville, KY; [2]Thomas Jefferson University, Philadelphia, PA; [3]Ohio State University, Columbus, OH; and [4]University of Manitoba, Winnipeg, MB, Canada.*

Idiopathic pulmonary fibrosis (IPF) is associated with increased deposition of extracellular matrix proteins, and lung fibroblasts are responsible for producing these pro-fibrotic proteins. One of the signals that evokes pro-fibrotic gene expression is a shift in the extracellular cysteine/cystine redox potential (E_h(Cys/CySS)) toward more positive (more oxidizing) potentials. Recently, we found that mouse lung fibroblasts can regulate their own extracellular E_h(Cys/CySS) and that changes in the activity of the CySS transporter Slc7a11 can change the value at which E_h(Cys/CySS) is maintained. Our hypothesis is that human lung fibroblasts from patients with IPF express low levels of SLC7A11 and produce an oxidizing extracellular E_h(Cys/CySS). IPF fibroblasts were isolated from explants of 6 IPF patients receiving lung transplant. Non-IPF fibroblasts were isolated from relatively normal lung tissues adjacent to cancerous tissues of 6 lung cancer patients. SLC7A11 mRNA levels were measured by qPCR. Concentrations of Cys, CySS, glutathione (GSH), glutathione disulfide (GSSG) and mixed disulfide (CySSG) were measured by HPLC. Nernst equation was used to determine the redox potentials. The data showed that extracellular E_h(Cys/CySS) was more oxidized for lung fibroblasts from IPF patients than those from non-IPF donors. Oxidation of E_h(Cys/CySS) in IPF fibroblasts was not due to decreased expression of SLC7A11. However, higher SLC7A11 expression was correlated with more reduced extracellular E_h(Cys/CySS) and more reduced intracellular E_h(GSH/GSSG) in non-IPF fibroblasts, but not in IPF fibroblasts. Therefore, SLC7A11-dependent regulation of extracellular and intracellular redox environments is lost in lung fibroblasts from IPF patients, suggesting that SLC7A11-independent mechanisms are responsible for aberrant redox regulation in this important effector cell of pulmonary fibrosis.

2552 Inhalation Co-exposure to Ultrafine Carbon and Ozone Leads to Significant Pulmonary and Systemic Oxidative Stress

N. Majumder[1,2], X. M. Williams[1], W. T. Goldsmith[1,2], R. A. Mark[3], J. Hubczak[4], V. K. Kodali[4], T. R. Nurkiewicz[1,2], A. Erdely[4], E. E. Kelly[1,2], and S. Hussain[1,2]. *[1]West Virginia University, Morgantown, WV; [2]Center for Inhalation Toxicology (iTOX), Morgantown, WV; [3]University of Pittsburgh, Pittsburgh, PA; and [4]NIOSH, Morgantown, WV.*

Particles and gases are integral components of ambient air pollution and both contribute significantly in adverse health outcomes. Recent epidemiologic data indicates that possible synergistic interactions between these components mediate the adverse phenotypes. Mechanistically, gaseous components can modify the particle surfaces and can reach distal portions of the lung, owing to the deeper penetrability of ultrafine particles. We hypothesize that ultrafine particles of carbon black (CB) and ozone (O_3) co-exposure will lead to significantly greater oxidative stress response in the lungs, heart and liver compared with individual/single toxicant exposures. We performed rodent (C57Bl/6J mice) whole-body inhalation exposures (air, CB, O_3 or CB+O_3) and studied acellular and cellular bimolecular free radical production by immuno-spin trapping. Mice were exposed to 2.0±0.02 ppm O_3 and/or 10±0.6 mg/m^3 CB for 3 hours (16 µg particle deposited dose). Aerosol mobility (140±2 nm), and aerodynamic (84±1 nm) diameters were measured by scanning mobility particle analyzer (SMPS 3938) and an electrical low-pressure impactor (ELPI+). Fourier transformed infrared (FTIR) spectroscopy demonstrated significant alteration in particle surface functional group composition after interaction with O_3. Ferric reducing ability of serum (FRAS) assay demonstrated significantly greater acellular oxidative potentials for co-exposure aerosol. A significantly greater increase in pulmonary and distal organ free radical production, xanthine oxidase activity and gene expression occurred after co-exposures compared with single exposures. In conclusion, our studies confirm interaction of gaseous and particle components of air pollution. By demonstrating distal organ oxidative stress response after pulmonary exposure, we describe a potential pathophysiologic mechanism for cardiovascular and hepatic dysfunction by air pollution exposure. Further mechanistic studies are underway to elaborate these findings using organoids and disease animal models. *Funding: NIH/NIGMS U54GM104942-03 (SH), NIH R01ES015022 (TRN), AHA 19TPA34850089, NIH HL 136383 (EK).*

2553 Glucocorticoids Regulate *SLC7A11* Expression and Sensitivity to Oxidative Stress

S. E. Lacher, D. Levings, J. Krznarich, M. Brendon, and M. Slattery. *University of Minnesota Medical School, Duluth, MN.*

SLC7A11 encodes an antiporter that exchanges glutamate for cystine. Cystine is a precursor to the antioxidant glutathione, and therefore, SLC7A11 activity increases cellular antioxidant capacity. *SLC7A11* is regulated by multiple stress responsive pathways, with altered expression implicated in multiple diseases. Using publicly available data we examined potential regulatory regions and hypothesized that the transcription factor (TF) glucocorticoid receptor (GR) represses *SLC7A11* expression. To test this, we treated A549 cells with ± 3µM mifepristone (MIF), a GR antagonist, for 24 hrs, then treated cells with ± 100nM dexamethasone (DEX), a GR agonist, for an additional 24 hrs. qRT-PCR measured expression of *SLC7A11* relative to a housekeeping gene, and the fold change relative to vehicle control was calculated. Treatment with DEX significantly repressed *SLC7A11* expression (0.43 ± 0.013, p=0.0001) and this was blocked by pre-treatment with MIF (0.90 ± 0.05), suggesting that DEX-mediated repression of *SLC7A11* is specific to GR. We then tested whether cells exposed to DEX are more susceptible to oxidative stress. A549 cells were treated with 100nM DEX (or vehicle) for 24 hours and then exposed to a wide concentration range of an inducer of oxidative stress, tert-Butyl hydroperoxide (TBOOH), or vehicle, and assessed for viability. Cells treated with DEX were more susceptible to TBOOH (+DEX EC50: 81.1µM, 0 DEX EC50: 230.9µM). qRT-PCR and TBOOH cytotoxicity experiments were repeated in HELA cells and rat astrocytes and the trends were consistent. Finally, we explored the potential *cis*-regulatory regions we identified at the *SLC7A11* locus using luciferase reporter assays; A549 cells were transfected with reporter constructs containing either the *SLC7A11* promoter, or the *SLC7A11* promoter plus *cis*-regulatory regions in intron 9 (I9) or intron 2 (I2). Following transfection, cells were treated with MIF and/or DEX in an exposure paradigm as described above. Repression was primarily mediated by the *cis*-regulatory regions in the promoter and I2. Further, we think that the repression in these regions is a result of GR tethering to another stress responsive TF, NRF2, and binding to an antioxidant response element. In summary: GR represses *SLC7A11* via *cis*-regulatory regions in the promoter and I2, likely via tethering to the TF NRF2. Repression of *SLC7A11* results in less exchange of glutamate for cystine, and this renders cells more susceptible to oxidative stress.

2554 Stat3 as a Novel Methylmercury-Induced Antioxidant Mechanism

B. Ferrer[1], F. Marques Gonçalves[1], A. B. Bowman[2], and M. Aschner[1]. *[1]Albert Einstein College of Medicine, Bronx, NY; and [2]Purdue University, West Lafayette, IN.*

Methylmercury (MeHg) is an environmental pollutant that affects the developing and the mature central nervous system. Despite extensive research over the past decades, the molecular mechanisms mediating MeHg neurotoxicity have not been fully elucidated. Oxidative stress, impairment of the antioxidant defense and disruption of the calcium homeostasis are some of the mechanism associated with MeHg toxicity. The induction of nuclear factor erythroid 2-related factor 2 (Nrf2) and its role activating antioxidant response under MeHg-induced oxidative injury focus the attention of the scientific community as a target to counteract MeHg toxicity. Recent studies show that the Nrf2 signaling pathway is insufficient to prevent MeHg damage but there may be other protective mechanisms. The signal transducer and activator of transcription 3 (STAT3) has a pivotal role in cell growth and survival. Some studies also showed that STAT3 plays a role controlling redox homeostasis, preventing oxidative stress by a mechanism that includes modulation of nuclear genes encoding for electron transport complexes (ETC) and antioxidant enzymes. STAT3 also acts by non-classical mechanism, via mitochondria localization where interacts with complex I, increasing membrane potential and promoting ATP synthesis. All these features make STAT3 a plausible mechanism to prevent MeHg toxicity, in conjunction or as alternative to Nrf2 signaling. Here, using an immortalized neuronal hypothalamic GT1-7 cell line we tested if MeHg is able to induce the STAT3 signaling pathway. Our data show that MeHg exposure is associated with upregulation of STAT3-Y705 phosphorylation, inducing its nuclear translocation and regulating STAT3 associated gene expression. In addition, MeHg is also able to induce the phosphorylation at STAT3-S727, which is implicated in its mitochondrial localization. Moreover we found that the inhibition of STAT3 phosphorylation exacerbates MeHg toxicity increasing oxidative stress and mortality. Overall, we show that MeHg is able to induce both classical (nuclear) and non-classical (mitochon-

drial) STAT3 functions. The augmentation of MeHg toxicity by the inhibition of this pathway suggests that STAT3 participates in the antioxidant defense against MeHg injury.

2555 Sulfide Detoxification Is Prioritized over Butyrate Oxidation in the Human Colon

A. P. Landry, S. Moon, H. Kim, P. K. Yadav, A. Guha, U. Cho, and R. Banerjee. *University of Michigan, Ann Arbor, MI.* Sponsor: B. Perera

Microbiota in the human gut metabolize fiber remnants from the diet to produce large quantities of butyrate, the primary energy source for colonic epithelial cells. In the mitochondria of these cells, short-chain acyl-CoA dehydrogenase (ACADS) is a flavoenzyme that catalyzes the initial step of butyrate oxidation, and relays the resulting electrons to the coenzyme Q_{10} pool. When ACADS is isolated from native or recombinant sources, a green color is observed in the protein that corresponds to its FAD cofactor bound to a coenzyme A persulfide (CoA-SSH). The CoA-SSH bound form of ACADS is inactive, and previous studies demonstrated that butyrate oxidation is impaired in colonic epithelial cells exposed to hydrogen sulfide (H_2S), suggesting that CoA-SSH may be generated under these conditions. H_2S, historically regarded as an environmental toxin, is produced at high concentrations by sulfate-reducing bacteria in the colon. However, toxic H_2S accumulation is prevented by sulfide quinone oxidoreductase (SQR), a mitochondrial membrane-bound flavoenzyme that oxidizes H_2S to a persulfide (R-SSH) with concomitant reduction of coenzyme Q_{10}. SQR is remarkably promiscuous in its use of acceptors to form persulfides, and was recently shown to contain an unusual active site cysteine trisulfide. We thus hypothesized that the source of CoA-SSH, and therefore ACADS inhibition, is H_2S oxidation via SQR activity utilizing CoA as an acceptor. In rapid kinetic studies, SQR facilitated sulfur transfer to coenzyme A, and steady-state kinetic assays further demonstrated that coenzyme A is a competent acceptor for the SQR reaction. Furthermore, SQR utilizing coenzyme A as an acceptor generates a charge transfer complex in ACADS corresponding to the CoA-SSH bound species, indicating that CoA-SSH is the persulfide product of the SQR reaction. As both ACADS and SQR relay electrons to coenzyme Q_{10}, competition over this substrate would hinder the effective clearance of toxic levels of sulfide. These studies implicate the inhibition of ACADS by CoA-SSH as a potential modulatory mechanism to reserve the coenzyme Q_{10} pool for SQR and prioritize sulfide detoxification. This would ensure that energy metabolism in the colon is not jeopardized during acute H_2S exposures.

2556 Peroxynitrite ($\pm CO_2$)-Mediated Oxidation of Dimedone Exemplifies Aliphatic Nitration: Significance to Nitration in Nitric Oxide-Producing Biological Systems

O. A. Agu[1], C. J. Deere[1], M. Claville[2], and R. M. Uppu[1]. *[1]Southern University and A&M College, Baton Rouge, LA; and [2]Hampton University, Hampton, VA.*

Nitric oxide ($^{\bullet}NO$) is a versatile hormone apart from being a toxin; $^{\bullet}NO$ manifests its toxicity through the formation of peroxynitrite (PN) and the subsequent reaction of PN with endogenous CO_2 resulting in the formation of nitrogen dioxide ($^{\bullet}NO_2$) and the carbonate radical ($CO_3^{\bullet-}$). Numerous studies from our laboratory and elsewhere have shown that PN ($\pm CO_2$) brings about the oxidation of a vast array of biological molecules including the nitration of free and protein-bound L-tyrosine (Tyr). The reaction of Tyr with PN-derived oxidants is often considered a hallmark of electrophilic aromatic nitration. Using ethyl acetoacetate (EAA) as a model compound, we have previously demonstrated a case for aliphatic nitration by PN ($\pm CO_2$). Now, after two decades of the original work on EAA, we were surprised to learn that there have been no other reported examples of aliphatic nitration by PN ($\pm CO_2$), especially those employing enolizable cyclic ketones. In view this and also in view of a growing number of reports of PN reaction with membrane lipids forming signaling nitro products, we have examined the reactions of 5-dimethyl-1,3-cyclohexanedione (dimedone) by PN at pH of 7.2. It was found that dimedone reacts in this system to form a purple colored product that has a broad absorption centered around 548 nm. The yield of this product was markedly enhanced (*ca.* 20-fold) in the presence of physiologically relevant concentrations of CO_2, meaning that the product(s) is a nitro derivative formed mainly from the reactions of $^{\bullet}NO_2$ and $CO_3^{\bullet-}$ with enolate form of dimedone. In the presence of CO_2, the yield of PN-mediated nitration increased with increase in the concentration dimedone and reached a plateau at concentrations above 15 mM. With varying concentrations of PN, the yield of nitrodimedone increased linearly with increase in the concentration. Unlike free 3-nitro-L-Tyr, the nitrodimedone is moderately sensitive to changes in the pH going from below 4 to above 10. Given the fact that there are numerous examples of the existence of enol and keto esters [acyl CoAs, phospho(enol)-pyruvate, etc] in biological systems, a detailed understanding of aliphatic nitration of dimedone can have significant implications to the $^{\bullet}NO$-producing biological systems especially in terms of the formation of certain long-acting $^{\bullet}NO$-like compounds. The reactions of PN with glucose, fructose, and certain other sugars have all been shown to have $^{\bullet}NO$-like activity.

2556a Blood Brain Barrier Impairment in the Context of Tobacco Smoke and HIV-1 gp120 Co-exposure

A. Bhalerao. *Texas Tech University Health Sciences Center, Amarillo, TX.* Sponsor: A. Bhalerao, American Association for the Advancement of Science

The rate of tobacco smoking is exceedingly high in HIV infected individuals (40-75%) when compared with the general population (15%). Furthermore, 50% of the HIV infected population exhibits neurological complications including NeuroAIDS. We hypothesize that the oxidative stress caused by tobacco smoking and HIV-1 envelope protein gp120 may have a contributory effect on the increasing burden of NeuroAIDS related morbidity and mortality in HIV infected individuals who smoke. Increase in oxidative stress has been associated with the initial upregulation and subsequent overwhelming of Nuclear factor (erythroid derived 2)-like 2 [NFE2L2 or Nrf2] which regulates the expression of antioxidant proteins. Oxidative stress is also known to cause Blood Brain Barrier (BBB) dysfunction by downregulation of tight junction (TJ) proteins. Thus, we seek to develop an understanding of the underlying mechanisms that may contribute to the BBB impairment in relation to Tobacco Smoke and HIV-1 gp120 co-exposure. We studied the effects of co-exposure of Tobacco Smoke Extract and HIV-1 gp120 on Primary Human Brain Microvascular Endothelial Cells (HBMECs) and Primary Human Astrocytes by measuring Oxidative Stress and subsequent Antioxidant response, cells were treated individually with HIV-1 gp120 and Tobacco Smoke extract. Gp120 dose for *in vitro* studies was selected based on a MTT cell viability study. We assessed barrier function by measuring transendothelial electrical resistance (TEER) and permeability. Total proteins were isolated from each treatment group and examined for tight junction proteins (Occludin, ZO-1) expression. Generation of ROS was detected by DCFDA assay. Immunocytochemistry was performed to further confirm check the expression of Nrf2. Co-exposure of Tobacco Smoke Extract and HIV-1 gp120 on HBMECs and Human Astrocytes showed decrease in - Cell Viability, Blood Brain Barrier Integrity and Antioxidant response and increase in oxidative stress compared to control and individual treatments. Decrease in TEER measurements and the parallel increase in permeability to FITC was observed. ZO-1 and Occludin expression levels were reduced in the co-exposed group. Activation of the Nrf2 with its reduced expression in a group with co-exposed treatment indicated oxidative damage. Co-exposure to tobacco smoke extract (TSE) and HIV-1 gp120 (gp120) further aggravated the BBB endothelium dysfunction thereby worsening cerebrovascular condition.

2557 Elucidation of the Mechanism Involved in the Induction of Chemokine CCL4 Expression by Methylmercury

M. Kim[1], T. Takahashi[2], T. Toyama[3], A. Naganuma[3], and G. Hwang[3]. *[1]Korea Institute of Toxicology, Jeongeup, Korea, Republic of; [2]Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan; and [3]Tohoku University, Sendai, Japan.*

Methylmercury is a harmful heavy metal found widely in the environment and causes central nervous disorders because this compound can cross the blood brain barrier. We have previously shown that C-C motif chemokine ligand 4 (CCL4) protects cultured neural cells from methylmercury toxicity and expression of CCL4 is specifically induced in mouse brain by methylmercury. In addition, the expression of CCL4 was induced prior to methylmercury toxicity, and CCL4 had a protective effect against methylmercury toxicity in mouse neural stem cells. These findings suggest that the induction of CCL4 expression by methylmercury may be a protective response to methylmercury toxicity. Therefore, elucidating the mechanism involved in the induction of CCL4 expression by methylmercury is important for understanding the brain-specific toxicity exhibited by methylmercury. In this study, we examined the transcriptional regulatory mechanism that induces CCL4 expression by methylmercury using C17.2 mouse neural stem cells. The promoter region of the CCL4 gene was analyzed by a reporter assay, revealing that the region up to 50 bp upstream from the transcription start site was necessary for inducing expression of CCL4 by methylmercury. Nine transcription factors that might bind to this upstream region and be involved in the induction of CCL4 expression by methylmercury were selected, and the induction of CCL4 expression by methylmercury was suppressed by the knockdown of serum response factor (SRF). In addition, the nuclear level of SRF was elevated by methylmercury, and an increase in the amount bound to the CCL4 gene promoter was also observed.

Furthermore, we examined the upstream signaling pathway involved in the induction of CCL4 expression by SRF, and confirmed that activation of p38 and ERK, which are part of the MAPK pathway, are involved. These results suggest that methylmercury induces the expression of CCL4 by activating SRF via the p38 and ERK signaling pathway. Our findings are important for elucidating the mechanism involved in the brain-specific induction of CCL4 expression by methylmercury.

2558 Evaluation Total and Speciated Urinary Arsenic and Risk of Acute Hepatitis E in the US Population

H. H. Rahman[1], P. J. Trainor[1], and S. R. Dipon[2]. *[1]New Mexico State University, Las Cruces, NM; and [2]Independent University, Dhaka, Bangladesh.*

Arsenic is a known toxic chemical and has immunomodulatory properties. Arsenic has the ability to change the susceptibility of infection in humans. Acute hepatitis E infection is an infectious disease; it can be self-limiting and in severe cases, can cause acute-on-chronic liver failure. The presence of Hepatitis E IgG (Immunoglobulin G) Antibody (IgG Anti-HEV) in blood represents acute hepatitis E infection in an individual. Very few studies have investigated the association between exposure to arsenic and acute hepatitis E infection risk in humans. The primary objective of this study was to assess the relationship between total urinary arsenic and speciated urinary arsenic (Urinary Arsenous Acid, Urinary Arsenic Acid, Urinary Arsenobetaine, Urinary Arsenocholine, Urinary Dimethylarsinic Acid, Urinary Monomethylarsonic Acid) and the presence of Hepatitis E IgG Antibody (IgG Anti-HEV). The 2011-201, 2013-2014, and 2015-2016 National Health and Nutrition Examination Survey (NHANES) III data set were analyzed, and participants were aged 20 years and older (n=7,061). We used weighted logistic regression to calculate Odds Ratios (OR) and Confidence Interval (CI) of the relationship between total and speciated urinary Arsenic concentrations and IgG Anti-HEV. For each analyte considered, a separate weighted logistic regression model was fitted. Each of these models regressed log-transformed analyte levels on the log-odds of the presence of IgG Anti-HEV. All pairwise Pearson correlation coefficients were computed for each of the urinary arsenic measurements. Of the included human subjects, 6,628 (93.9%) were negative for Hepatitis E IgG Antibody (IgG Anti-HEV) while 433 (6.1%) had a positive test for IgG Anti-HEV. Total urinary arsenic (OR= 1.16, CI= 1.04-1.30, p-value= 0.01), Urinary Arsenobetanine (OR= 1.17, CI= 1.08-1.27, p-value= 0.0006), and Urinary Dimethylarsinic (OR= 1.18, CI= 1.01-1.39, p-value= 0.04) were observed to be significantly associated with the increased risk of IgG anti-HEV. Elevated urinary arsenic was associated with the risk of acute hepatitis E infections in this study. Further research is needed to confirm the causal relationship between arsenic exposure and acute hepatitis E infections.

2559 Heavy Metals Concentrations and Physiochemical Characteristics of Underground Water Sources around the Open Dump Site, Igando, Lagos

O. O. Ogunrinola, O. Joshua, O. A. Ogunrinola, T. C. Onwordi, and B. O. Elemo. *Lagos State University, Lagos, Nigeria.*

The rapid urbanization and industrialization in the World causes Heavy metals contamination in water, which is one of the major quality issues in many developing Countries. Heavy metals in the earthly environment pose a serious risk to human health. This study measured the heavy metals concentration and physiological characteristics of underground water sources around the open dump site in Igando, Lagos Nigeria. 12 different locations of Underground water samples from dug wells and boreholes within a distance range of 0.07-0.72 km form the dump site was collected. Structured questionnaire was used to determine the perception of the residents around the dump site about ill health effect of heavy metal contaminated water on humans, were administered to 10 users of each water sources making a total of 120 respondents. The selected relevant physicochemical parameters (colour, pH, electric conductivity, total hardness, nitrate and phosphate) and heavy metals (copper, zinc, iron, lead, manganese, nickel and cadmium) in the samples were analysed using commercial kit and Flame Atomic Absorption Spectrometer. Investigation revealed that the farther away the underground water from the dump site the lower the physiochemical parameters. The results show that there is a high concentration of the heavy metals in the various underground water samples with lead, Cadmium, Iron and Nickel having mean concentrations above the permissible limits specified by World Health Organization (W.H.O) and Standard Organization of Nigeria (S.O.N) for drinking water. This study suggests that the underground water neither near nor far from the dump site is polluted with heavy metals and respondents using this water are ignorant of the risk to health.

2560 Genetic Inhibition of Liver Manganese Import Corrects Aberrant Liver Erythropoietin Production in a Mouse Model of Inherited Manganese Excess Due to Deficiency in the Manganese Transporter *Slc30a10*

M. Prajapati, C. Mercadante, H. Conboy, and T. Bartnikas. *Brown University, Providence, RI.*

Manganese (Mn) is a trace element essential for growth and development. Elevated levels of Mn can be toxic. Inherited diseases of Mn excess are caused by mutations in the Mn transport proteins SLC30A10 and SLC39A14. Though both are diseases of Mn overload, they do not showcase the same set of phenotypes: SLC30A10 mutations lead to high blood and tissue Mn levels, neurologic deficits, cirrhosis, and polycythemia whereas SLC39A14 deficiency results in high blood and tissue Mn levels (except liver) and neurologic deficits without cirrhosis or polycythemia. Patients with SLC30A10 mutations also have high serum levels of erythropoietin (Epo). These phenotypic differences led us to explore the unappreciated biological effects of Mn excess in the mammalian body. We developed a Slc30a10-deficient mouse model (*Slc30a10$^{KO/KO}$*), which recapitulated key human disease phenotypes including polycythemia and Mn accumulation in the blood and tissues (liver, bone, brain). Given that polycythemia is a unique manifestation of Mn toxicity, we aimed to understand how Mn overload results in polycythemia using *Slc30a10$^{KO/KO}$* mice as a tool. We hypothesized that Mn, like other divalent metals such as cobalt, acts as a 'hypoxia-mimetic' to upregulate expression of *Epo*, a hypoxia-regulated gene. Using RNA analyses, we identified liver as a key organ for aberrant Epo expression, rather than kidney, the physiological site of Epo expression. Expression profile of over 90 hypoxia-regulated genes using PCR arrays indicated upregulation of 24% genes in *Slc30a10$^{KO/KO}$* liver. Using gene-specific qPCR, we validated six genes (*Epo*, *Serpine1*, *Hk2*, *Anxa2*, *Lox*, and*Hif3a*) that showed highest differential expression. Next, we challenged our working model by genetically inhibiting liver Mn import by rendering mice deficient in Slc39a14, a Mn import protein responsible for liver Mn loading. Mice deficient in both Slc30a10and Slc39a14showed significantly lower liver Mn levels, liver *Epo* RNA levels, and red blood cell counts when compared to *Slc30a10$^{KO/KO}$* mice. RNA analyses also indicated a trend towards restoration of kidney *Epo* expression in *Slc30a10$^{KO/KO}$ Slc39a14$^{KO/KO}$* mice. Together, these studies suggest that liver Mn excess drives aberrant Epo expression in *Slc30a10$^{KO/KO}$* mice and add to our understanding of novel mechanisms of Mn toxicity.

2561 A Population Toxicokinetic Modeling of Mercury and Methylmercury in Human

M. Iwai-Shimada[1], K. Yaginuma-Sakurai[2], N. Tatsuta[3], K. Nakai[3], and S. Nakayama[1]. *[1]National Institute for Environmental Studies, Tsukuba, Japan; [2]Shokei Gakuin University, Sendai, Japan; and [3]Tohoku University Graduate School of Medicine, Sendai, Japan.* Sponsor: M. Iwai-Shimada

We have previously published about half-lives of whole blood and hair for methylmercury kinetics via tuna and swordfish intake (Yaginuma-Sakurai et al., J Toxicol Sci. 2012: 123-30). In this study, we aimed to carry out a detailed analysis of the population toxicokinetic modelling of methylmercury using data obtained from Yaginuma-Sakurai et al (2012). A bigeye tuna and swordfish equivalent to the tolerable weekly intake of methylmercury was ingested for 14 weeks, followed by an observation period of 15-28 weeks. Blood collection was performed each one week for 14 weeks, and every two weeks after 15-28 weeks (N = 27). The population toxicokinetics modelling of mercury and methylmercury was performed using plasma mercury concentration and plasma methylmercury concentration. As a basic model of population toxicokinetics, a proportional error model (log additive) of a one-compartment model with the best model fit was selected from information such as minimum AIC. As a result, the median of the calculated mercury elimination rate constant was 0.082, and the median half-life was calculated to be 59 days. The median value of methyl mercury elimination rate constant was 0.087, and the median half-life was calculated to be 56 days. The half-life of blood mercury shown in the previous study was 46 to 53 days, and almost equivalent results were obtained.

2562 Variation in Blood Lead Accumulation Is Strongly Influenced by Genetics and Diet

D. Cuomo, and D. Threadgill. *Texas A&M University, College Station, TX.*

Although physiological effects and public health concerns of the environmental heavy metal lead (Pb) are well documented, we know little about the genetic and/or dietary factors that determine individual variability in

susceptibility to lead poisoning. Traditional epidemiological approaches are limited in exploring factors contributing to differential susceptibility due to heterogeneity in genetic background and uncontrolled environments. These limitations are particularly problematic when using blood measurements of toxicants like Pb as a surrogate for exposure. To overcome these limitations, new genetically-diverse mouse resources such as the Collaborative Cross (CC) have been developed to better model the genetic diversity found in human populations under controlled environments. To specifically address the influence of genetic and dietary factors on Pb bioaccumulation, we utilized the CC to identify genetic polymorphisms that determine variation in Pb blood levels in the context of a common exposure level. Adult females from 50 different CC lines received either mouse chow or American diet - a dietary pattern characterized by high intake of sugar and fat - and Pb (0.1%) through drinking water *ad libitum*. CC lines showed significant variation in blood lead levels (BLLs) depending on genetic background, diet, and genetic background-by-diet interactions. Genetic association analysis identified haplotypes associated with variation in BLLs in response to diet. Distinct haplotypes correlated with elevated BLLs originated from the PWK strain, one of wild-derived founders of the CC. Using this model, we aim to elucidate mechanisms by which genetics and diet contribute to lead bioaccumulation, how these can be used to better evaluate exposure levels from indirect BLLs, and provide prevention strategies and dietary interventions to reduce adverse effects of lead exposure.

PS 2563 Chromium and Vanadium Have Gene-Environment Interactions in Shared Biological Pathways

A. K. Thompson, T. M. Everson, and M. O. Gribble. *Emory University, Atlanta, GA.*

The unregulated contaminants vanadium and chromium often co-occur in public drinking water systems in the United States, raising concerns about possible hazards from joint exposure. On October 9, 2019, we queried the Comparative Toxicogenomics Database (CTD), a publicly available curated database cataloguing gene-environment interactions, to explore possible shared toxicological pathways affected by these exposures. There were 149 genes suggested by scientific literature indexed in CTD to have interactions with vanadium for *Homo sapiens*, and 704 genes showing interactions with chromium for *Homo sapiens*, with 16 genes appearing in both lists: *ARNT, ATP2B1, CDK17, CDK6, CXCL8, HIF1A, IL6, INSIG1, MAPK1, MAPK3, MMP1, PTK2B, SLCO30A4, TIMP1, TNF,* and *TP53*. We entered these 837 unique genes interacting with either metal into the Database for Annotation, Visualization and Integrated Discovery (DAVID) version 6.8 as official gene symbols; 803 of the genes in this list were recognized with *Homo sapiens.* Using DAVID's Functional Annotation Tool allowed us to visualize affected toxicogenomic pathways from the KEGG PATHWAY database. The KEGG minimum threshold for genes present in enriched pathways was set to 2. The top hit was "Pathways in Cancer" with 84 pathway genes (P value 4.4 E-23, Benjamini P value 1.2 E-20). The next pathway hit was "Hepatitis B" with 42 pathway genes (P value 2.2 E-16, Benjamini P value 2.9 E-14). Some more specific, interesting pathways suggested were the "FoxO signaling pathway" with 39 pathway genes (P value 3.0 E-15, Benjamini P value 2.0 E-13), the "TNF signaling pathway" with 33 pathway genes (P value 1.0 E-13, Benjamini P value 4.5 E-12), the HIF-1 signaling pathway with 31 pathway genes (P value 1.7 E-13, Benjamini P value 5.6 E-12), and the PI3K-Akt signaling pathway with 57 pathway genes (P value 1.2 E-10, Benjamini P value 2.5 E-9). This hypothesis-generating analysis of publicly available toxicogenomic databases suggests several biological pathways that merit further investigation in joint-exposure drinking water experimental toxicology studies and in molecular epidemiology studies.

PS 2564 microRNA Expression Influences Methylmercury-Induced Mitochondrial Dysfunction

M. Martell, N. Crawford, and S. W. Caito. *Husson University, Bangor, ME.*

Mitochondrial dysfunction is a hallmark of several conditions, including Parkinson's disease and metabolic disorders. Methylmercury (MeHg) causes mitochondrial dysfunction through inhibiting respiration and inducing oxidative stress, however molecular targets contributing to MeHg-induced mitochondrial dysfunction have not been fully described. MicroRNA (miRNA) are emerging regulators of mitochondrial function and are responsive to environmental agents. We hypothesized that down regulating miRNA expression in *Caenorhabditis elegans* would exacerbate MeHg-induced mitochondrial dysfunction by suppressing mitoprotective miRNA. Worms that express mutations in *rrf-1* or *rrf-3* are more sensitive to the effects of miRNA, while worms that express mutant *pash-1* or *nrde-2* are more resistant to miRNA than wild type (N2) worms. MeHg significantly decreased oxygen consumption in N2 worms, which was further decreased in the miRNA resistant strains. Oxygen consumption was significantly improved following MeHg treatment in miRNA sensitive strains as compared to N2. Concurrent with the decrease in respiratory function was depolarization of the mitochondrial membrane potential by MeHg. miRNA resistant strains had significantly more membrane depolarization than N2, whereas miRNA sensitive strains had less depolarization than N2. MeHg decreased the mitochondrial mass of the worms and decreased the total mitochondrial DNA (mtDNA) copy number in N2 worms. This suggests that MeHg not only decreases the number of mitochondria, but also impairs the ability to replenish mitochondria following insult. Loss of mtDNA copy number and mitochondrial mass were exacerbated in the miRNA resistant strains, and were milder in the miRNA sensitive strains. Taken together, our data support a role for mitoprotective miRNA expression in response to MeHg exposure. Inhibition of protective miRNAs induces further damage to the mitochondria by MeHg.

PS 2565 Particulate Hexavalent Chromium Induces Cytotoxicity and Genotoxicity in Female and Male Fin Whale Cells

I. Meaza[1,2], R. M. Speer[1,2], J. H. Toyoda[1,2], and J. P. Wise Sr.[1,2]. *[1]Wise Laboratory of Environmental and Genetic Toxicology, Louisville, KY; and [2]University of Louisville School of Medicine, Louisville, KY.*

Hexavalent chromium is a global health concern, a known human carcinogen as well as reproductive and developmental toxicant. Although it is clear that DNA damage, manifested as strand breaks and chromosomal changes plays a central role, the mechanism underlying its carcinogenicity is uncertain. Chromium is a ubiquitous marine pollutant and high chromium levels have been reported in North Atlantic whales including fin whales. Whale species represent a good model for toxicological studies because despite the fact that marine mammals accumulate high amounts of pollutants due to their long lifespan and deep diving behavior, they are known to be less susceptible to develop cancer than humans. Studying the toxicity of chromium in whale cells might be key to acquire a better understanding of the underlying toxicity of chromium. Therefore, we hypothesized that acute (24 h) and prolonged (120 h) exposures of particulate Cr(VI) to fin whale male and female cells induces both cytotoxic and genotoxic effects. To investigate this, cytotoxicity was measured by the clonogenic assay also known as colony forming assay, which measures the ability of cells to proliferate and form colonies after the treatment. Clastogenicity was measured using the chromosome aberration assay. Intracellular chromium levels were also determined with Graphite Furnace Atomic Absorption Spectroscopy. As hypothesized, particulate Cr(VI) induced a cytotoxic and genotoxic response in a concentration dependent manner in cells from both sexes. Both acute and prolonged exposure induced similar amounts of cytotoxicity, but prolonged exposure induced less genotoxicity than acute exposure. Intracellular chromium was lower after prolonged exposure than acute exposure. Overall, compared to previous data in human cells, both fin whale sexes showed a resistance to Cr(VI), as prolonged particulate Cr(VI) exposures in human cells showed an increased amount of toxicity. This outcome suggests marine mammals may have developed cellular mechanisms to counterbalance chromium induced toxicity. In the future, assessing cellular mechanisms activated after the Cr(VI) exposure, such as, Cr transport, DNA repair and cell death pathways, could provide insights into why fin whale cells are relatively resistant to genotoxic agents. *Supported by NIEHS grant ES016893 (J.P.W.).*

PS 2566 Adverse Effect of Manganese Exposure on Adult Neurogenesis: Evidence from the Subventricular Zone (SVZ)-Derived Neurosphere Assay *In Vitro*

L. L. Liu, W. Jiang, and W. Zheng. *Purdue University, West Lafayette, IN.*

Manganese (Mn) is an essential metal to human health; however, excessive exposure to Mn is known to cause clinical symptoms with motor and non-motor dysfunctions similar, but not identical, to Parkinson's disease (PD). Earlier studies from this lab have established a detrimental effect of subchronic Mn exposure on adult neurogenesis (ANG) in SVZ. This study was designed to test the hypothesis that Mn exposure selectively affected the proliferation, migration, and differentiation of neural stem/progenitor cells (NSPCs) derived from the adult SVZ. Neurospheres were generated by isolating SVZ tissues from young adult mice (6-10 weeks old); cells were cultured in a growth factor-enriched medium. The newly formed neurospheres with the size of ~ 200 µm were selected and seeded on poly-L-ornithine-coated coverslips. The cultures were then treated with or without Mn-containing medium at 0, 0.1, 1.0, or 10.0 µM for five days. The cell proliferation, migration, and differentiation were determined by measuring the distance of newly generated cells migrated from neurospheres, by BrdU (5-Bromo-2′-deoxyuridine) incorporation assays, and by quantifying DCX and NeuN immunofluorescence, respectively.

Our data showed that *in vitro* Mn exposure significantly inhibited cell migration in a dose-dependent manner. For example, compared to the control group (628.64 ± 147.41 μm), Mn treatment at 10 μM reduced the migration distance (417.1 ± 57.31 μm) by 33.6% ($p<0.05$). The data from immunofluorescence assays did not reveal a significant change in BrdU(+) proliferating cells following Mn treatment at all dose levels. Interestingly, however, cell counts of DCX(+) neuroblasts per neurosphere suggested a significant reduction in Mn-treated cells at 10 μM (83.00 ± 23.26), as compared to the control group (241.3 ± 78.68), a reduction of 65.6% ($p<0.05$). Moreover, NeuN(+) mature neurons in the Mn-treated group at 10 μM (107.0 ± 19.52) in neurospheres were reduced by 33.5% ($p<0.05$) as compared to controls (161.00 ± 21.66). Taken together, these findings indicate that Mn exposure selectively affected the different stages of the AGN in SVZ, particularly on migration and differentiation of newly formed cells. How this may influence Mn caused motor or non-motor dysfunctions remains unclear and thus deserves further investigation. Mechanistic investigation of key signaling pathways in Mn-induced aberrant SVZ neurogenesis is currently in progress.

2567 Identification of Methyltransferases for Production of a Urinary Selenometabolite, Trimethylselenonium

Y. Ogra, Y. Fukumoto, Y. Tanaka, and N. Suzuki. *Chiba University, Chiba-shi, Japan.*

Selenium (Se) is an essential element for animals, and mostly excreted into the urine. Within the nutritional level to the low toxicity level, the major urinary metabolite is *Se*-methylseleno-*N*-acetyl-galactosamine (MeSeGalNAc). The second major urinary selenometabolite is trimethylselenonium ion (TMSe), which is simply the methylated compound of selenide, a key metabolic intermediate. Two methyltransferases are speculated to involve in the Se methylation. Thiopurine *S*-methyltransferase (TPMT) is first identified to catalyze sulfur methylation of sulfhydryl group in 6-mercaptopurine. TPMT is also suggested to perform a Se methylation. The other is indolethylamine *N*-methyltransferase (INMT). In human, a genome-wide association study for the TMSe-producing and non-producing individuals revealed the correlation between single nucleotide polymorphisms in *INMT* gene and the concentration of TMSe in blood and urine. However, molecular mechanisms underlying the methylation from selenide to TMSe are still unclear. We revealed that these two methyltransferases cooperatively and substrate-specifically catalyzed the selenide methylation to form TMSe.

2568 Active Bacterial Copper-Efflux Response Contributes to Environmental Toxicity in *Caenorhabditis elegans*

C. M. Shafer, P. Allard, and M. McEvoy. *University of California Los Angeles, Los Angeles, CA.*

Environmentally ubiquitous transition metals challenge prokaryotic and eukaryotic species through uncontrolled redox cycling. When these ions are overly abundant, all extant organisms contain largely conserved mechanisms (chelation, sequestration or excretion) to minimize damage and increase chances for survival. However, organismal toxicity is not only dependent on absolute abundance, but also speciation, complexation, and other environmental factors that contribute to overall ion availability. For instance, lower concentrations of copper (Cu) are more toxic to *Caenorhabditis elegans* (*C. elegans*), a free-living nematode, when grown on a diet of dead *Escherichia coli* (*E. coli*), as opposed to *E. coli* that is alive. The cause of this discrepancy goes beyond passive metabolic functions because cadmium (Cd), another transition metal, is equally toxic to *C. elegans* regardless of the bacterial status. From these observations, we hypothesize that an active and specific bacterial response mediates Cu toxicity in higher organisms. To test this hypothesis, we took advantage of the *C. elegans*/*E. coli* model system to examine bacterial factors that contribute to the environmental toxicity of Cu. Using *E. coli* knockouts with 100%, 50% and 25% of wildtype Cu-efflux capacity, we discovered a significant relationship between this active bacterial response and the severity of metal toxicity in *C. elegans*. Comparing defined Cu-toxicity endpoints in *C. elegans* fed *E. coli* with wildtype Cu-efflux capacity (100%) to those fed *E. coli* with reduced efflux capacity (25 to 50%), we observed 1) reduced lethality from 8.5 days of median survival up to 14.5 days ($p > 0.0001$), 2) a 7.6% ($p=0.0001$) increase in length independent of dauer arrest, 3) a 10-fold ($p=0.0008$) reduction in cumulative risk for egg-laying defects comparable to no-exposure control risk levels, and 4) reduced transcription of a known *C. elegans* metal-response marker. Conversely, overall body burden of the metal in *C. elegans* appeared unaffected by bacterial Cu-efflux capacity and entirely dependent on $CuSO_4$ supplementation in growth media. Current results support the bacterial Cu-response as an important contributor to the severity of metal toxicity in higher organisms. Ongoing work seeks to better define the *C. elegans* transcriptional activity during these conditional Cu exposures.

2569 *In Vivo* Dosing with Cadmium Causes Decreased Glucose-Stimulated Insulin Secretion in Isolated Pancreatic Islets

A. Barakat[1], P. Lamar[1], R. Kissell[1], S. Ahmed[1], M. El Muayed[2], and J. Edwards[1]. [1]*Midwestern University, Downers Grove, IL; and* [2]*Northwestern University, Chicago, IL.*

Diabetes mellitus (DM) is a growing worldwide epidemic. Decreased insulin secretion in the face of insulin resistance is the hallmark of type 2 DM. Epidemiological and experimental studies show that exposure to the metal cadmium (Cd) is associated with pre-DM, DM and altered plasma insulin. How Cd disrupts pancreatic islet function and glucose-stimulated insulin secretion is not known. The objective of the current study was to begin to characterize the *in vivo* toxic effects of Cd on pancreatic islets. To do this, we used a model of long-term Cd exposure by administering Cd in the form of $CdCl_2$ (0.6 mg/kg/day 5 days per week for up to 12 weeks) in male and female Sprague Dawley rats. Pancreatic islets were isolated from 6 and 9 week treated animals and allowed to recover overnight. Islets were then incubated in high (4.5 mg/ml) glucose-containing buffer for 6 hours. Samples of buffer were collected and islets lysed. Percent insulin release was quantified by measuring buffer insulin content normalized to islet lysate insulin. After 6 weeks of treatment, percent insulin release (mean ± SE) from saline-treated control female and male animals were 30.3 ± 9.2% and 38 ± 8.87%, respectively. Cadmium treatment resulted a decrease in percent insulin secretion with 23.3 ± 1.9% and 19.3 ± 5% for female and male animals, respectively. After 9 weeks of treatment, percent insulin secretion from female and male control-treated animals were 29.7 ± 7.8% and 45 ± 17.6%, respectively; with Cd treatment the average values were 22 ± 4.5% and 19.6 ± 11% for female and male animals, respectively. Two-way ANOVA indicated significant differences between control and Cd-treatment groups; however, post-hoc Tukey's tests did not indicate statistically significant changes. These data from 6 and 9 week treated animals show that Cd exposure results in significant reductions in glucose-stimulated insulin secretion from pancreatic islets. There was no apparent time-dependent response indicating that this effect is independent of increasing Cd accumulation within pancreatic islets that occurs over time. This study reinforces that Cd is a diabetogenic substance that acts by altering pancreatic islet function.

2570 The Role of Activator Protein 1 (AP-1) and Nuclear Protein 1 (Nupr1) in Nickel-Induced Carcinogenesis

A. Murphy, N. Roy, H. Sun, C. Jin, and M. Costa. *NYU School of Medicine, New York, NY.*

Nickel (Ni) is used in a variety of industries including stainless and alloy steel production, electroplating, ceramics, pigments, and as a chemical intermediate, primarily because of its desirable properties such as corrosion resistance, heat resistance, hardness, and strength. Ni is also a well-known human carcinogen based on its ability to cause cancers of the lung and nasal cavity, and several millions of people are occupationally and environmentally exposed to nickel worldwide. However, the mechanisms of Ni carcinogenicity remain elusive. Nupr1, a small stress protein, is involved in cell transformation and carcinogenesis. Nupr1 has been implicated in a number of cancers including lung, breast, and pancreatic cancers. In this study, we found using quantitative real-time PCR and Western blotting that Nupr1 expression was increased following Ni exposure at both the mRNA and protein levels in human bronchial epithelial cells (BEAS-2B) in a dose-dependent manner. Nupr1 was also upregulated in Ni-transformed cells, suggesting that induction of Nupr1 may play important roles in Ni-induced carcinogenesis. To investigate which regulatory regions within the Nupr1 promoter are responsible for transcriptional activation following Ni exposure, the Nupr1 promoter (-2500 to +500) was cloned and inserted into luciferase reporter constructs. Promoter bashing experiments determined a region that mediates Ni-induced Nupr1 transcriptional activation. Promoter activation by Ni in a stable transfection model is also being investigated. Computational prediction of transcription factor binding sites identified an AP-1 motif within the region identified. In fact, mRNA and protein expression of AP-1 subunits c-JUN, c-FOS, ATF-2, and FOSL1 were found to be increased in a dose-dependent manner following Ni exposure in BEAS-2B cells and in human embryonic kidney cells (HEK-293). Notably, knockdown of AP-1 (c-JUN and c-FOS) using RNA interference suppressed Ni-induced Nupr1 expression, indicating that Ni induces Nupr1 through upregulating AP-1 expression. In summary, this study demonstrates that Ni is capable of inducing AP-1, which regulates the expression of Nupr1 and may

contribute to Ni-mediated carcinogenesis. Understanding the mechanisms governing Ni-induced carcinogenesis may apply to additional environmental and occupational carcinogens, and provides valuable insight into the carcinogenic process in general, which may be useful for identifying potential chemotherapeutics.

2571 Proximal Tubular Hypertrophy Enhances Basolateral Uptake of Mercury

K. E. Matta[1], C. C. Bridges[1], L. Joshee[1], and D. Barfuss[2]. *[1]Mercer University School of Medicine, Macon, GA; and [2]Georgia State University, Atlanta, GA.*

Approximately 15% of the United States population has been diagnosed with chronic kidney disease (CKD). CKD is characterized by a progressive and permanent loss of functioning nephrons. Following this loss, the remaining functional nephrons undergo compensatory changes including increased renal blood flow, increased single nephron glomerular filtration rate (SNGFR), and cellular hypertrophy. We hypothesize that compensatory changes in proximal tubular cells leads to enhanced cellular uptake of mercury (Hg). Mercury is a ubiquitous environmental toxicant to which humans are exposed through various routes. Patients with CKD may be more susceptible to Hg and thus, it is important to understand how Hg is handled in kidneys of these patients. We hypothesize that compensatory hypertrophy of proximal tubules leads to an increase in the uptake and accumulation of Hg. Furthermore, we propose that hypertrophied tubules are more sensitive to the toxic effects of Hg. To test these hypotheses, we used *in vitro* and *in vivo* models. Basolateral uptake of Hg, as a conjugate of glutathione (GSH; GSH-Hg-GSH), was measured in isolated non-perfused proximal tubules from control and nephrectomized rabbits. The effects of Hg on biochemical aspects of oxidative stress were measured in kidneys from rats exposed to Hg. These findings show that hypertrophied tubules take up and accumulate more Hg than normal tubules. In addition, hypertrophied tubules appear to be more sensitive to the effects of Hg than normal tubules. These data provide important information regarding the handling of mercuric ions in patients with renal insufficiency.

2572 Toxicity Profile of a Novel Analogue of Carboplatin in Cellular Models of Cancer

V. Veletanlic, and B. B. Williams. *Western Kentucky University, Bowling Green, KY.*

There are currently three FDA platinum compounds approved for use as chemotherapeutics, where each drug has variable efficacies for different cancer types depending on the tissue where the cancer originated. The approved compounds are platinum(II) complexes with four coordination sites on the platinum atom allowing two types of ligands to attach: leaving ligands, which are removed from the platinum atom in solution, and non-leaving ligands, which remain complexed to the platinum in solution. This study aims to examine the potency of a novel analogue and compare it to one of the approved drugs, carboplatin. Carboplatin, the preferred compound used to treat ovarian and small-cell lung cancers, has a characteristic cyclobutanedicarboxylate leaving ligand and two ammonia non-leaving ligands. Our novel compound, 1,1-cyclobutanedicarboxylato(ethylenediamine)platinum (II), or Pt(en)CBDCA, has an ethylenediamine group in place of the ammonia ligands. We hypothesize that the efficacies of platinum compounds vary due to differences in the leaving and non-leaving ligands. To understand the impact of this structural change, we are investigating the analogue's effects on cell viability by performing MTT assays in three distinct human cancer cell lines. Preliminary data shows a large difference between IC-50 values of the melanoma cells and the colorectal cells treated with both Carboplatin and Pt(en) CBDCA. Given that intracellular accumulation is typically correlated to toxicity, we hypothesize that structural differences may alter intracellular accumulation of the compounds. To test our hypothesis, we are examining intracellular levels of both carboplatin and Pt(en)CBDCA using atomic absorption spectroscopy. In this study, we aim to correlate the intracellular concentration of platinum with cell survival response to create a toxicity profile of these compounds.

2573 Investigating a Role for Gut Microbes in Modulating the Toxicokinetics of Methylmercury

I. N. Krout, and M. Rand. *University of Rochester, Rochester, NY.*

Methylmercury (MeHg) poses a risk to human health due to its widespread prevalence and its potential as a developmental neurotoxicant, capable of causing a range of neurocognitive and neuromotor deficits, particularly after *in utero* exposure. Human MeHg exposure is primarily through the consumption of predatory fish. With fish consumption rising globally, exposure to MeHg is inevitably difficult to regulate. To protect the developing fetus, regulatory agencies have established a reference dose for MeHg, creating a "one size fits all" standard for fish consumption. The inability to eliminate MeHg from the human diet, and the "one size fits all" regulatory approach, underscores a need to investigate inter-individual differences in MeHg toxicokinetics and susceptibility. Prior studies, and evidence from our lab analyzing MeHg elimination in individuals consuming fish, demonstrate high variability in their MeHg half-lives ($t_{1/2}$), ranging from 30 to >120 days. It has also been shown, in both rodents and humans, that antibiotic exposure increases the $t_{1/2}$ of MeHg. These findings lead us to hypothesize a role for the gut microbiome in impacting the kinetics of MeHg metabolism and excretion. Specifically, we hypothesize the presence of gut bacterial species capable of demethylating MeHg to produce inorganic Hg, a form more rapidly eliminated. Bacterial genes identified within the mer operon, specifically, organomercurial lyase (MerB) and mercury reductase (MerA), are capable of MeHg demethylation and reduction to Hg^0 respectively. The presence of merB and merA in the human gut and their role in MeHg metabolism has not been rigorously investigated. We are therefore exploring the MeHg metabolizing activity of plasmid expressed merB and merA together and in isolation, in *E. coli* cultures. Expression of merB/A together can demethylate and reduce MeHg. Notably, we see that merB alone can accomplish efficient MeHg demethylation, but we observe substantial differences in demethylation rates depending on the species from which the merB is derived. We will investigate the metabolic role of gut-localized MeHg demethylation activity of merB by populating the gut of axenic flies with merB expressing *E. coli*. Results from our study will help to derive controlled assays to elucidate the gut microbiome's role in modulating the toxicokinetics of MeHg and elucidate mechanisms that potentially influence MeHg half-life variability in humans. *Supported by NIEHS R01ES030940 and T32ES007026.*

2574 The Inhibitory Effect of Hexavalent Chromium in Myogenic Differentiation

S. Liu[1], H. Sun[2], and M. Costa[2]. *[1]New York University Langone Medical Center, New York, NY; and [2]NYU School of Medicine, New York, NY.*

Chromium is a metallic element found widely in rocks, soil, plants and animals. Chromium III is a nutritional supplement whose mode of action as such is not well defined. In contrast hexavalent chromium (Cr(VI)) is about 500 -1000 times more toxic than Cr(III) toxic and is an established human carcinogen. Acute exposure to Cr(VI) may affect the skin, kidneys, lungs and gastrointestinal track. Chronic human exposure in occupational settis is associated with nasal and lung cancers. Cr(VI) can cross the placenta and induce development toxicity. Myogenesis is a process of formatting muscular tissue, especially during embryonic development. Since studies in chromium VI induced myotoxic are currently lacking, the aim of the present study was to investigate the toxicological effect of Cr(VI) on C2C12 myoblasts, particularly during myogenic differentiation. We exposed C2C12 myoblast to different doses of Cr(VI) and measured the viability of C2C12 cells. Non-toxicity doses of 2 μm and 5 μm were selected to study the effect of Cr(VI) on myogenic differentiation. We found that Cr(VI) exposures inhibit C2C12 myoblast differentiation in a dose-dependent manner. Consistent with the defective myogenic differentiation, several myogenic differentiation makers, such as MCK, myogenin, myomaker and myomerger, were significantly altered following Cr(VI) treatment. Taken together, our study is the first to evaluate the toxicological effect of Cr(VI) on myoblast differentiation and represents a model system to study the effects of Cr(VI) on human cell differentiation.

2575 Reduction of Erythropoietin Production through Inhibition of HIF-1 Transcriptional Activity by Cadmium

M. Tokumoto, J. Lee, and M. Satoh. *Aichi Gakuin University, Nagoya, Japan.*

Cadmium (Cd) is one of the toxic heavy metals widely present in the environment. Cd is contained in grains such as rice and seafood such as oysters. Therefore, there are concerns about the health effects of long-term intake of Cd through these foods. Chronic Cd exposure causes renal toxicity, especially proximal tubular damage. In addition, Cd causes renal anemia. This is mainly due to reduced production of erythropoietin (EPO), one of the hematopoietic factors produced in the kidney. *EPO* is a gene regulated by the hypoxia inducible factor 1 (HIF-1). HIF-1 is known to be a heterodimer consisted of HIF-1 alpha and HIF-1 beta (aryl hydrocarbon receptor nuclear translocator: ARNT). In this study, we examined the effect of Cd on the transcriptional activity of HIF-1 and the gene expression level of EPO. Human kidney proximal tubular epithelial cells (HK-2 cells) were treated with Cd under serum-free conditions.

The transcriptional activity of HIF-1 in HK-2 cells treated with Cd decreased compared to the control. *EPO* mRNA levels were significantly decreased depending on the treatment concentration and treatment time of Cd. Moreover, *EPO* mRNA levels were decreased to approximately 50% in siRNA-treated *HIF-1 alpha* knockdown cells. However, Cd remarkably induced HIF-1 alpha protein levels. On the other hand, ARNT protein levels were decreased in HK-2 cells treated with Cd. These results suggest that Cd may cause renal anemia by reducing EPO production in human kidney proximal tubular epithelial cells through inhibition of HIF-1 transcriptional activity. In addition, Cd may inhibit HIF-1 transcriptional activity via suppression of ARNT protein levels. *This work was supported by the Study of the Health Effects of Heavy Metals, organized by the Ministry of the Environment, Japan.*

2576 Associations between Metal Levels in Whole Blood and IgE Concentrations in Pregnant Women Based on Data from the Japan Environment and Children's Study

M. Tsuji[1], C. Koriyama[2], Y. Ishihara[3], M. Yamamoto[4], and T. Kawamoto[1].
[1]University of Occupational and Environmental Health, Kitakyusyu, Japan; [2]Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima, Japan; [3]Hiroshima University, Hiroshima, Japan; and [4]National Institute for Minamata Disease, Ministry of the Environment, Minamata, Japan.

Allergic diseases can potentially affect the course of pregnancy, and poorly controlled allergic diseases during pregnancy are associated with high mortality, low birth weights, and congenital malformations. Various changes occur in pregnant women compared to those who are not pregnant, and pregnant women tend to have higher metal concentrations in their bodies. Recently, the immunotoxic properties of metals have been pointed out and some studies have reported that there are relationships between metal exposures and IgEs. Therefore, we have tried to clarify the relationships between metal concentrations in blood and IgEs in pregnant women. We investigated the relationship between metal concentrations in whole blood and IgEs (total and specific) in 14,408 pregnant women who participated in the Japan Environment and Children's Study. Concentrations of the metals Cd, Pb, Hg, Se, and Mn, as well as serum total and allergen-specific IgEs for egg white, house dust-mites (HDM), Japanese cedar pollen (JCP), animal dander, and moth, were measured. Allergen-specific IgE(s) were divided based on concentrations <0.35 or ≥0.35 UA/mL, and the metal levels were divided into quartiles (Q1-Q4) according to increasing heavy metal levels. There were significant relationships between HDM-specific IgE and Hg Q4; JCP-specific IgE and Hg Q3 and Q4; JCP-specific IgE and Se Q2, Q3, and Q4; animal dander-specific IgE and Hg Q3 and Q4; animal dander-specific IgE and Se Q3; and animal dander-specific IgE and Mn Q2 and Q3. The odds ratio (OR) of HDM- and animal dander-specific IgE decreased as the Hg concentration increased (p values for the trends were 0.010 and 0.006, respectively). Conversely, the OR of JCP-specific IgE increased as the Hg and Se concentrations increased (p values for the trends were both <0.001). This is the first study to link metal concentrations with IgEs in pregnant Japanese women. We showed that metal exposures may be related to both increases and decreases in allergen-specific IgEs and that JCP-specific IgE, in particular, was positively related to Hg concentrations.

2577 Hepatic Processing of Mercuric Ions Is Required for Renal Excretion

C. Bridges[1], D. W. Barfuss[2], L. Joshee[1], K. E. Matta[1], and J. T. Buchanan[1].
[1]Mercer University School of Medicine, Macon, GA; and [2]Georgia State University, Atlanta, GA.

Mercury (Hg) is a prevalent environmental toxicant to which humans are exposed regularly. Renal excretion of mercuric species is the primary means of removal and studies suggest that the primary species of Hg delivered to the kidney is a glutathione conjugate (GSH-Hg-GSH). The route by which Hg becomes bound to GSH is not understood. We hypothesize that mercuric ions within the body must be delivered to the liver where they are conjugated to GSH. Formation of GSH-Hg conjugates may facilitate subsequent renal filtration and excretion. To test this hypothesis, we measured disposition of Hg in control Wistar rats and in rats in which the hepatic artery and portal vein were ligated to prevent blood delivery to the liver. Rats were injected with 0.5 µmol/kg/2 mL $HgCl_2$ containing radioactive Hg and were euthanized after one hour. The amount of Hg in kidneys, liver, and blood was measured. In addition, biochemical assays were used to measure parameters of GSH synthesis. Following exposure to $HgCl_2$, the renal burden of Hg in rats with ligated livers was reduced significantly compared with that of normal rats. Exposure to a GSH-Hg-GSH conjugate increased the renal burden of Hg in rats with ligated livers. Furthermore, exposure to Hg increased the hepatic expression of glutathione-S-transferase. Collectively, these data suggest that mercuric ions are processed by the liver to generate mercuric species (e.g., GSH-Hg-GSH) that can be filtered and excreted by the kidney.

2578 Acute Effects of Inhaled Tungsten Particles on the Lung Microenvironment

K. Burton, C. McVeigh, E. Barr, G. Herbert, R. Hunter, S. Medina, S. Lucas, A. Ali, M. Campen, and A. M. Bolt. *University of New Mexico, Albuquerque, NM.*

Individuals are exposed to high levels of tungsten through inhalation, particularly in occupational (range: 0.024-3.14 mg/m^3) and military (range: 1.95-3.08 mg/m^3) settings. Inhalation exposure to tungsten metal-alloy particles has been associated with increased incidence of lung pathologies, including interstitial lung disease and lung cancer. However, very little is known about the molecular mechanisms underlying the contribution of tungsten exposure to these pathologies. The present study examined if inhalation exposure to tungsten metal particles caused acute damage to the lung microenvironment that could contribute to these long-term lung pathologies. A total of 24 female Balb/c mice were exposed to control (filtered air), 0.50 mg/m^3 (low concentration), or 1.5 mg/m^3 (high concentration) tungsten metal particles (< 2 µm) in a whole-body inhalation chamber for 4 hrs. Tissue samples were collected at day 1 and day 7 post-exposure for analysis. A significant accumulation of tungsten was measured in the lung and bone post exposure by inductively coupled mass-spectrometry (ICP-MS), but no accumulation was detected in the bronchoalveolar lavage fluid (BALF) or plasma. Additionally, there was a significant increase of macrophage and neutrophil infiltration into the lung following exposure, however no significant changes in total protein in the lung (marker of cellular damage) or changes in peripheral blood counts were observed. The generation of reactive oxygen species (ROS) was evaluated in dissociated lung tissue by DCFDA staining, and no changes in ROS levels were observed following exposure. Interestingly, an increase in the percentage of activated fibroblasts (α-SMA$^+$) in the lung was observed in the high exposure group. Taken together, these findings demonstrate that acute inhalation exposure to tungsten particles, at levels commonly observed in occupational and military settings, resulted in changes to the lung microenvironment that may promote the onset or exacerbation of lung diseases. Current work is focused on exploring these observations through the use of *in vitro* multi-cell lung models and chronic exposure animal models. *Funding: The University of New Mexico College of Pharmacy and INBRE P20GM103451.*

2579 Biomarkers of Acute Kidney Injury in Metal Exposed, War-Injured Veterans: Preliminary Results

M. Reback[1,2], S. Hines[1,2], M. McDiarmid[1,2], C. Brown[2], and J. Gaitens[1,2].
[1]Baltimore VA Medical Center, Baltimore, MD; and [2]University of Maryland School of Medicine, Baltimore, MD.

The ongoing conflicts in Iraq and Afghanistan have exposed numerous US service members to trauma from blasts and explosions, oftentimes resulting in retained metal fragments of unknown composition. While high-dose acute exposures to metals such as arsenic and cadmium are widely known to be nephrotoxic, studies have also shown renal injury from chronic, low-level metal exposures. As such, veterans who have on-going systemic metal exposure from embedded fragments may be at risk for kidney injury. To investigate this issue, 421 veterans, identified from the Department of Veterans Affairs' (VA) Toxic Embedded Fragment registry, across 5 VA medical centers are being asked to complete medical history and exposure questionnaires along with spot urine collection. We present here preliminary data for the first 119 enrolled veterans. Urine samples were analyzed for levels of 14 metals commonly found in fragments or known to be carcinogenic, along with 10 protein markers of kidney injury. All urine metal results were creatinine-adjusted and dichotomized based on the upper limit of normal in unexposed populations. Linear regression was used to examine the effect of having at least one elevated metal concentration on renal protein markers while controlling for other factors associated with renal injury. The study population was predominantly male (96.6%) with a mean age of 41.2 years and average time since injury of 12.4 years. Over half (56.3%) of veterans had at least one elevated urine metal, the most common of which were zinc (49.6%), aluminum (6.7%), and tungsten (3.4%). Except for interleukin-18, the majority of renal protein results fell within normal ranges. Initial findings showed that the presence of an elevated urine metal concentration was significantly associated with seven of ten renal injury markers after adjustment for age and NSAID use. However, concerns about the unusual number of elevated zinc results prompted removal of zinc from the analyses. After zinc removal, only 23 (19.3%) veterans had at least one elevated urine metal concentration and

a significant association with 3 renal injury markers remained (N-acetyl-β-D-glucosaminidase, total protein, and albumin). While most renal protein results fell within the normal range, our preliminary findings suggest that long-term monitoring to assess adverse renal effects may be warranted in veterans with retained fragments.

2580 Exposure to Lead and Cadmium, and Health Effects in Abandoned Metal Mine Area Inhabitants of Korea

J. Park[1], J. Mun[1], D. Na[1], B. Choi[1], S. Eom[2], H. Kim[2], Y. Hong[3], and J. Sakong[4]. *[1]Chung-Ang University, Seoul, Korea, Republic of; [2]Chungbuk National University, Cheongju, Korea, Republic of; [3]Dong-A University, Busan, Korea, Republic of; and [4]Yeungnam University, Daegu, Korea, Republic of.*

People living near abandoned mine area are at risk of metal exposure. In this study, we surveyed 4500 inhabitants (male: 1768, female: 2732) around 104 abandoned metal mines during 2013-2017 (the 2nd phase health survey in Korea). The mean age of study subjects were 68.5 years-old. The concentrations of lead (Pb) and cadmium (Cd) in whole blood and Cd in urine were analyzed by a graphite furnace atomic absorption spectrometer. The geometric mean of BPb, BCd and UCd were 2.27 μg/dL (male: 2.71 μg/dL, female: 2.03 μg/dL), 1.42 μg/L (male: 1.18 μg/L, female: 1.60 μg/L), and 1.66 μg/g creatinine (male: 1.13 μg/g creatinine, female: 2.13 μg/g creatinine), respectively. Exposure level to metals was lower than the 1st phase health survey with 38 abandoned mines in Korea (2008-2011), but was higher than the general population. BPb was significantly higher in males than in females while BCd and UCd were significantly higher in females than in males. In this study, BPb was the highest in the age group of 40-59 then decreased, while BCd and UCd were increased by the eighties. Furthermore, negative relations observed between BPb and Cd in blood and urine in this study subjects. These findings indicate that abandoned mine area inhabitants have been exposed to Cd continuously even though the mines were closed several decades ago. Also, 252 of 4500 subjects exceeded the threshold of BCd or UCd, and some of them also observed health effects such as kidney and bone damage. Taken together, inhabitants in abandoned mine area are aged mostly and might be susceptible to toxic metal such as Cd, therefore, it is necessary continuous monitoring and careful attention in environmental health.

2581 Inhibition of Red Blood Cell Development by Arsenic-Induced Disruption of GATA-1

S. Medina[1], X. Zhou[1], A. M. Bolt[1], G. Wan[1], H. Xu[2], F. T. Lauer[1], S. C. Wang[3], S. W. Burchiel[1], and K. J. Liu[1]. *[1]University of New Mexico, Albuquerque, NM; [2]East China University of Science and Technology, Shanghai, China; and [3]Institute of Hematology and Blood Diseases Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Tianjin, China.*

Anemia is a hematological disorder that adversely affects the health of millions of people worldwide. Although many variables influence the development and exacerbation of anemia, one major contributing factor is the impairment of erythropoiesis. Normal erythropoiesis is highly regulated by the zinc finger (ZF) transcription factor GATA-1. Disruption of the ZF motifs in GATA-1, such as produced by germline mutations, compromises the function of this critical transcription factor and causes dyserythropoietic anemia. Herein we report that arsenic, a widespread environmental toxicant, selectively inhibits erythropoiesis through the disruption of GATA-1 ZFs, utilizing a combination of *in vitro* and *in vivo* studies. We found that arsenic interacts with the N- and C-terminal ZF motifs of GATA-1, causing zinc loss and inhibition of DNA and protein binding activities, resulting in dyserythropoiesis and an imbalance of hematopoietic differentiation. For the first time, we show that exposures to a prevalent environmental contaminant compromises the function of a key regulator of erythropoiesis, producing effects functionally similar to inherited GATA-1 mutations. These findings highlight a novel molecular mechanism by which arsenic exposure may cause anemia and provide critical insights into potential prevention and intervention for arsenic-related anemias. *This work was supported by the National Institutes of Environmental Health Sciences R01 ES029369 (K.J.L), R01 ES019968 (S.W.B.), and University of New Mexico Clinical and Translational Science Center Grant Number UL1TR001449 (S.W.B.).*

2582 Comparison of Toxicokinetics of Methylmercury in Diabetic KK-Ay Mice and C57BL/6 Mice

M. Yamamoto[1], R. Yanagisawa[2], M. Mogi[3], M. Shudo[3], M. Nakamura[1], H. Kashiwagi[1], M. Kudo[1], A. Sakai[4], and S. Shuto[5]. *[1]National Institute for Minamata Disease, Ministry of the Environment, Minamata, Japan; [2]National Institute for Environmental Studies, Tsukuba, Japan; [3]Ehime University, Toon, Japan; [4]Nippon Medac, Tokyo, Japan; and [5]Hokkaido University, Sapporo, Japan.*

One modifier of methylmercury (MeHg) metabolism and its toxicokinetics is the metabolic disturbance associated with a disease. However, the toxicokinetics of Hg when disturbed by glucose metabolism have not yet been clarified. The present study aimed to elucidate the differences in MeHg toxicokinetics when disturbed by glucose metabolism between diabetic KK-Ay mice and non-diabetic BL/6 mice using the Kp value, the equilibrium ratio between the drug concentrations in the organ and the plasma. A single dose of MeHg (0.2 mg Hg/kg BW) was administered to 12-week-old KK-Ay and BL/6 mice. After 4, 7, 11, and 14 d, the total mercury (T-Hg) concentration in samples of blood and tissue (brain, kidney, liver, and pancreas) was determined using a thermal decomposition Hg analyzer. The Kp value in the brain samples of the KK-Ay mice tended to reach a plateau after 11 d, but that in samples from the BL/6 mice continued to increase up to 14 d. The Kp value in the liver in both the KK-Ay and BL/6 mice tended to reach a plateau at 11 d. The Kp value in the kidneys of the KK-Ay mice remained almost constant from 4 to 14 d, but that in samples from the BL/6 mice continued to increase up to 14 d. The Kp value in the pancreas of the KK-Ay mice decreased continuously up to 14 d, but that in samples from the BL/6 mice remained almost constant from 4 to 14 d. These findings indicated that the uptake and excretion of MeHg in each organ differed between the diabetic KK-Ay mice and the non-diabetic BL/6 mice. These results will be useful for understanding MeHg metabolism when glucose metabolism is disturbed by a disease such as diabetes.

2583 Detoxification Mechanisms in Nematode *Caenorhabditis elegans* Exposed to Nickel

B. Tang, P. Williams, J. Wang, and L. Tang. *University of Georgia, Athens, GA.*

Occupational and environmental exposure to nickel has been known to be carcinogenic and allergenic in human populations. Developing methods for protecting organisms in nickel-polluted environments settings is contingent upon the understanding of cellular detoxification mechanisms. *Caenorhabditis (C.) elegans* is a powerful model organism for investigating toxicological processes, and provides several advantages for deciphering the mechanisms of metal detoxification. *C. elegans* harnesses multiple detoxification mechanisms to maintain metal homeostasis. Members of the heavy metal tolerance factor 1 (HMT-1) which belong to the "B" branch of the ATP-bindings cassette (ABC) transporters superfamily, are required for detoxification of heavy metals. Phytochelatins (PC) are a class of glutathione-derived peptides that maintain metal homeostasis via binding metal ions. The enzyme, phytochelatin synthase 1 (PCS-1), synthesizes PC in response to toxic metal exposures. The pcs-1 and hmt-1 genes are co-expressed in the nematode's coelomocytes, which act as liver cells by reprocessing and detoxifying pseudocoelomic fluid from harmful ingested substance. The objective of this study was to investigate roles of the metal-detoxifying mechanisms described above in nickel tolerance in *C. elegans*. The wild-type N2 nematodes, single knockout strains, VF2 (pcs-1 null) and VF3 (hmt-1null), and double knockouts strains, VF9 (pcs-1+hmt-1) and VF14 (hmt-1+coelomocytes), were exposed to a series of concentrations of nickel sulfate (0 to 500 μmol/L). The high-throughput platform analysis (COPAS Biosort and WMicroTracker) were used to measure different endpoints, including growth, reproduction, feeding, and locomotion. Following exposure nickel sulfate induced significant toxic effects on growth, reproduction, feeding, and locomotion in exposed wild-type *C. elegans*. Significant differences were found between the wild type and mutant strains in response to nickel exposure. The EC50 of locomotion in wild type N2, mutant VF2, VF3, VF9 and VF14 were 36.46, 30.44, 23.39, 21.94 and 18.96 μM, respectively. These data suggest that pcs-1 and hmt-1 pathways and coelomocytes are involved in nickel detoxification, which may be used as a novel model for studying nickel-induced toxic effects and mechanisms.

2584 Assessing the Effects of Cr(VI) on CTCF Binding and Localized Transcription Dysregulation

A. P. VonHandorf, H. A. Zablon, J. W. Biesiada, M. Medvedovic, and A. Puga. *University of Cincinnati, Cincinnati, OH.*

Hexavalent chromium (Cr(VI)), is a well-established respiratory carcinogen widely used in several industries. While inhalation is a main source of exposure in occupational settings, millions of people are chronically exposed through ingestion of contaminated drinking water, creating an increased risk of gastrointestinal cancer, though the mechanisms remain unclear. Our previous findings using ATAC- and MNase-seq demonstrated that Cr(VI) exposure resulted in differentially accessible chromatin regions enriched with motifs for CTCF, a key regulator of transcription and chromatin architecture. In our current study, we used ChIP-seq to test the hypothesis that Cr(VI) disrupts the interaction of CTCF with its cognate motifs, altering proximal chromatin architecture and regulation of gene expression. Following exposure to 1 μM Cr(VI) for 48 hours, we identified differentially bound sites containing the motif, with the trend favoring reduced CTCF binding in the presence of Cr(VI). The mRNA and protein expression of CTCF and cohesin components were not appreciably affected, suggesting that disrupted binding affinity is the result of Cr-mediated interference of CTCF interaction with chromatin. To assess the impact on local transcriptional regulation, we selected for motifs within ±1.5 Kb of a transcriptional start site, mapping the closest gene's expression using a previously published RNA-seq dataset. Functional enrichment analyses for significantly affected genes identified key factors in chromatin organization and chromatin modifying enzymes, most notably arginine methyltransferases, supporting the notion that Cr promotes changes in chromatin architecture. To better understand how architectural shifts affect gene expression profiles, we are attempting to identify Cr-susceptible chromatin loops within topologically associated domains (intraTAD) by applying a machine learning approach to a multifaceted ChIP-seq dataset of transcription factors and histone modifications. Our findings suggest that Cr(VI) exposure disrupts the interactions of CTCF with a subset of its binding sites, either directly or indirectly, which may alter the transcription of genes within functional networks associated with chromatin organization. *Acknowledgements: Supported by NIEHS R01ES010807 and NIH 5T32ES007250.*

2585 Diffusion Mechanism, Equilibrium, and Kinetics of Nickel (II) Ions Adsorption onto White Croaker Fish Scales

C. T. Onwordi[1,2], C. C. Uche[2], and L. F. Petrik[2]. *[1]Lagos State University, Lagos, Nigeria; and [2]University of the Western Cape, Cape Town, South Africa.*

The absorption removal of Ni (II) ions from aqueous solution was investigated by purverised white croaker fish scale (FS) in a batch process. The FS was characterised by Fourier transform infrared (FTIR) before and after the adsorption. The optimum conditions and % adsorption of the Ni (II) ions were found to be the following: pH 7.0; 94.1%, adsorbent dose 20 g/L; 80%, concentration 50 mg/L; 88.3%; contact time 90 mins; 89% and temperature 323 K; 93% respectively. The equilibrium adsorption data was applied to Langmuir, Freundlich, Temkin, and Dubinin-Kaganer-Raduskevich (DKR). The equilibrium was fully fitted with Langmuir and the dimensionless separation factor R_L signifies a favourable adsorption of Ni (II) ions FS. The adsorption kinetics studies reveal that the adsorption of Ni (II) ions onto FS was pseudo-second order chemisorption and follow film diffusion as well as intra-particle pore diffusion mechanism. Thermodynamics study showed that the adsorption is endothermic and spontaneous. The study shows the potential capacity of fish scale in the effective removal of Ni (II) ions from aqueous solution.

2586 Metabolism Shift in Cr(VI)-Transformed Cells Causes Epigenetic Changes and Promotes Tumorigenesis

M. Clementino, W. Fenske, Y. Li, P. Yang, M. Lin, J. Xie, C. Yang, and Z. Wang. *University of Kentucky, Lexington, KY.*

Cancer cells display a metabolic shift from oxidative phosphorylation to glycolysis under normoxia condition. Metabolic shift is important for the production of anabolic building blocks for developing hallmarks of cancer. Certain metabolites produced from shifted metabolism could function as substrates or regulators for epigenetic modifiers. Hexavalent chromium (Cr(VI)) chronic exposure induces malignant transformation of human bronchial epithelial (BEAS-2B) cells, displaying cancer stem cell (CSC)-like property and tumorigenesis. This study investigated whether Cr(VI)-transformed cells display abnormal metabolism and its role in Cr(VI)-induced CSC-like property and tumorigenesis. It was found that compared to passage-matched control cells, Cr(VI)-transformed cell [BEAS-2B-Cr(VI)] displayed glycolytic shift, Which could be reversed under a no glucose culture condition. Moreover, culturing BEAS-2B-Cr(VI) cells in no glucose medium impaired their CSC-like property and tumorigenesis. Mechanistic studies revealed that the levels of histone acetylation marks are up-regulated in BEAS-2B-Cr(VI) cells. The expression level of ACLY (ATP Citrate Lyase), a gene that produce acetyl co-A for histone acetylation, is drastically increased in BEAS-2B-Cr(VI) cells. Moreover, the expression level of c-Myc, a gene that plays critical roles in cancer stemness and metabolism, was also increased greatly in Cr(VI)-transformed cells. Cr(VI)-transformed cell cultured under no glucose condition showed reduced levels of ACLY, c-Myc and histone acetylation marks. Moreover, inhibition of ACLY with a pharmacological inhibitor greatly reduced the levels of histone acetylation marks and c-Myc in Cr(VI)-transformed cells and their CSC-like property. Knockdown of c-Myc in Cr(VI)-transformed cells reversed their glycolytic shift, histone acetylation, CSC-like property and tumorigenesis. Together these findings suggest that metabolic shift in Cr(VI)-transformed cells increases histone acetylation through ACLY, which in turn up-regulates the expression of ACLY and c-Myc establishing a positive feedback loop between metabolic shift and epigenetic deregulation and promoting CSC-like property and tumorigenesis.

2587 Cadmium Renal Toxicity through the Suppression of Gene Expression of GLUT4

J. Lee, M. Tokumoto, and M. Satoh. *Aichi Gakuin University, Nagoya, Japan.*

Cadmium (Cd) causes renal toxicity through the proximal tubular cell damage. Previous studies revealed that Cd caused the gene expression disruption in proximal tubular cells. However, the transcription factors that regulate the expression of genes associated with Cd renal toxicity are poorly understood. We found MEF2A (myocyte enhancer factor 2A) transcription factor which is involved in Cd toxicity in HK-2 human proximal tubular cells, using protein/DNA binding array and RNAi method. Next, it was investigated which downstream factor of MEF2A is associated in Cd toxicity in HK-2 cells. MEF2A is reported to regulate the gene expression of *SLC2A4*, which encodes GLUT4 (glucose transporter 4) protein. We found that *SLC2A4* expression is regulated by MEF2A in HK-2 cells. Moreover, Cd decreased not only the mRNA level of *SLC2A4* but also the protein level of GLUT4 in HK-2 cells. In addition, *SLC2A4* knockdown by siRNA conferred the toxicity to HK-2 cells. On the other hand, GLUT2 protein is reported to be expressed abundantly in the mammalian kidney. However, the knockdown of the GLUT2 encoding gene, *SLC2A2*, did not induce the toxicity in HK-2 cells. Furthermore, *MEF2A* knockdown did not inhibit the gene expression of *SLC2A2* in HK-2 cells. GLUT4 is involved in glucose transport into the cells. Therefore, it was examined whether Cd or *SLC2A4* siRNA treatment affect the glucose level in HK-2 cells. Not only Cd treatment but also *SLC2A4* siRNA treatment significantly decreased glucose level in the cells. Furthermore, HK-2 cells incubated in glucose free medium showed the decrease in cell viability compared to that incubated in normal medium. These results suggest that the pathway of Cd renal toxicity through the inhibition of the MEF2A activity involves the cellular glucose level decrease *via* the suppression of *SLC2A4* gene expression.

2588 Integrin α4 Depletion Suppresses Arsenic and Benzo[α]pyrene Co-exposure-induced Cancer Stem Cell-Like Property by Inhibiting the Non-canonical Hedgehog Pathway

J. Xie, Y. Li, P. Yang, M. Lin, W. Fenske, M. Clementino, M. B. Uddin, H. Tao, C. Yang, and Z. Wang. *University of Kentucky, Lexington, KY.*

Arsenic (As) and benzo[α]pyrene (BaP) are among the most common environmental carcinogens causing lung cancer in humans; and As and BaP co-exposure synergizes in inducing lung tumorigenesis. However, the mechanism of the synergistic carcinogenic effect of As and Bap co-exposure remains elusive. The goal of this study was to investigate the mechanism of As and BaP co-carcinogenesis. We found that As and Bap co-exposure synergizes in inducing cancer stem cell (CSC)-like property, which is stronger than that induced by exposure to As or BaP alone. It was further determined that the expression level of integrin α4 (ITGA4) is highly up-regulated in As and Bap co-exposure-transformed human bronchial epithelial cells [BEAS-2B-A+B]. To determine the role of ITGA4 up-regulation in As and BaP co-exposure-induced CSC-like property and tumorigenesis, we stably knocked down ITGA4 expression in BEAS-2B-A+B cells using ITGA4 targeting shRNA lentiviral particles. It was found that stably knocking down the expression of ITGA4 in BEAS-2B-A+B cells significantly decreased their CSC-like property and tumorigenicity in mice. Mechanistic studies revealed that Hedgehog (HH) pathway, a master

regulator of developmental processes whose dysregulation has been linked to a variety of cancers, was turned off in ITGA4 knock down BEAS-2B-A+B cells. It was further determined that ITGA4 knock down suppresses non-canonical HH signaling pathway by decreasing the expression and nuclear localization of activator Gli (GLI^A). Moreover, inhibition of the HH pathway significantly reduced the CSC-like property of As and BaP co-exposure-transformed cells. Together, these findings indicate that ITGA4 depletion suppresses As and Bap co-exposure-induced cancer stem cell-like property by inhibiting the non-canonical HH signaling pathway.

2589 Comprehensive Study on the Target Transcription Factors in Cadmium Renal Toxicity

M. Satoh, J. Lee, and M. Tokumoto. *Aichi Gakuin University, Nagoya, Japan.*

Cadmium (Cd) is an environmental contaminant known to exert toxic effects on various tissues such as kidney, liver, lung, testis and bone. Especially, proximal tubular cell damage is characterized as Cd-induced renal damage. Previous studies revealed that the disruption of gene expression is involved in Cd-induced renal toxicity. However, the transcription factors that regulate the expression of genes associated with Cd renal toxicity are poorly understood. In this study, we screened transcription factors whose activities were changed by Cd treatment in not only HK-2 human proximal tubular cells but also NRK-52E rat proximal tubular cells, using Protein/DNA binding array. In HK-2 cells, Cd increased the binding activities of 20 transcription factors by more than 2-fold; also, Cd decreased those of 28 transcription factors, among 345 transcription factors. In addition, in NRK-52E cells, Cd increased the activities of 6 transcription factors by more than 2.0-fold and decreased those of 15 transcription factors by less than 0.5-fold, among 65 transcription factors. We focused on the transcription factors whose activities were decreased by Cd; therefore, it is examined which transcription factors might decrease cellular viability by their knockdown using the RNAi method. As the result, the each knockdown of ARNT, MEF2A, HIF-1, GATA-1, GATA-3, GATA-6, FOXF1, and YY1 transcription factors conferred the cell viability defection. Interestingly, several downstream factors such as BIRC3 [baculoviral IAP (inhibitor of apoptosis protein) repeat containing 3; known as cIAP2] and UBE2D (ubiquitin-conjugating enzyme E2D) are involved in apoptosis related Cd toxicity. These results suggest that the gene expression disruption through the changes in transcription activities is one of the main pathways in Cd renal toxicity.

2590 Humanizing the *Borcs7/As3mt* Locus Establishes Human-Like Patterns of Arsenic Metabolism in Mice

M. Styblo[1], J. Snouwaert[1], L. Jania[1], C. Douillet[1], H. El-Masri[2], D. J. Thomas[2], and B. Koller[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

Both mice and humans metabolize inorganic arsenic (iAs) via reactions catalyzed by arsenic (+3 oxidation state) methyltransferase (AS3MT/As3mt) to yield monomethyl-As (MAs) and dimethyl-As (DMAs) metabolites. However, mice metabolize iAs more efficiently than humans, resulting in a faster clearance, which may explain why some of the adverse effects of iAs exposure have been difficult to reproduce in laboratory mice. The goal of the present study was to generate a mouse strain in which iAs metabolism resembles that in humans. Embryonic stem cells (ESCs) expressing human *AS3MT* were created by syntenic replacement of the mouse *Borcs7/As3mt* locus with human the *BORCS7/AS3MT* locus. ESCs carrying the humanized locus were used to generate the *AS3MT/BORS7* (hu/hu) humanized mouse line. The concentrations of iAs and its metabolites were measured in urine of wild-type (WT) and hu/hu mice after a single oral dose of iAs (20 ng/g b.w.) and urine and tissues after a 4-week exposure to 400 ppb iAs in drinking water. Hu/hu mice excreted 20% (males) and 35% (females) of the oral dose over 72 hours as compared to 51% and 76% excreted by WT mice. DMAs represented >97% of total As (tAs) in urine of WT mice, but only 40-60% in urine of hu/hu mice (iAs and MAs accounted for 29-54% and 10-17%, respectively). Similar differences in the proportions of As species were found in urine of WT and hu/hu mice exposed to iAs for 4 weeks; tAs concentration was lower in urine of hu/hu mice. After 4 weeks, livers of hu/hu mice contained 20 times (males) and 30 times (females) more tAs than livers of WT mice. iAs and MAs represented 80-86% and 14-20% of tAs in livers of hu/hu mice, respectively, while DMAs accounted for 85-95% of tAs in livers of WT mice. Significant differences in tAs levels and proportions of As species were also found in kidneys; iAs represented 40-50% and MAs 45-55% of tAs in kidneys of hu/hu mice, but only 10-20% and 4-9% in kidneys of WT mice. In summary, iAs metabolism (detoxification) in hu/hu mice is less efficient than in WT mice, resembling the rate and patterns of iAs metabolism in humans. Thus, this humanized mouse strain may be a more adequate model for laboratory studies aiming to reproduce in mice the adverse effects of iAs reported in humans. *This abstract does not reflect US EPA policy.*

2591 Methylmercury-Induced Lipid Accumulation in *Caenorhabditis elegans* Is Dependent on microRNA Expression

T. Nielsen[1], F. Imtiaz[1], N. Crawford[1], M. Martell[1], J. L. Newell-Caito[2], and S. W. Caito[1]. *[1]Husson University, Bangor, ME; and [2]University of Maine, Orono, ME.*

Dyslipidemia is a hallmark of metabolic conditions, such as obesity. Epidemiologic data support an association between blood mercury levels with obesity, lipid dysregulation, and increased visceral adipose tissue. In obesity, activation of adipogenic transcription factors and expression of adipogenic microRNAs (miRNAs) drive the hypertrophy and hyperplasia of adipocytes. We have previously shown that methylmercury (MeHg) increases the expression of adipogenic transcription factors in *Caenorhabditis elegans*; however, there is limited information on how MeHg affects microRNA profiles. We investigated whether altering miRNA expression could prevent lipid accumulation in the worm. Worms that express mutations in *rrf-1* or *rrf-3* are more sensitive to the effects of miRNA, while worms that express mutant *pash-1* or *nrde-2* are more resistant to miRNA than wild type (N2) worms. miRNA sensitive strains were more resistant to MeHg toxicity than N2, while the miRNA resistant strains were more sensitive to MeHg toxicity. These data suggest that the worms express pro-survival miRNA in response to MeHg, which is amplified in the sensitive strains, but absent in the resistant strains. miRNA sensitive strains accumulated less triglycerides and fat deposits than N2 worms. In contrast, miRNA resistant strains had exacerbated triglyceride levels and fat deposition than N2. These data suggest that anti-adipogenic miRNA are enriched in the miRNA sensitive strains, while they are prevented from altering metabolism in the miRNA resistant strains. Behaviors associated with fat accumulation were assessed in the transgenic worms exposed to MeHg. MeHg increases food consumption in N2 worms, which was prevented in the miRNA sensitive worms. Furthermore, miRNA sensitive worms showed improved locomotion and foraging behaviors than the N2 or miRNA resistant worms exposed to MeHg. Together, our data suggest that miRNA expression play important roles in survival responses and lipid homeostasis following MeHg exposure.

2592 Renal Anemia in *itai-itai* Disease: A Case Series Study of Medical Records of the Patients

H. Horiguchi[1], K. Aoshima[2], and E. Oguma[1]. *[1]Kitasato University School of Medicine, Sagamihara, Japan; and [2]Hagino Hospital, Toyama, Japan.*
Sponsor: M. Satoh

Itai-itai disease (IID), characterized by renal tubular dysfunction and osteomalacia, is the most severe form of chronic cadmium (Cd) poisoning developed among female farmers in the heavily Cd-polluted Jinzu River Basin in Japan. Recent researches demonstrated that the patients often suffer from renal anemia, derived from insufficient production of erythropoietin (EPO) from the kidney. In order to clarify the clinical feature of renal anemia in IID, we performed a case series study on the patients with IID, especially in reference to anemia, using electronized archives prepared from their medical records preserved in Hagino hospital. From 288 cases in the archives, we picked out 283 ones (23 males and 260 females, mean age 74.6±8.4 years) whose peripheral blood hemoglobin (Hb) data were available. We collected their clinical data, including age, sex, Hb, erythrocyte counts, hematocrit, serum iron and ferritin levels, history of treatment, etc. Because Hb levels were measured by a cyanmethemoglobin method (in 1975 and after then) or a Sahli method (in 1975 and before then), we analyzed the cases separately by the methods to measure Hb. More than 95% of the cases were suffered from anemia, and about 60% of female cases in 1975 and after then were judged as severe anemia (less than 7 g/dL of Hb). There was no significant relationship between Hb and age. There were 16 cases whose serum EPO levels were measured. Among them, 14 cases were judged as renal anemia, demonstrated by the low levels of serum EPO despite low levels of Hb. However, because there were quite a few cases showing macrocytic or hypochromic anemia, additional mechanisms, such as insufficiency of vitamin B_{12} or iron, might be involved in the development of anemia in IID. According to history of treatment in the cases with renal anemia, EPO substitution therapy was effective for recovery of erythropoiesis, but iron deficiency attenuated its effect. These results indicate that renal anemia, often advancing in severity, is a very important intrinsic clinical sign in IID, and EPO substitution therapy along with iron supplement is recommended for renal anemia in patients with IID.

2593 Sodium Arsenite Alters Glucose Regulation-Associated Transcripts in Sperm Cells of C57BL/6J Mice

A. Venkatratnam. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Exposure to inorganic arsenic (iAs) is associated with both cancer and other diseases such as diabetes in both humans and rodents. In mammals, prenatal exposure to iAs is associated with alterations in the epigenome that are associated with adverse birth outcomes or increased disease risk later in life. In terms of an underlying mechanism, studies have identified altered gene expression and DNA methylation changes as potential mechanisms tied to iAs-driven health effects. Although the effects of prenatal iAs exposure has been assessed, the contribution of preconception exposure to disease risk in offspring has never been systematically studied. In this study, we hypothesized that sub-chronic preconception exposure to iAs would lead to changes in transcript levels regulated through epigenetic mechanisms in parental germline cells that will be inherited by offspring. Adult male and female C57BL/6J mice were exposed to sodium arsenite (0 or 200 ppb) in drinking water for 10 weeks. On week 10, fasted blood glucose and fasted plasma insulin levels were measured and showed no treatment-related effects. iAs treatment was terminated prior to mating and the female mice were closely monitored for pregnancies. Animals from the parental generation were euthanized either prior- or post-mating period. RNA-sequencing was conducted in oocytes and sperm cells from the parental generation. Transcript levels of protein tyrosine phosphatase non-receptor type 2 (*Ptpn2)* were significantly upregulated and gene expressions of endosialin (*Cd248)*, chemokine ligand 8 (*Ccl8)* were found to be significantly down-regulated in sperm cells with iAs exposures. In addition, expression of major vault protein (*Mvp*) and Ras-Related Protein Rab-3D (*Rab3d)* mRNAs were also found to be differentially expressed in relation to exposure. Pathway enrichment analysis in sperm cells revealed perturbation of extracellular matrix (ECM) signaling, protein kinase B, insulin-like growth factor binding, and other pathways that are associated with glucose dysregulation. Results of small-RNA and DNA methylation analyses in sperm cells are currently being analyzed. In summary, these data help address molecular mechanisms underlying iAs-associated disease in response to preconception exposure. A follow-up study will be conducted in the offspring from this study to investigate the relationship to health outcomes.

2594 A Mechanism Underlying the Enhancement of Methylmercury Toxicity through Activation of Transcription Factor HOXB13

T. Toyama, S. Xu, R. Nakano, T. Hasegawa, A. Naganuma, and G. W. Hwang. *Tohoku University, Sendai, Japan.*

Excessive consumption of methylmercury-contaminated fish cause severe central nervous system injury, such as in Minamata disease. Recent epidemiological studies have suggested excessive intake of methylmercury during pregnancy to have an adverse effect on the fetal neural development. However, the molecular mechanisms underlying methylmercury-induced central nervous system injury are still only poorly understood. We recently found that homeobox protein B13 (HOXB13), a transcription factor, is related to methylmercury toxicity; however, the downstream factor involved in enhancing methylmercury toxicity remains unknown. To elucidate the mechanisms involved in the enhancement of methylmercury toxicity by HOXB13, we searched the genes whose expression is induced by methylmercury via HOXB13, using a microarray analysis, and then examined the relationship between a gene, in which some change was recognized after HOXB13 knockdown, and methylmercury toxicity. Methylmercury induced the expression of oncostatin M (OSM), a cytokine belongs to interleukin-6 family, and this was remarkably suppressed by HOXB13 knockdown. OSM knockdown also conferred resistance to methylmercury in HEK293 cells, and no additive methylmercury resistance was observed when both HOXB13 and OSM were knocked down. The binding of HOXB13 to OSM gene promoter was increased by methylmercury, indicating the involvement of HOXB13 in the enhancement of its toxicity. Since addition of recombinant OSM to the medium enhanced methylmercury toxicity in OSM-knockdown cells, extracellularly released OSM was considered to enhance methylmercury toxicity via membrane receptors. We discovered TNF receptor 3 (TNFR3) as the potential candidate involved in the enhancement of methylmercury toxicity by OSM. Overall, we report, for the first time, that HOXB13 is involved in enhancement of methylmercury toxicity via OSM expression induction, and that the synthesized OSM causes cell death by binding to TNFR3 extracellularly.

2595 Oral and Inhalation Bioaccessibility of Cobalt and Nickel in Metal Alloys: A Critical Consideration for Site-Specific Human Health Risk Assessments and Read Across

M. Suh[1], A. Verwiel[2], and D. Proctor[1]. *[1]ToxStrategies Inc., Mission Viejo, CA; and [2]ToxStrategies Inc., San Rafael, CA.*

For risk assessment, nickel and cobalt are evaluated as specific chemicals or pure metal because bioavailability and toxicity vary by extracelluar and intracellular ion solubility. However, nickel and cobalt in alloys, such as stainless steel, do not fit these paradigms because ion solubility may be highly limited by an impervious chromium oxide layer that forms on the surface. Hence, metal ions are not readily released from alloys into biological fluids (limited bioaccessibility and bioavailability). *In vitro* bioaccessibility (IVBA) or bioelution is a test method based on simulated biological fluids to estimate *in vivo* conditions. Arsenic and lead in soil have been tested extensively; IVBA has been used by US regulators for risk assessment and is also under consideration by ECHA for read across. However, for cobalt and nickel, limited *in vitro* and *in vivo* data are available. To expand the database of cobalt and nickel in alloy impacting environmental media, we conducted inhalation and oral IVBA studies using simulated lysosomal and gastric fluids to estimate bioaccessibility of cobalt and nickel in media from 3 facilities in the US Thirty-nine samples of soil, dust, and baghouse dust were tested. Cobalt and nickel content in the samples ranged from 16 to 14,000 mg/kg and from 16 to 45,000 mg/kg, respectively. In simulated lysosomal fluid, bioaccessibility of cobalt and nickel were 4.7% to 21.1% and 3.9% to 10.8%, respectively. In simulated gastric fluid, bioaccessibility of cobalt and nickel were 0.7% to 12.2% and 0.2% to 26%, respectively. Bioaccessibility of cobalt and nickel were inversely related to the cobalt and nickel content in the samples; the results were consistent with a previous bioaccessibility study that we conducted. These data add to the weight of evidence that metals in alloys are resistant to bioelution, have relatively lower potential for absorption as compared to the forms used in animal bioassays, which are the basis of toxicity criteria. Our studies further confirm that bioelution methods should be used for read across and in human health risk assessment.

2596 Integrating Physiologically Based Kinetic Models with Transcriptomics to Support Risk Assessment in Toxicology

P. Singh[1], T. Y. Doktorova[1], T. E. Exner[1], G. Dogruer[2], N. I. Kramer[2], and B. Hardy[1]. *[1]Edelweiss Connect GmbH, Basel, Switzerland; and [2]Institute for Risk Assessment Sciences, Utrecht, Netherlands.*

Transcriptomics is a powerful tool in safety assessment which is used to gain a better understanding of the adverse effects associated with chemical exposures in humans and animals. This technique allows for the identification of toxic specific biomarker genes and to follow their expression changes over time. In this study, we use physiologically-based kinetic (PBK) models in combination with transcriptomics data to explain differences in expression patterns over time and between species. In brief, human and rat *in vivo* and *in vitro* data from kidney and liver tissues, exposed to metals, cadmium and lead was selected and subjected to analyses. Focus was put on transporters and metallothioneins(Mts) genes, to see how dose dependent cadmium correlation to Mts can be reflected in these genes' transcriptomics profiles and how transporter proteins influence the expression pattern of their corresponding genes affecting the absorption, distribution and excretion of these metals. The results indicate that PBPK based simulations of validated cadmium and lead exposure scenarios can be linked to the time profile of transcriptomics analyses. Differences in chemical accumulation between tissues and species indeed help explain the variation in the gene expression levels. The effectiveness of this integrative approach makes PBK models more dynamic which can further aid chemical safety assessment by effectively identifying genes playing a role in disease ontology.

2597 Hematological Profile and Mercury Exposure in Adolescents from the Colombian Caribbean

A. Manjarres-Suarez, and J. Olivero-Verbel. *Universidad de Cartagena, Cartagena, Colombia.*

The blood is a tissue susceptible to cytotoxic agents, in particular, heavy metals such as mercury (Hg). High levels of Hg in humans have received special attention due to the extensive number of adverse effects documented on many systems. In this context, adolescents are a vulnerable group, since some organs are still undergoing development. In general, one of the main routes

of human exposure to Hg is through the consumption of contaminated fish. Therefore, fishing communities located in coastal areas with known Hg releases, for instance, from extinct chloralkali factories, are at risk of developing health problems. The purpose of this research was to study the relationship between hematological parameters and Hg exposure in adolescents living on Tierrabomba Island, a place located near an industrial zone, and in an age-matched group from San Onofre, a distant, non-industrial, coastal community, used for comparison purposes. Hematological parameters were evaluated using an automatized equipment and total Hg in hair was measured employing a direct Hg analyzer. There were significant differences between group means for almost all parameters measured in red blood cells, with greater values found in Tierrabomba, except for RDW. For the white line cell, leucocytes and granulocytes displayed higher values in San Onofre, whereas lymphocyte and monocyte counts were bigger in Tierrabomba. Volunteers from the reference area had mean hair Hg concentrations larger than those from Tierrabomba Island, although in both sampling sites more than 49% of participants had Hg concentrations above international guidelines. For all participants, Hg levels were negative correlated with mean corpuscular hemoglobin concentration (r=-0.162, p=0.024). In the industrial site, Hg correlated with the percentage of monocytes (r=0.193, p=0.041), while in the reference site the association was registered with mid-sized cells (r=0.223, p=0.044). These results suggest that even a low Hg exposure could alter the hematological profile in adolescents. *Colciencias-UniCartagena. Grants 778, 2017 (110777757883); 727, 2015.*

PS 2598 Comparison of Atomizer Design and Concentration of Metals/Elements in Aerosols from Three Generations of Electronic Cigarettes

M. Williams, K. Bozhilov, J. Li, and P. Talbot. *University of California Riverside, Riverside, CA.*

Since their introduction in 2004, electronic cigarettes (EC) have evolved into three distinct generations of devices, which include the cig-a-likes, clearomizers, and mods. The atomizer, which heat the e-fluid, contains various metal components and is important as it affects the performance of ECs and what transfers into the aerosol. The purpose of this study was to examine the elements/metals in EC atomizers and the elements/metals in EC aerosols as a function of evolution, puffing topography, and collection method. Data were consolidated on atomizers from 32 brands representing three generations of ECs (cig-a-likes including cartomizers and disposables, clearomizers, and mods). The atomizers were dissected and photographed using a stereoscopic microscope, then elements in atomizer components were analyzed using scanning electron microscopy and energy dispersive spectroscopy. The concentration of 19-37 elements/metals in aerosols was determined using inductively coupled plasma optical emission spectroscopy. EC atomizers across all generations contained a filament(s) (usually nichrome) and wicks (silicon, cotton). Other major components were: a thick wire (copper, nickel), joints between wires (tin/lead solder, brass clamps, brazing of wires, a sheath(s) (fiberglass)), and Polyfil fibers. Some third-generation models of EC lacked several of these components in their atomizers. Of 37 elements studied, 12 (aluminum, calcium, chromium, copper, iron, lead, magnesium, nickel, silicon, sodium, tin and zinc) were frequently present in EC aerosols across all three generations. Calcium, silicon, and tin often had the highest concentrations (0.012-1.124 mg/L, 0.021-5.581 mg/L, and 0.001-2.645 mg/L, respectively). For some elements, such as arsenic, copper, iron, nickel, lead, tin, the concentration increased in aerosols as voltage/power increased with the introduction of clearomizers and mods. Many of the elements detected in the aerosols originated from components in the atomizers. Concentrations of some elements, such as chromium, lead, and nickel, were higher in aerosols of the later generation ECs and may present a health risk.

PS 2599 Cadmium Accumulation and Effects in Insulin-Producing Beta Cells in the Context of Type 2 Diabetes

W. P. Wong[1], J. Wang[1], J. R. Edwards[2], and M. El Muayed[1]. *[1]Northwestern University Feinberg School of Medicine, Chicago, IL; and [2]Midwestern University, Downers Grove, IL.*

Introduction: Failure of insulin-producing beta-cells in pancreatic islets of Langerhans in the setting of insulin resistance is the underlying cause for type 2 diabetes mellitus (T2DM). Only a third of individuals with significant insulin resistance develop beta-cell failure and diabetes. Genetic susceptibility, lifestyle, and environmental factors contribute to beta-cell failure in T2DM. Environmental contributors toward beta-cell failure in type 2 diabetes mellitus are underexplored. Others and we previously provided evidence for a correlation between cadmium (Cd) exposure and T2DM as well as the accumulation of cadmium in insulin-producing pancreatic beta-cells. We also previously described the presence of a relatively high concentration of Cd in primary insulin-producing islets of Langerhans isolated from the general US population that is correlated with age, supporting prior evidence of a gradual tissue accumulation over time. Furthermore, we found an avid uptake of Cd in isolated insulin-producing beta-cells, likely related to their high endowment of zinc (Zn) transporters and high Zn turnover. In order to recapitulate the effect of chronic Cd exposure on beta-cells *in vivo*, we established murine oral Cd exposure model for the study of Cd-induced dysglycemia. Herein, we report our current findings related to this effort. Methods: C57Bl/6N mice were exposed to $CdCl_2$ or vehicle in drinking water. Obesity and insulin resistance were achieved by placing the animals on high fat diet (42% calories from fat). Results: We established that an oral $CdCl_2$ exposure protocol that consists of a loading period with 0.5mM $CdCl_2$ in drinking water for 120 days followed by a washout period of 90 days yielded blood and islet Cd concentrations within the range found in human blood and islets, thereby representing a relevant islet Cd concentration. In this model, we found significant impairment of insulin secretion during *in vivo* hyperglycemic clamp studies. Next generation mRNA sequencing studies demonstrate a time-dependent alteration in the gene expression profile of insulin-secreting islets of Langerhans in response to Cd exposure. 199 and 206 differentially expressed (DE) genes were found at 1 month and 4 months of exposure respectively. The overlap between the DE genes at these time points was only partial, suggesting time-dependent dynamic effects of Cd on islet physiology.

PS 2600 Chromate-Induced Loss of E2F1 Inhibits RAD51 Response in Homologous Recombination Repair

R. M. Speer[1], X. Zhou[2], K. Liu[2], C. L. Browning[1,3], K. Kondo[4], and J. P. Wise, Sr.[1]. *[1]University of Louisville, Louisville, KY; [2]University of New Mexico, Albuquerque, NM; [3]Brown University (Current Position), Providence, RI; and [4]Tokushima University, Tokushima, Japan.*

Lung cancer is the leading cause of cancer death, however the mechanisms of how lung carcinogens cause cancer are poorly understood. Metals including hexavalent chromium [Cr(VI)] are known to induce chromosome instability, an early event in lung cancer. Failure of homologous recombination repair is a key mechanism of chromosome instability. We have shown particulate Cr(VI) causes DNA double strand breaks and prolonged exposure impairs the effector step of homologous recombination targeting the RAD51 protein. It is currently unknown how Cr(VI) impairs RAD51 function. This study considers the effects of particulate Cr(VI) on transcription of RAD51 specifically focusing on its primary transcription factor, E2F1. The objective of this study was to show prolonged exposure to particulate Cr(VI) inhibits RAD51 expression by affecting E2F1-mediated transcription of RAD51. We found exposure to particulate Cr(VI) reduced RAD51 and E2F1 mRNA and whole cell and nuclear protein levels. Next we showed E2F1 knockdown inhibited the RAD51 response to particulate Cr(VI) by reducing RAD51 expression and nuclear foci formation. Finally, *in vitro* Cr-binding showed Cr(III), not Cr(VI) can bind to acetylated lysine as a potential physical-chemical mechanism of Cr-inhibited function. *This work was supported by the National Institute of Environmental Health Sciences [ES016893 to J.P.W], the Jewish Heritage Foundation for Excellence [JPW], and the NIEHS T32 Training Grant [5T32ES011564-12 to JPW and RMS].*

PS 2601 A Mechanism Underlying Methylmercury-Induced TNF-α Expression in Mouse Brain

T. Hoshi, T. Toyama, A. Naganuma, and G. Hwang. *Tohoku University, Sendai, Japan.*

Methylmercury has been known as a potent neurotoxicant, however the mechanism involved in its neurotoxicity is not fully elucidated. Recently, we found that the TNF-α might play a part in the selective damage of neurons by methylmercury in mouse brain, however the underlying mechanism of its induction is obscure. In this study we examined the responsible cells that involved in the induction of TNF-α by methylmercury to elucidate the detailed mechanism of TNF-α induction by methylmercury in mouse brain. Seven days after subcutaneous injection of C57BL/6 mice with saline or methylmercuric chloride (25 mg/kg) and TNF-α mRNA were determined in the brain by *in situ* hybridization. We found that TNF-α was hardly expressed in the saline-administered group, whereas TNF-α-expressing cells were observed in the whole brain in the methylmercury-treated group. It has been reported that astrocyte and microglia are involved in the induction of TNF-α. Next, we performed immunostaining using antibodies for GFAP or IBA1, which are specifically expressed in astrocyte and microglia, respectively. The TNF-α-expressing cells did not overlap with the GFAP-positive cells, but with the IBA1-positive cells. The results indicate that microglia are mainly involved in TNF-α induction by methylmercury in mouse brain. In addition, methylmercury induced TNF-α

expression in mouse primary microglia and mouse microglial cell line BV-2. MAP kinase pathways are known to be mainly involved in TNF-α induction in microglia. Methylmercury induced phosphorylation of JNK, p38 and ERK, the major MAP kinases, in a does dependent-manner in BV-2 cells. However, an inhibitor of JNK or ERK did not affect TNF-α induction by methylmercury, whereas p38 inhibitor significantly suppressed it. Pretreatment of actinomycin D, a transcription inhibitor, suppressed TNF-α induction by methylmercury. This indicates that several transcription factors may be involved in this induction. Therefore, we performed knockdown of NF-κB (p65) or AP-1 (cJun and/or cFos), which is a transcription factor involved in TNF-α expression and found that only the p65 knockdown partially suppressed TNF-α induction by methylmercury. These results suggest that methylmercury induces TNF-α induction via activating p38 and p65 in microglia.

PS 2602 Blood Metal Correlations in an Urban Population in Brazil

M. M. Paoliello. *Albert Einstein College of Medicine, Bronx, NY.*

Human biomonitoring (HB) approaches have been used to address the relationship between environmental exposures to metals, body burden, and possible adverse health effects. The body burden of metals depends on several factors, such as toxicokinetics, exposure routes and frequencies of exposure. Therefore, HB studies should also consider the possible interaction between metals given that metals share exposure sources and metabolic pathways. A cross-sectional census-based design study was conducted in 2011, enrolling 903 subjects living in an urban population in Southern Brazil. Blood levels of the arsenic (As), cadmium (Cd), cobalt (Co), copper (Cu), iron (Fe), lead (Pb), magnesium (Mg), manganese (Mn), mercury (Hg), molybdenum (Mo), selenium (Se) and zinc (Zn) were quantified by ICP-MS. The aim of the study was to evaluate whether a correlation existed between blood metal levels in a group of hypertensive and non-hypertensive subjects. Using the software R, Pearson's correlation coefficients were calculated to determine correlations between these metals. The following positive correlations ($p<0.01$) were observed in the non-hypertensive group: Cu and Zn (r= 0.709), Fe and Se (r=0.507), Fe and As (r=0.605) and Mg and Fe (r=0.688). In the hypertensive group, correlations between blood Cu and Zn levels (ρ=0.665), blood Fe and As (ρ=0.630) and blood Mg and Fe levels (ρ=0.678) were observed. Few epidemiological studies have addressed and even less so accounted for the potential correlation between metals in the analysis of metal-related health effects. Here, we establish that HB of blood metal levels must take into account interactions between metals, reflecting real life exposure scenarios.

PS 2603 The Fate of Cells That Escape Cr(VI)-Induced Cell Death

S. S. Wise, and J. P. Wise. *University of Louisville, Louisville, KY.*

Hexavalent chromium (Cr(VI)) compounds are known human lung carcinogens; but the carcinogenic mechanism is poorly understood. Cr(VI) induces DNA damage which normally leads to apoptotic responses to avoid transformation and carcinogenesis. Evasion of apoptosis is a hallmark of carcinogenesis, but it is unknown how Cr(VI)-damaged cells are able to escape cell death. We exposed human lung cells to low concentrations of zinc chromate for 6 months (0.0125, 0.025 and 0.05 ug/cm^2). Growth parameters, and chromosome instability were measured every 10 days throughout treatment; soft agar growth was measured in the middle and at the end of treatment. Increases in chromosomal alterations were observed beginning at day 10 and increased with time, increases in numerical chromosome instability were observed before increases in structural instability. No growth in soft agar occurring during the exposure period. At the end of treatment cells were seeded at colony forming density, 10 surviving colonies for each treatment group were randomly selected, expanded into cell lines and characterized to determine permanent changes. All control clones had normal a chromosome complement. 20, 90 and 50 percent of treated clones exposed to 0.0125, 0.025 and 0.05 ug/cm^2 zinc chromate for 6 months exhibited permanent chromosome instability long after the removal of treatment. Eighty percent of abnormal clones were highly aneuploid, containing stable translocations but also many unstable numerical and structural changes. In addition 90% of the abnormal clones were able to grow in soft agar. Future work will identify chromosome specific targets and investigate how they are targeted. These data support a hypothesis that Cr(VI)-treated cells can evade apoptosis and transform into chromosomally unstable cells that continue to survive and grow. *This work was supported by NIEHS grant ES016893 (J.P.W.) and the University of Louisville School of Medicine Basic Grant Program (S.S.W).*

PS 2604 Blood Lead Levels among Auto Mechanics and Health Care Workers in the Gambia: A Case-Control Study

E. Sangyang[1], E. Egiebor[2], P. Bass[3], A. Jabbi[3], M. Ndow[3], O. Adeyemi[4], and L. Fuortes[5]. *[1]Western Kentucky University, Bowling Green, KY; [2]University of Illinois, Springfield, IL; [3]University of the Gambia, Birkama, Gambia; [4]University of Illinois at Urbana-Champaign, Urbana, IL; and [5]University of Iowa, Iowa City, IA.*

Lead is one of the most widely distributed and mobilized environmental pollutants with potential for adverse health effects to humans, especially in unregulated workplaces like the auto-repair industry. In this study, we identified blood lead levels among occupationally exposed workers. The study was conducted among workers in the auto repair workers, and healthcare workers in urban Greater Banjul Metropolitan area of The Gambia. 145 auto repair workers participated as cases and 68 healthcare workers as controls. 69% of cases were between the ages of 18 and 30 years, 24.1% were between 31 to 50 years, and 6.2% were 50+ years. For the control group, 44.1% were between 18 and 30 years; 48.5% between 31 and 50 years; and 7.4% were 50+ years. The study included workers from all sections of auto repair and healthcare industries. LeadCare® II Blood Lead Testing System was used to measure blood lead levels among participants. Blood lead reference level of 5 µg/dL recommended by the CDC was adopted and blood lead levels above 5µg/dL indicated 'elevated' lead exposure. Distribution of blood lead levels by age, gender, ethnicity, marital status, use PPE amongst other variables were examined. Results showed that more than two-third of the participants 50+ years in both the case and control groups had high blood lead levels. Less than half of the participants between 18 and 30 years in the control group had high blood lead level, and more than two-third in the case group had high blood lead level. Years of work had increased odds for high blood lead levels. Workers who worked in the industry for 4 to 9 years (OR=1.45; 95% CI=0.36-5.82); and 10+ years (OR=2.69; 95% CI=0.70-10.34) had increased odds for high blood lead levels. Increased odds for high blood lead levels were found for panel beating (OR=1.49; 95% CI=0.43-5.15) and for no PPE use (OR=21.99; 95% CI=1.39-346.95). The epidemiology of blood lead levels among occupationally exposed workers in The Gambia is similar to those in other low-income countries. This study further emphasis the need to promote and legislate PPE use in occupationally exposed workers.

PS 2605 Systematic Characterization of Hexavalent Chromium and Potential Female Reproductive Outcomes: Application of US EPA Critical Appraisal Tools and Stepwise Inclusion of Mechanistic Data

D. Wikoff[1], A. Franzen[2], G. Chappell[1], M. Harris[3], and C. Thompson[3]. *[1]ToxStrategies Inc., Asheville, NC; [2]ToxStrategies Inc., Monroe, LA; and [3]ToxStrategies Inc., Katy, TX.*

Though female reproductive toxicity has not been the primary endpoint of focus in previous risk assessments for hexavalent chromium [Cr(VI)], additional studies have been published since authoritative assessments. Herein, the objective is to: (1) build on previous assessments, including both newer studies of apical outcomes and mechanistic data, and (2) apply systematic review methods to contribute in developing best practices in systematic review. Evidence was identified using a modified search strategy from the USEPA-IRIS Cr(VI) protocol to identify studies specific to female reproductive effects, resulting in 21 potentially relevant studies in experimental animals (no human data were identified as relevant) characterizing apical outcomes. These studies were then divided into lines of evidence by endpoint (e.g., implantation loss, number of live pups). Critical appraisal, conducted on the experimental level, involves assessment of reporting quality, risk of bias (RoB), and sensitivity, results of which highlight the need for topic-specific refinements to differentiate elements of validity. An added metric in the reporting quality assessment specific to oral feeding studies was to consider the potential reduction of Cr(VI) to Cr(III) and its impact on exposure. The findings determine the need to systematically review the mechanistic data (and demonstrate a stepwise application of systematic review). Initial evaluations of the utility and feasibility of mechanistic data were also conducted based on assessment of high-throughput screening (HTS) data from the ToxCast/Tox21 screening programs. Cr(VI) was tested in 22 assays related to endocrine signaling and exhibited inconsistent results between assays. In order to integrate these data systematically, observed activity (e.g., receptor antagonism) require additional assessment, including critical appraisal and biological-pathway-based considerations (including dose) relative to the potential for adversity. This application highlights the advantages of applying systematic review techniques as part of best practices and the complexities in applying such methods in a reproducible, rigorous, and topic-specific manner to a heterogeneous data set.

2606 Rodent Hair Is a Poor Biomarker for Internal Exposure Dose of Manganese

F. M. Yanko[1], R. C. Balachandran[1], C. N. Rivers[1], S. Tabbassum[1], P. Morcillo[2], A. Akinyemi[2], F. Chen[2], A. C. Pfalzer[3], L. Nie[1], M. Aschner[2], and A. B. Bowman[1]. *[1]Purdue University, West Lafayette, IN; [2]Albert Einstein College of Medicine, Bronx, NY; and [3]Vanderbilt University Medical Center, Nashville, TN.*

Manganese (Mn) is an essential metal in the human body implicated in numerous biological processes including insulin signaling and maintaining normal brain and nerve function. Currently, commonly used biological specimens as biomarkers of over-exposure to Mn include blood, urine, plasma, nails, and hair. The motivation for this study is the absence of evidence for hair as a biomarker to quantify internal *vs* external exposure. Two rodent models of C57BL/6J mice and Sprague Dawley rats were exposed in two blocks of 3 subcutaneous injections every 3 days starting on day 0 and 20. The control group received two blocks of saline (vehicle), the second treatment group received two blocks of Mn (50 mg/kg $MnCl_2 \cdot 4H_20$) and the third group received one block of Mn injections and one block of methylmercury (MeHg) injections. MeHg was used as a positive control (3mg/kg) as it has been shown to accumulate in hair upon internal exposure. Hair was collected from the animals on days 0 and 60 of the study from all treatment groups. The animals were sacrificed on day 60 of the study and tissue samples including brain, liver, and kidney were collected. Mn concentrations in the hair samples were quantified by inductively coupled plasma-mass spectrometry (ICP-MS). Methods for washing and digesting hair samples have been established in the human biomarker literature and were applied here to detect Mn using ICP-MS. Our results from the mice show no significant correlation between internal Mn dose and hair Mn content, whereas hair Hg was significantly elevated in exposed *vs* non-exposed samples ($p<0.001$). We are in process of analyzing the hair samples from rats for hair Mn content. Additionally, whole body Mn content in rats and mice is also being evaluated with *In Vitro* Neutron Activation Analysis (IVNAA). Overall, we find no evidence to support the use of hair as a valid biomarker for internal exposure to Mn at a neurotoxic level.

2607 Prolonged Particulate Hexavalent Chromium Exposure Disrupts Centrosome Regulation Proteins and Causes Centrosome Amplification

J. H. Toyoda[1], J. Martino[1], K. Kondo[2], and J. P. Wise Sr.[1]. *[1]University of Louisville, Louisville, KY; and [2]Tokushima University, Tokushima, Japan.*

Hexavalent chromium [Cr(VI)] is a well-known lung carcinogen with environmental and occupational exposure risks. A key mechanism for Cr(VI) carcinogenesis is induction of chromosome instability (CIN), including changes in chromosome number which can arise due to centrosome amplification. Centrosome amplification is observed in many types of cancers and is present in neoplasias, tumors, and is associated with aggressive cancers. This study examines centrosome amplification in Cr(VI)-exposed human lung cells and human lung tissue, and investigates the mechanism of Cr(VI)-induced centrosome disruption in human lung cells. Our hypothesis is Cr(VI) disrupts proteins that regulate centrosome duplication, leading to centriole disengagement and centrosome amplification. Centrosome amplification was measured by fluorescent immunostaining of gamma-tubulin, a centrosome marker, in lung tumor tissue from chromate workers and in Cr(VI)-exposed human lung cells. In Cr(VI)-exposed human lung cells, centriole disengagement was analyzed by fluorescent immunostaining of centrioles with CNAP1 and centrin, markers for the proximal and distal centriole ends. Protein extracted from Cr(VI)-exposed human lung cells was analyzed by western blot. During interphase in normal cells, centriole engagement blocks premature centrosome duplication. Our findings show increasing concentrations and prolonged exposure to Cr(VI) increased centriole disengagement in human lung interphase cells. We also measured decreased protein levels of the separase inhibitors, securin and cyclin B1, which are key to regulating the centrosome cycle. Supernumerary centrosomes were observed in human lung tumor tissue from chromate workers. Together, these data demonstrate prolonged Cr(VI) exposure induces centriole disengagement, centrosome amplification, and causes decreased levels of proteins that inhibit centriole disengagement. Ongoing studies using securin and separase siRNA knockdown are elucidating the role of these proteins in the Cr(VI) carcinogenic mechanism. *This work was supported by NIEHS grant R01ES016893 (J.P.W.) and T32-ES011564 (J.H.T.).*

2608 Formation of Plumbojarosite (PLJ) Reduces Bioavailability of Soil-Borne Lead (Pb)

R. Karna[1], M. Noerpel[2], C. Nelson[3], B. Elek[4], K. Herbin-Davis[3], G. L. Diamond[5], K. D. Bradham[3], K. Scheckel[2], and D. J. Thomas[3]. *[1]US Army Corps of Engineers, Vicksburg, MS; [2]US EPA, Cincinnati, OH; [3]US EPA, Research Triangle Park, NC; [4]Oak Ridge Institute for Science and Education, Research Triangle Park, NC; and [5]SRC Inc., Syracuse, NY.*

Exposure to Pb during early life has long-lasting adverse effects on health. Ingestion of Pb-contaminated soil is a major route for exposure of children to this toxic metal. Soil remediation procedures that alter physiochemical properties of soil-borne Pb can limit exposure by reducing gastrointestinal Pb uptake. A novel approach for remediation of soil Pb uses addition of iron (Fe) sulfate and application of heat to promote formation of PLJ, a poorly soluble Pb-Fe sulfate compound. Here, two Pb-contaminated soils and samples of a low-lead soil spiked with various Pb compounds (i.e., carbonate, chloride, phosphate, or sulfate) were treated to convert native Pb species to PLJ. We used a mouse assay to examine tissue Pb distribution after ingestion of diets amended with untreated or treated soils. Bone and blood Pb levels were determined to evaluate uptake across the gastrointestinal barrier. For both Pb-contaminated soils and all Pb compounds, bone and blood Pb levels were significantly lower ($P<0.001$, student t-test) in mice that consumed diets amended with treated soils than in mice that consumed diets amended with untreated soils. After treatment, estimated relative bioavailability (RBA) of Pb in both soils and for all Pb compounds were reduced by more than 90% compared to RBA estimates for untreated soils or compounds. X-ray absorption spectroscopy was used to determine Pb species in soil-amended diets and in feces excreted by mice consuming these diets. Treatment of Pb-contaminated soils or Pb compounds consistently converted more than 90% of all Pb species in these materials to PLJ. Speciation of Pb in feces from mice fed diets containing soils or Pb compounds treated to promote PLJ formation found no evidence that ingested PLJ underwent chemical transformation during transit of the gastrointestinal tract. This evidence suggests that formation of PLJ could be an effective strategy to reduce the RBA of Pb in soil and minimize this medium's role as a source of exposure to Pb in young children. *This abstract does not represent US Environmental Protection Agency policy.*

2609 Mechanism of Cadmium Carcinogenesis—Epigenetic Modification and the Induction of CSC-Like Cells

H. Lin, Y. Li, Z. Wang, and C. Yang. *University of Kentucky, Lexington, KY.*

Cadmium (Cd) is a ubiquitous pollutant in the environment and a known carcinogen causing lung cancer. However, the mechanism of Cd carcinogenesis has not been well defined. Cd is considered a weak mutagen and has been suggested that it causes non-genotoxic effects such as epigenetic modifications. The goal of this study is to investigate the role and mechanism of epigenetic deregulations in Cd exposure-induced cell transformation, cancer stem cell (CSC)-like cell property and tumorigenesis. After 9 months of Cd exposure, malignant transformation of immortalized human bronchial epithelial cells (BEAS-2B) was evidenced by increased formation of colonies in soft agar, suspension culture spheres and tumor formation in nude mice. Suspension sphere formation assay demonstrated that Cd-transformed cells display CSC-like property, which was further evidenced by increased aldehyde dehydrogenase (ALDH) activity, up-regulated CD133 expression level, as well as increased expression of several stemness-related proteins, including Nanog, Oct4, Klf4, Klf5, and c-Myc. That only CD133-positive population capable of forming spheroids suggests that CD133 could be a cell surface marker of the induced CSC-like population. Increased levels of DNA and histone methyltransferases, as well as elevated levels of histone 3 lysine 9 and 27 methylation indicate that chronic Cd exposure causes epigenetic dysregulations. In addition, several oncogenic long non-coding RNAs (lncNRAs), such as DUXAP10 and HOTAIRM1, were found up-regulated in Cd-transformed cells. Moreover, knockdown of DUXAP10 leads to decreased expression of stemness-related genes and reduced number of suspension culture spheres. In conclusion, long term Cd exposure causes cell malignant transformation. The transformed cells displayed CSC-like property. Epigenetic dysregulations may contribute to Cd-induced CSC-like property and cell transformation.

2610 Loss-of-Function Variant in the BCRP/*ABCG2* Transporter Increases Cadmium Renal Injury *In Vitro*

X. Wen[1,2], C. Doherty[2], B. Buckley[2], and L. M. Aleksunes[1,2]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; and [2]Environmental and Occupational Health Sciences Institute, Piscataway, NJ.*

Cadmium is a high priority environmental pollutant present in tobacco smoke and contaminated foods. With chronic exposure, cadmium accumulates in multiple tissues including the kidneys where it causes toxicity. The breast cancer resistance protein (BCRP, *ABCG2*) is an efflux transporter in kidney tubules that facilitates the urinary secretion of drugs and toxins. Our previous studies indicate that the *ABCG2* genetic variant Q141K (C421A) reduces transport of BCRP substrates due to altered membrane trafficking. In the current study, we sought to 1) assess the *in vitro* ability of BCRP to efflux cadmium and protect kidney cells from injury and 2) determine whether this protection is disrupted by the Q141K variant. Cadmium ($CdCl_2$) accumulation and cellular stress and toxicity were assessed in human embryonic kidney 293 (HEK293) cells stably expressing plasmids containing an empty vector (EV), BCRP wild-type (WT), or BCRP variant (Q141K) gene. Intracellular $CdCl_2$ accumulation was significantly higher in EV cells compared to BCRP WT cells, confirming that cadmium is a novel substrate of BCRP. Following exposure to $CdCl_2$ (2.5 to 10 μM) for 48 h, greater apoptosis (100-300%) was observed in EV cells compared to WT BCRP cells. Exposure to $CdCl_2$ (0.5 and 1 μM) induced mRNA and protein expression of stress-related genes including metallothionein 1A and 2A (MT-1A and 2A), NAD(P)H quinone dehydrogenase 1 (Nqo1), and heme oxygenase (HO-1) to a greater extent in EV cells compared to WT BCRP cells. While the BCRP Q141K variant protected against $CdCl_2$-induced activation of stress pathways and cytotoxicity compared to EV cells, the extent of protection was less than that observed with WT BCRP. In conclusion, the BCRP/*ABCG2* transporter protects against cadmium toxicity through active efflux from kidney cells, a response that is limited by the loss-of-function Q141K genetic variant. *Supported by R01ES029275 and P30ES005022.*

2611 Trophic-Level Interactive Effects of Dietary Nutrients (Phosphorus and Nitrogen) on the Toxicities of Cadmium, Arsenic, and Their Binary Mixtures

O. M. Awoyemi, A. Peace, and G. D. Mayer. *Texas Tech University, Lubbock, TX.*

Various anthropogenic activities alter the concentrations of dietary nutrients in environmental media. These stoichiometric changes may interact with the uptake and effects of metals in exposed organisms. It is therefore important to assess trophic-level interactive effects of the changes in media and dietary nutrients on the toxicities of metals; to provide nutrient-mediated risk factors of toxic metals exposures in environmental media. This study investigates the single and joint toxicities of cadmium (Cd) and arsenic (As) in algae, *Scenedesmus acutus* and *Daphnia pulex*, under varied media and dietary phosphorus (P) and nitrogen (N) conditions. Acute studies were conducted to assess the IC_{50}s (7 d) and LC_{50}s (24, 48, 72, and 96 h) of the metals (Cd and As) against *S. acutus* and *D. pulex*, respectively, when acting singly and as a binary mixture. Algae growth rate and the 7-d IC_{50}s were determined under low (20% P, 25% N), median (60% P, 62.5% N) and optimum (100% P, 100% N) dietary nutrients of a COMBO media. Chronic studies (14 d – 21 d) were conducted to assess the developmental (survival, growth), reproductive (brood size, timeline), behavioral (distance moved, velocity, acceleration) and physiological (feeding, heartrate, respiration) responses of *D. pulex* exposed to Cd (0, 18.75, 37.5 and 75.0 μg/L) and As (0, 625, 1250 and 2500 μg/L) under low, median and optimum media and dietary P and N conditions. Results showed enhancement of Cd and As toxicities (singly and mixture) against *S. acutus* and *D. pulex* cultured under low P and low N conditions. There was a concentration-dependent decrease in *S. acutus* growth rate with IC_{50}s in the order Cd+As > Cd > As in Low P > Low N > COMBO media with evidences of hormesis. Furthermore, binary mixtures of Cd and As against *D. pulex* were additive (24 h) and synergistic (> 24 h) with significant interaction ($p<0.05$) effects of media nutrients, Cd and As on algae growth, and survival, reproduction, physiology and behavior of *D. pulex*. The importance of taking into account the interactive effects of contaminant mixtures and dietary nutrients in environmental media on toxicity outcomes for effective risk assessment was discussed.

2612 Understanding the Role of the Manganese Transporter Slc30a10 in Developing Mice

H. Conboy, M. Prajapati, C. Mercadante, and T. Bartnikas. *Brown University, Providence, RI.*

Manganese (Mn) is an essential, but potentially toxic trace metal acquired through the diet. Mn excess leads to a Parkinson's-like disorder which is most commonly seen in industrial workers. Young individuals are believed to be particularly susceptible to the irreversible damages of Mn excess due to poor development of regulatory absorption and excretion pathways. Therefore it is important to better understand early mechanisms of Mn metabolism to prevent Mn toxicity. In 2012, the first case of inherited Mn excess was identified. Patients exhibited systemic Mn excess, liver cirrhosis, a Parkinson's-like disorder, and polycythemia (increased red blood cell counts). Mutations were identified in SLC30A10. In this study, we hypothesize that SLC30A10 plays a key role in Mn homeostasis during development. To address this, we generated a global Slc30a10-deficient (*Slc30a10$^{KO/KO}$*) mouse line. *Slc30a10$^{KO/KO}$* mice are smaller than wild-type littermates. Postnatal day (P) 14 *Slc30a10$^{KO/KO}$* mice exhibit comparable Mn levels as *Slc30a10$^{+/+}$* mice. However, by P21 *Slc30a10$^{KO/KO}$* mice exhibit a 17-fold increase in liver Mn levels. Interestingly Mn levels in *Slc30a10$^{KO/KO}$* mice decrease in the liver by P28, suggesting the development of other Mn excretion pathways. To evaluate the development of Mn excretion in developing mice, a radioactive approach was utilized. In this experiment, ^{54}Mn is injected intraperitoneally at P14. Whole body counts are then recorded every other day until the time of harvest. While *Slc30a10$^{KO/KO}$* mice develop severe Mn excess, the development of the capacity to excrete Mn is only delayed, not abolished, in these mice. This suggests that factors other than Slc30a10 play key roles in the development of Mn excretion. We hypothesize that the development of Mn excretion is both Slc30a10- and Mn-dependent. When *Slc30a10$^{KO/KO}$* mice are raised on a Mn-deficient diet, the development of Mn excretion is further delayed despite attenuated tissue Mn excess. We speculate that Slc30a10-independent mechanisms of excretion are induced when tissue Mn levels exceed a threshold, but this threshold decreases with age. We predict developing mice require a higher threshold of Mn to develop the ability to excrete Mn when compared to older mice. Overall, this study establishes early mechanisms of Mn regulation and suggests Slc30a10 plays a critical role in preventing Mn toxicity during development.

2613 Cellular and Molecular Mechanisms Underlying Arsenic-Associated Dysregulation of the Glucocorticoid Receptor (GR) Signaling Pathway in the Placenta

C. J. Meakin, J. T. Szilagyi, and R. C. Fry. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

In utero exposure to inorganic arsenic (iAs) is linked to many early and later life adverse health effects. The development of these health outcomes may be related to altered function of nuclear transcription factors in the placenta, such as the glucocorticoid receptor (GR). We have previously shown that placental exposures to environmentally-relevant levels of iAs are associated with a dysregulation in placental mRNA expression and DNA methylation of GR-associated genes that play a role in fetal growth and development. Of relevance to iAs-associated health outcomes is the metabolism of iAs into its monomethylated (MMAs) and dimethylated metabolites (DMAs), which have different toxicological endpoints compared to iAs. Given this, we investigated cellular mechanisms that underlie observed modulation of the placental GR signaling pathway, and to determine if iAs metabolites alter expression of GR genes. JEG-3 cytotrophoblasts were treated with non-toxic doses of iAs^{III} (0.5-3 μM) and MMA^{III} or DMA^{III} (0.05-0.25μM) for 24 hours. To examine if GR signaling cellular processes may be dysregulated by iAs exposure, we evaluated GR activation and nuclear translocation, among others in the iAs treated samples. A reduction in nuclear translocation of the GR was observed following iAs exposure, which may drive the observed repression of GR-associated mRNA expression at higher doses of iAs. A biphasic dose-response was observed with GR activation following iAs treatment, with low doses hyperactivating GR, and high doses reducing GR activity. These data are important as they coincide with previously observed biphasic responses in GR-associated gene expression following iAs treatment. MMA^{III} and DMA^{III} were found to be associated with alterations in eight GR-associated genes including metallothionein 2A (*MT2A)*, interleukin 6 Receptor (*IL6R),* and TNF alpha induced rotein *(TNFAIP)*, which play a role in placental pathophysiology and fetal development. This study builds on previous evidence from our lab that iAs disrupts GR signaling in the placenta, provides a novel cellular mechanism that may underlie iAs alterations in placental GR signaling, and demonstrates a relationship between iAs metabolite exposure and genomic modulation of the GR-pathway in the placenta.

2614 Arsenic and Benzo(a)pyrene Co-exposure-Transformed Cells Display Apoptosis Resistance by Upregulating Mcl-1 Expression Level through Synergistically Activating the PI3K/Akt Pathway

P. Yang, Y. Li, J. Xie, M. Lin, F. William, C. Marco, M. B. Uddin, H. Tao, C. Yang, and Z. Wang. *University of Kentucky, Lexington, KY.*

Both arsenic (As) and benzo(a)pyrene (BaP) are known human carcinogens causing lung cancer. Human exposure to As and BaP is common and co-exposure to As and BaP could cause more than an additive effect than exposure to As or BaP alone. Our recent study showed that As and BaP co-exposure caused a synergistic effect in inducing cell malignant transformation, cancer stem cell (CSC)-like property and tumorigenesis. However, the underlying mechanism remains largely unknown. Evading apoptosis is one of well-established hallmarks of cancer. The goal of this study was to investigate whether As and BaP co-exposure-transformed cells display apoptosis resistance, which contributes to their increased malignant property. It was found that As and BaP co-exposure transformed cells (BEAS-2B-As+BaP) exhibit a significantly stronger resistance to apoptosis induced by treatment with ABT-737, etoposide, cisplatin or doxorubicin. Mechanistic studies revealed that BEAS-2B-As+BaP cells have a significantly higher expression level of the anti-apoptotic protein Mcl-1 than that of cells transformed by exposure to As (BEAS-2B-As) or BaP (BEAS-2B-BaP) alone. Stably knockdown Mcl-1 greatly reduced apoptosis resistance of BEAS-2B-As+BaP cells to ABT-737 treatment. Mcl-1 knockdown in BEAS-2B-As+BaP cells also significantly reduced their CSC-like property. Further mechanistic studies revealed that As and BaP co-exposure increases Mcl-1 level by synergistically activating the PI3K/Akt pathway. Pharmacological inhibition of PI3K/Akt significantly reduced Mcl-1 level in BEAS-2B-As+BaP cells and decreased their resistance to apoptosis induced by ABT-737 treatment. In contrast, stably expressing a constitutively active Akt (myr-Akt) reversed the effect of PI3K inhibition on Mcl-1 level and apoptosis resistance. It was further determined that PI3K/Akt pathway activation up-regulates Mcl-1 level in BEAS-2B-As+BaP cells by increasing Mcl-1 protein stability through reducing Mcl-1 ubiquitination. Together, these findings suggest that As and BaP co-exposure-transformed cells display a stronger resistance to apoptotic cells death, which may contribute significantly to the synergistic carcinogenic effect of As and BaP co-exposure.

2615 Alteration of *Drosophila* Nrf2 Signaling in Developing Neuromuscular Compartments Mediates Methylmercury Impacts on a Neuromotor Behavior

J. T. Gunderson, and M. D. Rand. *University of Rochester, Rochester, NY.*

Methylmercury (MeHg) is a developmental toxicant. Exposure to MeHg *in utero* can lead to neurocognitive and neuromotor deficits in children. The presentation of neuromotor deficits suggests that MeHg may contemporaneously target developing neurons and muscles. Induction of oxidative stress is an established mechanism of MeHg toxicity, in which the Nrf2 antioxidant pathway is a recognized protective mechanism. Tissue-specific investigations into the role of Nrf2 moderating MeHg-induced oxidative stress have been limited to cell culture, making it difficult to pair findings with a neuromuscular output. *Drosophila melanogaster* contains a homologous inducible antioxidant pathway, whereby the *Drosophila* CncC protein is the ortholog to the mammalian Nrf2 protein. Nrf2 and CncC are both negatively regulated by Keap1. Our lab has established eclosion, a neuromuscular behavior required for adult *Drosophila* emergence from the pupal case, as a sensitive functional output of MeHg toxicity. Developmental exposure to MeHg induces a "balling" or myosphere phenotype in the developing indirect flight muscles (IFMs). We hypothesize that increased CncC signaling across various developmental windows and neuromuscular compartments will enhance eclosion ability and protect muscle development by reducing MeHg-induced oxidative stress. Utilizing the GAL4/UAS transgene technique, an increase in CncC signaling via CncC overexpression or knockdown of Keap1 exclusively in developing CNS neurons, motor neurons, or musculature rescues eclosion ability upon MeHg exposure. With epifluorescence imaging, we observe a decrease in myosphere numbers in the developing IFMs with increased CncC signaling in muscles or neurons upon MeHg exposure. Measuring relative ROS levels, through the DCF-DA assay, indicated that a tissue-specific increase in CncC signaling decreases MeHg-induced ROS, suggesting rescue in eclosion and IFM development by increased CncC signaling occurs via reducing MeHg-induced ROS. These findings support the notion that sensitive non-neuronal target tissues of MeHg toxicity exist, providing evidence that neuromotor deficits seen in children with *in utero* MeHg exposure could be caused by disruption in both neurogenic and myogenic processes. Future research will be aimed at understanding myogenesis as a target in MeHg-mediated neuromuscular behavioral deficits. *Supported by R01ES025721 and T32ES007026.*

2616 Using Gene Expression Analysis to Support Risk Assessment of Metal Mixtures in Freshwater Systems

D. L. Cucchiara[1], D. A. Arndt[1], J. S. Meyer[2,3], C. D. Vulpe[1], and J. F. Ranville[2]. *[1]University of Florida, Gainesville, FL; [2]Colorado School of Mines, Golden, CO; and [3]Applied Limnology Professionals LLC, Golden, CO.*

Mining waste can impact ecosystems worldwide, and the associated releases of potentially toxic metals may threaten human and environmental health. Current regulation of metal-impacted freshwaters is informed using bioavailability models such as the Biotic Ligand Model (BLM). The BLM predicts toxicity based on water chemistry at an impacted location and on the consequent inferred accumulation of metals in the organism. Typically, these models assume additive toxicity in metal mixtures, meaning the total toxic effect is approximately a linear combination of the toxicities of each metal when acting alone. In previous work, we demonstrated that at median concentrations of both metals, some mixtures of Cd and Zn and some mixtures of Cd and Ni result in less-than-additive, acute toxicity (i.e., a protective effect) to *Daphnia magna*, an aquatic invertebrate. We also demonstrated, using RNA-seq and inductively coupled plasma - mass spectrometry (ICP-MS) that the protective (less-than-additive) effect observed in Cd-Zn mixtures does not appear to be fully explained by simple competition between the two metals for binding to a biotic ligand. RNA-seq data suggests that a mechanistic physiological response contributes to the Cd-Zn mixture effects. *Daphnia* exposed to moderately toxic doses of Cd alone differentially expressed over 1000 genes (DEGs) at False Discovery Rate (FDR) <0.1. Interestingly, in the Cd-Zn mixture at the same Cd concentration, the number of DEGs decreased to 291. Of the 291 DEGs, 282 were shared between Cd and the Cd-Zn mixture. Exposure to Zn alone at the same Zn concentration as in the mixture resulted in only 24 DEGs. We suggest that these finding are not consistent solely with metal-metal binding competition at a biotic ligand. Biological-pathway and cellular-process analyses support an organismal physiological response as a key role in the less-than-additive (protective) effects. Diverse cellular responses were identified in the Cd-only exposure that are consistent with the observed toxicity, including induction of the unfolded protein response (UPR), antioxidant responses such as induction of glutathione biosynthesis, glutamate-mediated signaling, and down regulation of genes related to digestive proteolytic enzymes. Interestingly, several key responses appear to be mitigated in the mixture treatment group. Specifically, the induction of the unfolded protein response and the glutamate-mediated signaling were not observed in Cd-Zn mixture. Some biological effects, such as the induction of glutathione, are present in both the Cd-only treatment and the mixture treatment. These finding are consistent with a model in which Cd is still bioavailable in the mixture, but Zn may prevent deleterious physiological effects. An enhanced understanding of the interaction between Cd and Zn (as well as Cd and Ni) will allow development of more accurate models of metal-mixture toxicity for use in risk assessments. Overall, this work indicates an important role for an internal physiological interaction in the presence of metal mixtures. More work is required to better understand that role.

2617 Selenium Protection against Inorganic Mercury-Induced Cytotoxicity via Modulating Oxidative Stress in PC12 Cells

K. F. Hossain, and M. Kurasaki. *Hokkaido University, Sapporo, Japan.*

Mercury (Hg) in its all forms, including inorganic Hg (iHg) is an environmental contaminant that could induce toxicity and diseases in human. However, a little has been known about the underlying mechanisms responsible for iHg toxicity. Selenium (Se) is an essential trace element, recognized as an antioxidant and protective agent against metal toxicity. The purpose of this research was to elucidate the molecular mechanism of iHg induced toxicity as well as, to investigate the ameliorative effects of Se against iHg induced toxicity in PC12 cells. Cytotoxic assays have been shown that iHg (5 μM) induced oxidative stress and intrinsic apoptotic cell death *via* oxidizing glutathione, damaging DNA, degrading cell membrane integrity, down-regulating mTOR, p-mTOR, akt, ERK1 and caspase 3, and up-regulating cleaved caspase 3 and cytochrome c release in PC12 cells upon 48h of exposure time. Moreover, flow cytometry analysis confirmed iHg induced apoptosis in the cells. Again, co-treatment of Se (5 μM) appeared to inhibit intrinsic apoptosis and oxidative stress induced by iHg (5 μM) *via* boosting GPx amount, improving glutathione content, limiting DNA degradation, improving cell membrane integrity, up-regulating mTOR, p-mTOR, Akt, ERK1and caspase 3, and down-regulating cleaved caspase 3 and cytochrome c leakage in PC12 cells. In addition, flow cytometry analysis confirmed Se-protection of cells from iHg induced apoptosis. The contribution of nrf2 and HO-1 activation was not significant in iHg-toxicity or Se-protection mechanisms in PC12 cells. In conclusion, these results suggested that glutathione level decrease plays a critical role in iHg induced oxidative stress and co-treatment of Se attenuates iHg-cytotoxicity through its antioxidant properties.

2618 Manganese-Induced Parkinsonism Is Not Associated with Dopamine Neuron Loss in the Midbrain of Nonhuman Primates or SLC39A14 Knockout Mice

A. N. Rodichkin[1], M. Edler[2], J. McGlothan Dziedizic[1], and T. Guilarte[1]. *[1]Florida International University, Miami, FL; and [2]Kent State University, Kent, OH.*

Humans with chronic exposure to high levels of Mn exhibit parkinsonism with dystonia that is refractory to L-dopa, an effective therapy used in idiopathic Parkinson's disease (iPD). iPD is characterized by degeneration of dopaminergic (DA) neurons in the substantia nigra pars compacta (SNpc) and the presence of Lewy bodies whereas Mn-induced neurotoxicity results in cell loss and gliosis in the globus pallidus, inhibition of striatal dopamine release, and an apparent absence of Lewy bodies and DA neuron loss in the SNpc. A major limitation of prior neuropathological investigations in animal models of Mn-induced parkinsonism was the lack of unbiased stereological quantification of DA neuron numbers in the SNpc. Here, Mn-exposed non-human primates and a genetic mouse model of Mn-induced parkinsonism were used to ascertain if neurotoxic brain levels of Mn impacted dopamine neuron density (TH Nv) or soma volume in the SNpc. Adult male cynomolgus macaques (ages 6-11 years) were given saline (n = 15) or 50 mg/mL of MnSO4 monohydrate (n = 8) intravenously twice per week for a minimum of one year. Several animals also received amphetamine (AMPH, 2 mg/kg) during PET scans to measure dopamine release in the frontal cortex. TH Nv was quantified for the entire SNpc in macaques and mice, as well as in the dorsomedial (DM) and ventrolateral (VL) subfields in macaques. Mn exposure was not associated with DA neuron loss in the SNpc regardless of AMPH exposure in macaques (p's ≥ 0.19) or in adult *SLC39A14*-KO male (p = 0.96) compared to control macaques or WT adult mice. Mn treatment in macaques was correlated with significantly decreased VL SNc TH soma volume (p = 0.02), and Mn-treated macaques with AMPH exposure for PET imaging had greater DM and total SNc TH Nv compared to both PET-imaged controls and non-imaged Mn-treated animals (p's = 0.01). Furthermore, the motor function deficits that were observed in the SLC39A14-KO mice were not associated with striatal dopamine depletion. These data support previous findings in humans that Mn exposure spares the DA system in the SNpc and that Mn-induced parkinsonism and iPD are distinct diseases with different neuropathological etiologies. *Funding: NIH R01ES010975, TRG.*

2619 Trace Element and Blood Film Biomonitoring in Adolescents from Fishing Communities at the Caribbean

A. Manjarres-Suarez[1], A. Gonzalez-Montes[1], J. Galvis-Ballesteros[1], J. De la Rosa[2], and J. Olivero-Verbel[1]. *[1]Universidad de Cartagena, Cartagena, Colombia; and [2]Universidad de Huelva, Huelva, Spain.*

Human activities performed with inadequate regulation and supervision, increase the load of trace elements in the environment resulting in pollution. This situation is a growing problem in public health since there is a continuous exposure to these chemicals in people who live near to industrial areas, in particular, for some vulnerable groups, especially adolescents, due to their stage of development. Analysis of these elements in human hair has been reported as an indicator of regional geochemistry and health status. The aim of this study was to evaluate the relationships between hair trace element levels and the different blood cell types in adolescents living on Tierrabomba Island, Colombia, located near an industrial area. Individuals from San Onofre, a non-industrial site, were used as reference. Hair samples were collected to quantify trace metals by ICP-MS and peripheral blood samples to perform blood film analysis. Boron, arsenic, cadmium and tungsten levels were greater in Tierrabomba Island. Scandium, cobalt, zinc, yttrium, tin and barium concentrations were superior in the reference site. Statistical differences between studied groups were registered for several blood smear parameters, such as lymphocyte, eosinophil and monocyte percentages, as well as for hypochromia and anisocytosis. Barium content was associated with fish consumption. A significant positive correlation was found for scandium and neutrophils (r=0.156, *p*=0.017), but it was negative for lymphocytes and platelets. Cadmium, vanadium, nickel, molybdenum, copper, tin, barium, tungsten and lead correlated negatively with platelets. Arsenic was positively linked to eosinophils (r=0.130, p=0.047). Interestingly, yttrium correlated with micronucleus frequency (r=0.148, *p*=0.024). These results indicate exposure to trace elements is a risk factor for the blood system health in adolescents from fishing communities. *Colciencias-University of Cartagena (Grant 110777757883, 778/2017; 727-2015).*

2620 Kiwifruit Peel Beads for Removing Heavy Metals from Drinking Water by Biosorption

R. J. Singh, C. E. Martin, D. Barr, and R. J. Rosengren. *University of Otago, Dunedin, New Zealand.*

Contamination of drinking water with heavy metals is a serious concern and sustainable techniques are being developed to cater to communities across the globe for the low-cost removal of these toxicants. Biosorption is one such method because of its advantage of being economical and generating non-toxic sludge. In this study, chemically unmodified kiwifruit peels (KP) were immobilised on sodium alginate as beads and used to study the biosorption removal of arsenic (As V) and six heavy metals, namely, cadmium (Cd II), chromium (Cr VI), copper (Cu II), mercury (Hg II), lead (Pb II) and nickel (Ni II) from a cocktail solution at low concentration (0.1 mg L-1) and neutral pH conditions simulating that of drinking water. Results showed that KP bead biosorbed Cd, Cu, Ni, Pb, Hg, Cr and As ions with approximately 92%, 84%, 75%, 67%, 56%, 34% and 17% biosorption, respectively at equilibrium and neutral pH. Kinetic data were modelled by standard biosorption models such as film diffusion (FD), pore diffusion (PD), pseudo-first order (PFO), pseudo-second order (PSO) and Elovich equation. The rate of diffusion and surface attachment was the fastest for Hg followed by Cd and Ni ions. Elovich Equation was the least fitting model suggesting that the biosorption of ions by KP bead was not by chemisorption. Thermodynamic studies revealed that the biosorption of ions by KP bead were endothermic reactions that were spontaneous and physical in nature. KP beads can, therefore, be used as effective biosorbents for removing heavy metals from drinking water.

2621 Synthesis and Structural Analysis on Ionic Triphenyltin Chloride Complexes with Oxalic Acid

J. Witter, X. Song, T. Henry, and W. Li. *University of the District of Columbia, Washington, DC.* Sponsor: R. Sneed

There is a large need for the development of novel metal-based anticancer agents due to the low solubility and high organ toxicity of metal-based compounds such as cisplatin and its analogues. Triorganotin derivatives have been the interest of many chemists due to their biological properties against bacteria, fungus, and cancer cell lines. However, their applications are limited due to their poor water solubility. On the other hand, ionic triorganotin complexes may have improved solubilities due to their partially ionic characteristics. Our hypothesis is that ionic triorganotin derivatives will have better solubility and better activity as potential anticancer agents with reduced toxicity. Therefore, the goal of the research is to synthesize triphenyltin complexes with ionic characteristics. Syntheses of the ionic triphenyltin complex involved the reaction of a diprotic carboxylic acid, with triphenyltin hydroxide or chloride in the presence of di-ethylamine. IR/NMR spectroscopy and X-Ray Crystallography studies showed that an ionic triphenyltin complex was successfully obtained in both reactions. The ionic complex consists of a triorganotin anionic moiety, and a diethylammonium as the counterion. The anionic triphenyltin moieties has a distorted cis-trigonal bipyramid (TBP) geometry with two carbon and one oxygen atom occupying the equatorial positions and an oxygen atom and phenyl group occupying the axial positions. The ionic complex is essentially a dimer through extensive hydrogen-bonding network between the carboxylate groups (OCO) and the N atom from the ammonium cation. The results indicate ionic triphenyltin complexes can be successfully obtained in a substitution reaction of either triphenyltin chloride or hydroxide with a diprotic oxalic acid in the presence of an organic amine. Future studies will be focused on collecting data on its aqueous solubility and biological activity.

2622 Overexpression of hsa-miR-186 Induces Anchorage-Independent Growth and Chromosomal Alterations in Arsenic-Exposed Human Keratinocytes: A Preliminary Study

A. Lykoudi[1], A. Cardoso[1], J. Wu[2], S. Wise[1], and J. States[1]. *[1]University of Louisville, Louisville, KY; and [2]Southern Medical University, Guangzhou, China.*

Chronic arsenic (As) exposure through drinking water is a global health issue, affecting >200 million people. As is a group I human carcinogen and a clastogen causing chromosomal instability (CIN). Skin is the primary target organ for As toxicity. miRNA dysregulation and CIN are suggested mechanisms of As carcinogenesis. hsa-miR-186 is overexpressed in As-induced squamous cell carcinoma relative to premalignant hyperkeratosis. Predicted targets of miR-186 are cell cycle proteins, thus overexpression of miR-186 likely leads to CIN

and aneuploidy, which are features of cancer. We showed that overexpressing miR-186 in HaCaT cells increased numerical and structural chromosomal abnormalities. miR-186 overexpression drives malignant transformation of HaCaT cells by induction of CIN and potentially accelerates As-induced transformation. Stable clones of HaCaT transfected with miR-186 expression vector or empty vector were maintained under puromycin selection. Selected clones exposed to 0 or 100 nM As, were cultured for 10 weeks. Anchorage independent growth was tested in soft agar colony formation assay. Giemsa banding was used to produce karyotypes and cytogenetic analysis for CIN was performed. HaCaT overexpressing miR-186 and exposed to As exhibited signs of anchorage independent growth since single cells formed clusters of cells in agar while HaCaT transfected with vector control did not. As-exposed HaCaT that overexpress miR-186 also contained additional chromosomal material in one of the four copies of chromosomes 1 and 11; increases in double minute chromosomes; two copies of the abnormal isochromosome 9q and one extra chromosome 18. HaCaT authenticity was validated by the presence of reported marker chromosomes and STR mapping. Consistent chromosomal abnormalities and increased growth ability in agar were observed in As exposed miR-186 overexpressing keratinocytes, suggesting contribution of CIN to malignant transformation. Only one clone was tested per group and these karyotypic changes might be that clone's feature and not an effect of As toxicity. Thus, future research using additional clones is warranted.

2623 Impact of Arsenic Exposure on Wound Healing in Down Syndrome

K. M. Prutton, J. Marentette, J. Lo, and J. Roede. *University of Colorado Anschutz Medical Campus, Aurora, CO.*

Down syndrome (DS) is characterized by a complex phenotype including intellectual disability, developmental complications, and an increased risk of chronic health conditions like congenital heart defects and early onset Alzheimer's disease. Complications with tissue regeneration - synonymous with wound healing - have also been reported in DS. It is important to note that tissue regeneration processes are similar regardless of etiology of the wound. These observations and reports of impaired wound healing with age strengthens the use of DS has a model for accelerated or atypical aging. The main aim of the current study was to characterize the wound healing response in normal and trisomy 21 cells, and to investigate the Gene x Environment interaction between DS and the ubiquitous environmental contaminant, arsenic (As). Arsenic is a naturally occurring metalloid, common groundwater contaminant, and exposure has been reported to alter wound healing processes. Here we show that DS fibroblasts, in response to a scratch wound, took significantly longer to complete wound closure, and released substantially less PGE_2 compared to euploid controls. Additionally, after exposure to environmentally-relevant concentrations of sodium arsenite, we found that As had a greater impact on cell proliferation and necrosis in trisomy 21 cells. We also found that DS fibroblasts have decreased basal gene expression of COX-1 and COX-2 and increased basal gene expression of PTGES. These are key arachidonic acid metabolizing genes, with alterations having potential to impair wound healing. Furthermore, young DS fibroblasts show decreased basal protein abundance of COX-1 and COX-2 that does not recover to control basal levels following a mechanical scratch. Our results demonstrate DS-mediated alterations in the tissue regeneration process, that can be negatively impacted by As exposure. Due to a possible lifelong disability of dysfunctional wound healing, the involvement of tissue regeneration mechanisms in various biological systems, and the passive nature by which individuals are exposed to As, these data can be applied to developmental toxicology, aging, regenerative medicine, and ultimately the treatment of those affected and not affected by trisomy 21.

2624 Mutational Processes of Arsenic and UV Co-exposure on Skin Cancer Genomes

X. Zhou[1], Y. Guo[1], L. B. Alexandrov[2], L. G. Hudson[1], and K. J. Liu[1].
[1]University of New Mexico, Albuquerque, NM; and [2]University of California San Diego, San Diego, CA.

Arsenic is a human co-carcinogen at environmental levels. Experimental and epidemiological evidence indicates that low levels of arsenic in combination with other environmental insults such as ultraviolet radiation (UV) increases skin carcinogenesis. However, little is known about the mutagenetic processes of arsenic and UV co-exposure. Recent advances in next generation sequencing (NGS) and computational biology introduced powerful tools to analyze signatures of mutational processes. In this work, we extracted, identified, and characterized specific mutational signatures of arsenic exposure and arsenic-UV co-exposure in normal human keratinocytes using single cell whole genome sequencing. Arsenic-UV co-exposure signature differs from either the UV signature or arsenic signature, suggesting co-exposure has unique mutational process versus single exposures. Analyzing single nucleotide variation (SNVs) in whole genome sequencing results from 368 skin cancer patients from the TCGA database suggested over 40% of the cases have mutational signatures of arsenic-UV co-exposure compared to 4% of cases for the arsenic signature. In contrast, there was no evidence for UV or arsenic-UV co-exposure signatures based on SNVs from 396 bladder cancer patients. These results not only defined an arsenic-induced mutational signature for the first time, but also demonstrated the mutational signature of arsenic-UV co-exposure and in skin cancers.

2625 Decreased Expression of Schlafen 12 in Arsenic- and Cadmium-Induced Urothelial Cancer

A. Lohnes, D. Green, S. Jacobs, and B. Voels. *Cankdeska Cikana Community College, Fort Totten, ND.* Sponsor: S. Somji

Arsenic and cadmium (Cd^{2+}) are environmental carcinogens associated with the development of urothelial cancer. Previous studies have shown that both arsenite (As^{3+}) and Cd^{2+} can transform the normal immortalized urothelial cell line UROtsa, into malignant lines that form tumors in immune compromised mice. These tumors resemble urothelial carcinomas with focal areas of squamous differentiation. The Schlafen family of proteins consists of short, intermediate, and long isoforms of structurally related proteins. Schalfen 12 (SLFN12) is an intermediate length member (67 kDa) expressed in human tissues with no known function. Overexpression of SLFN12 has been previously associated with increased expression of dipeptidyl-peptidase 4, E-cadherin expression, and epithelial differentiation in prostate cell lines suggesting that it is associated with a less aggressive type of a cancer. Since SLFN12 is associated with differentiation of tumors, we were interested in determining if SLFN12 is expressed in the As^{3+} and Cd^{2+}-transformed cell lines and their corresponding tumor heterotransplants along with other human bladder cancer cell lines. Our data shows that in the transformed cell lines, there was a decrease in expression of SLFN12 when compared to the non-transformed UROtsa cells. The expression was increased in the tumors produced by these transformed cells, however the staining was restricted to the more undifferentiated areas of the tumors compared to the well differentiated centers of the tumor nests. In commercially available bladder cancer cell lines RT4, HT 1197, HT 1376, T24/83, and UM-UC-3, there was reduced expression of SLFN12 when compared to the UROtsa parent cells. In human bladder cancers the expression of SLFN12 was localized to areas that were poorly differentiated. In conclusion, our study shows that the SLFN12 is expressed in the normal undifferentiated basal layer of the urothelium and its expression is restricted to the poorly differentiated areas of bladder cancers thus suggesting a role of SLFN12 in differentiation of bladder cancers.

2626 Arsenic Exposure Impairs Intestinal Cell Differentiation in Adult Mice

J. T. Jatko, and L. J. Bain. *Clemson University, Clemson, SC.*

Arsenic (As) is a toxicant found in drinking water and food, that is known to impair cell fate determination and differentiation in stem cells, neurons, and muscles. The intestines are a highly proliferative tissue, whose epithelial cells turn over every 3-7 days to compensate for constant abrasion. The supply of cells is maintained by resident stem cells that differentiate to form multiple types of intestinal epithelial cells. Even though the primary route of arsenic exposure is via ingestion, very little is known about its effects on intestinal cell proliferation and differentiation. Therefore, the purpose of this study is to investigate the effects of arsenic on intestinal proliferation and differentiation. Adult mice were exposed to 0 or 100ppb of arsenite in drinking water for 5 weeks, and intestinal tissue collected. To assess whether arsenic exposure inhibited cell differentiation, specific markers for terminal, transit amplifying (TA), and stem cells (ISC) of the intestinal epithelium were analyzed by qPCR. There was a 39% decrease in transcript levels for the ISC marker $Lgr5^+$, and a 49% and 42% decrease in transcript levels in the secretory fated Paneth and Goblet cells, respectively. No significant changes *in trans*cript levels were observed in the absorptive cells, though there was a 30% decrease in absorptive TA cell marker Hes1. Math1 transcript levels expressed by secretory TA cells were also reduced by 31%. Reductions in Lgr5 protein expression via immunohistochemistry results were concordant with qPCR data, and alternations in crypt morphology were also seen in the arsenic exposed animals. To investigate a possible mechanism behind the reduction of intestinal cell types, Indian hedgehog (Ihh) transcript expression was analyzed by qPCR. Ihh is a signal that is expressed in terminal epithelial cells that stimulates the mesenchymal tissue beneath the epithelium to release proliferation and differentiation signals to the ISC and TA cells. Its expression was significantly reduced by 34% in the arsenic exposed animals. To further investigate the significance of Ihh pathway impairment, target genes responsible in cell proliferation and differentiation, Gli1 and BMP4 respectively, will be analyzed by

qPCR and immunoblotting. The results show that intestinal stem cell differentiation is negatively impacted by arsenic in drinking water, potentially due to disruption of the Ihh.

2627 Effects of Arsenic (As)-Contaminated Soil Exposure on Gut Bacteria and Its Relationship with Oral Bioaccessibility of As Using a Multi-Compartment *In Vitro* Gastrointestinal Model

J. L. Griggs[1], K. Lu[1], L. Chi[1], M. Kohan[2], N. M. Hanley[2], K. Herbin-Davis[2], D. J. Thomas[2], and K. D. Bradham[2]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]US EPA, Research Triangle Park, NC.*

The World Health Organization and the Agency for Toxic Substances and Disease Registry describes As as a "significant potential threat to human health" due to high toxicity and worldwide prevalence that results in exposure of millions of people. Understanding factors that affect As bioaccessibility and the effects of ingested As on the gastrointestinal system provides insights into risk from exposure and the potential for adverse health effects. We developed a novel multi-compartment (stomach, small intestine, and colon) simulated gastrointestinal model system (GIMS) that is inoculated with microorganisms sourced from ceca or feces of mice. During four weeks post inoculation, we used 16s rRNA gene sequencing to characterize bacterial composition of the colonic phase before and after aliquots of fluids from the GIMS were exposed to 50 ppm of As in contaminated soils. We also determined percent bioaccessibility of total As at each phase of digestion (i.e. stomach, small intestine, and colon) using instrumental neutron activation analysis. After inoculation with fecal bacteria (GIMS fecal) or cecal bacteria (GIMS cecal), bacterial composition of the colon stabilized at weeks 3-4. After stabilization, GIMS fecal colon fluid contained six different bacteria families from four phyla before and after exposure to arsenic-contaminated soils. After As exposure, more As dissolved in GIMS fecal stomach phase than in either small intestine or colon phases. After system stabilization, GIMS cecal colon fluid contained nine different bacteria families from four phyla in the no exposure group alone. Family Rikenellacaeae within phylum Bacteroidetes, made up >5% of the total bacteria composition in the no exposure group at weeks 3-4. After exposure to arsenic, family Rikenellaceae, were greatly reduced in one arsenic-exposed group and absent in three other arsenic-exposed groups. As was found to disrupt gut bacteria composition in an *in vitro* system inoculated with cecal bacteria. The effect of As-induced changes in cecal microbiota on As bioaccessibility is under investigation. *This abstract does not reflect US EPA policy.*

2628 Inhibition of Cellular Proliferation Effects the Sub-Type of Urothelial Cancer Caused by Arsenic Exposure

A. Mehus, S. H. Garrett, D. A. Sens, and S. Somji. *University of North Dakota, Grand Forks, ND.*

Environmental exposure to arsenite (As^{+3}) has a strong association with the development of human urothelial cancer (UC). This cancer is the 5th most common cancer in men and the 12th most common cancer in women. Muscle invasive urothelial cancer (MIUC) can be grouped into basal or luminal molecular subtypes based on their gene expression profile. The basal subtype is more aggressive and can be associated with squamous differentiation that is characterized by high expression of several keratins (KRT1, 5, 6, 14, and 16) and epidermal growth factor receptor (EGFR) within the tumors. The luminal subtype is less aggressive and is predominately characterized by elevated gene expression of peroxisome proliferator-activated receptor-gamma (PPARγ), FOXA1, and GATA3. We have previously shown that As^{3+}-transformed urothelial cells (As-T) exhibit a basal subtype of UC expressing genes associated with squamous differentiation. In this study, we were interested in determining if the molecular subtype of the As-T cells could be altered by inducing the expression of PPARγ and inhibiting the proliferation of the cells. For this purpose the As-T cells were treated with Troglitazone (TG, PPARG agonist, 10 μM), PD153035 (an EGFR inhibitor, 1 μM) or a combination of TG and PD for 3 days. The results obtained demonstrate that treatment of the As-T cells with TG upregulated the expression of PPARγ and FOXA1 whereas treatment with PD decreased the expression of some of the basal keratins. However, a combined treatment of TG and PD resulted in a significant decrease in the expression of basal keratins (KRT1, KRT5, KRT6, KRT14 and KRT16). Thus, our data suggests that inhibition of proliferation facilitates the upregulation of genes involved in maintaining the luminal subtype of UC and this may have implications in treatment of UCs. *In vivo* animal studies would be needed to address the efficacy of using proliferation inhibitors and/or PPARγ agonists to reduce tumor grade/stage of MIUC.

2629 Effects of Arsenicals (Asi, MMA, and DMA) on the Cell Cycle in Bladder Cells HTB-2/HAS3MT

A. Hernandez-Zavala. *Instituto Politecnico Nacional, Mexico City, Mexico.*

Arsenic (As) is a ubiquitous element, it is found in both organic and inorganic form, the latter being the most toxic. The As is ingested, undergoes a process of biotransformation by the arsenic enzyme 3 methyl transferase (As3MT). The effects of As on health are multiple presenting non-carcinogenic and carcinogenic effects and the toxic effects reported are only for inorganic As (As), so the objective of this study was to evaluate the effect of arsenical metabolites (Thus, MMA and DMA) on the cell cycle, in a bladder cell line (HTB-2 / HAS3MT). To determine the toxic effects of inorganic arsenic and its metabolites, different tests were carried out with two cell lines, of bladder epithelial origin, the first used as a control, HTB-2 / WT and the second which is stably transfected with the gene of the As3MT, named as HTB-2 / HAS3MT. The cell viability was determined, obtaining a concentration-response relationship between the different concentrations of sodium arsenite [0.1, 1. 2.5 and 5 μM] and the percentage of living cells at times of 4 and 24 hours. Subsequently, the percentage of cells in the different phases of the cell cycle was determined, performing a concentration response curve, where an increase in the percentage of cells in the S phase was observed, but also an increase in the cells in the G2 / M phase at high concentrations. The generation of reactive species was quantitatively determined, and the results showed a concentration-response relationship when the cells with sodium arsenite were exposed to different concentrations [0, 0.1, 1. 2.5 and 5 μM] at 4 and 24 hours. We can conclude that the toxic effects HTB-2 / HAS3MT are due to the presence of metabolites (MMA and DMA), which have a toxicity greater than Asi.

2630 Arsenic Alters ECM to Impair Skeletal Muscle Regeneration

M. McCormick[1], S. Shinde[2], T. Anguiano[2], W. Tang[1], F. Ambrosio[2], and A. Barchowsky[2]. *[1]Johns Hopkins University, Baltimore, MD; and [2]University of Pittsburgh, Pittsburgh, PA.*

Skeletal muscle extracellular matrix (ECM) drives conversion of muscle stem cells into either functional or dysfunctional states. Environmental exposure to arsenic weakens skeletal muscle regenerative capacity, and we tested the hypothesis that arsenic diminishes ECM integrity by altering collagen composition and crosslinking. To identify arsenic-induced ECM changes *in vivo*, mice were exposed to 100ppb arsenic in drinking water for 5 weeks. The tibialis anterior muscles were then injured with cardiotoxin and allowed to heal for 10 days. Analysis of muscle sections revealed that arsenic-exposed tissue repaired poorly with reduced levels of collagen 3 (Col3) and Col6 at the injury site. Treated muscle fibers had smaller cross-sectional area and fewer nuclei with lysyl oxidase (LOX), which contributes to collagen crosslinking, nuclear size and chromatin compaction. These changes were recapitulated in primary myofibroblasts cultured with 20nM arsenic for 24h. The arsenic was removed, and cells were allowed to elaborate ECM for 3d. Treated cells had enlarged nuclei and elevated levels of Col4, while Col3 and Col6 were reduced. Arsenic treatment impairs mitochondrial function to epigenetically alter progenitor cell fate, and we tested whether treatment with SS-31, a mitochondrial protectant peptide, could reverse arsenic effects on the ECM. Myofibroblasts were again exposed to arsenic for 24h, and some cell groups were treated with SS-31 as ECM elaborated. SS-31 dramatically increased arsenic-inhibited Col3 levels. These findings suggest that arsenic may impair muscle regenerative capacity by promoting ECM remodeling and altering LOX and collagen levels. Loss of nuclear LOX is consistent with larger, more open nuclei. SS-31 treatment restored the ECM collagen profile, implicating mitochondria as the target of arsenic-promoted dysfunctional ECM and muscle regeneration. *Supported by NIH grant 5RO1ESO23696-04.*

2631 Arsenic-Perturbed Gut Microbiota Activated Intestinal FXR Signaling and Increased Serum Ceramide Levels in Mice to Cause Glucose Intolerance

L. Chi, P. Tu, Y. Yang, H. Ru, and K. Lu. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

The gut microbiota plays a key role in arsenic toxicity, as we and others have demonstrated in a number of recent studies. In particular, arsenic exposure disturbs gut microbiota community composition and alters functional genes and metabolites. Meanwhile, arsenic is known to induce glucose intolerance. However, it is still unclear whether and how the arsenic-disturbed gut microbiota causatively affects glucose homeostasis. To address this gap, we transplanted the gut microbiota from mice with arsenic-induced glucose intoler-

ance to microbiota-depleted mice, followed by glucose tolerance tests. Mice received arsenic-perturbed gut microbiota had impaired glucose tolerance, similar to what observed in donor animals exposed to arsenic. This finding clearly shows that the arsenic-perturbed gut microbiota causatively led to glucose intolerance. In addition, the gene expression level of *Fgf15* and *Shp* in distal ilea was significantly higher in mice with arsenic-perturbed gut microbiota than mice transplanted with normal gut microbiota, which indicated the activated intestinal FXR signaling. Moreover, the gene expression level of multiple ceramide synthases, including *CerS4*, *CerS5*, and *CerS6*, was significantly increased in the distal ilea of mice transferred with arsenic-perturbed gut microbiota, consistent with increased ceramides in sera. Ceramide synthases are the downstream genes of FXR signaling in intestines. In adipose tissues of mice transplanted with arsenic-perturbed gut microbiome, we found that the expression of key genes that regulate glucose homeostasis was significantly changed, including the down-regulated *Chrebp* and up-regulated *Pck2*, which could promote the development of glucose intolerance. Taken together, our current study demonstrates that the causative role of gut microbiota in arsenic-induced glucose intolerance for the first time, and provides a potential molecular mechanism about how arsenic-perturbed gut microbiota may affect host glucose homeostasis.

2632 Arsenite Alters Structure and Function of Alternative Splicing Regulator ZRANB2 by Displacing Zinc from Zinc Finger Motifs

M. Banerjee, A. P. Cardoso, A. Lykoudi, D. W. Wilkey, W. H. Watson, N. C. Garbett, M. L. Merchant, J. Pan, S. N. Rai, and J. C. States. *University of Louisville, Louisville, KY.*

Exposure to arsenic, a class I carcinogen, affects 200 million people globally. Skin is the major target organ but molecular etiology remains unclear. Arsenite (As^{3+}) can displace zinc (Zn^{2+}) from C3H1 and C4 zinc finger domains, affecting protein function. Zinc finger proteins play key roles in RNA binding and splicing. Using an established HaCaT cell line model of arsenic-induced squamous cell carcinoma, we demonstrated occurrence of global dysregulation of alternative splicing during carcinogenesis. ZRANB2, an alternative splicing regulator with two C4 zinc knuckle motifs integral to its structure and splicing function was chosen as a candidate for this study. We hypothesized that As^{3+} could potentially displace Zn^{2+} from ZRANB2 possibly altering its structure, expression and splicing function. As^{3+}/Zn^{2+} binding (One-site specific binding non-linear model) and mutual displacement experiments (log(inhibitor) vs. response non-linear model) were performed with synthetic apo-peptides corresponding to each ZRANB2 zinc finger motif. A combination of intrinsic fluorescence, UV spectrophotometry, zinc colorimetric assay and ESI-MS/MS was used to characterize metal binding/mutual displacement. ZRANB2 expression in HaCaT cells acutely exposed to As^{3+} (0 or 5 μM; 0-72 h) was examined by RT-qPCR and immunoblotting. TRA2B splicing was monitored by RT-PCR. As^{3+} was found to bind to, as well as displace Zn^{2+} from, each zinc finger motif ($p<0.05$; ANOVA). Also, Zn^{2+} displaced As^{3+} from As^{3+}-bound zinc finger motif acutely ($p<0.05$; ANOVA) but long incubation favored As^{3+} binding. As^{3+} exposure induced ZRANB2 protein expression between 3-24 h ($p<0.05$; ANOVA), but not steady state ZRANB2 mRNA. ZRANB2-directed TRA2B splicing was impaired ($p<0.05$; ANOVA) between 3-24 h post exposure. Arsenic exposure displaces Zn^{2+} from ZRANB2 zinc fingers, changing its structure and compromising splicing of its targets. ZRANB2 protein expression increases in response. Arsenic exposure could be modulating global alternative splicing profile by dysregulating ZRANB2 and other splice regulators, many of which are zinc finger proteins.

2633 Assessing the Role of Chronic Arsenic in Disrupting the EGFR-Signaling Axis

C. Kim, and B. P. Ceresa. *University of Louisville, Louisville, KY.*

Lung cancer is the leading cancer in the US, and Kentucky leads the nation with the highest lung cancer death rates. Although smoking is associated with lung cancer development, 20% of patients who die from lung cancer in the US, have never smoked, suggesting there are other risk factors. One of these risk factors is arsenic exposure. Fifteen percent of the US population drinks domestic well water, and in many areas, this unregulated well water contains levels of arsenic that exceeds the Environmental Protection Agencies (EPA) recommended levels. *Though there is a strong association between arsenic exposure and lung cancer development, the clear mechanism is unknown.* Further, previous studies have shown acute arsenic exposure increases expression of the epidermal growth factor receptor (EGFR), a cell surface receptor tyrosine kinase that is associated with many different types of cancer, including lung cancer. We hypothesize that chronic arsenic exposure disrupts the EGFR endocytic trafficking, leading to increased receptor expression. This project examines the impact of chronic "environmentally relevant" levels of arsenic on the EGFR expression, distribution and trafficking. A non-malignant human bronchial epithelial cell line, Beas-2B cells were exposed to 100 nM sodium arsenite for 24 weeks. This concentration was chosen, as it is the average blood arsenic level in individuals who are exposed to high levels of arsenic. The chronic arsenic exposure increased EGFR protein expression levels and its activity, increased transcription and protein levels of TGFα, and altered the distribution of the EGFR. TGFα, unlike the other EGFR ligands, diverts the stimulated receptor from lysosomal degradation. Consistent with an increased protein level of TGFα, we observed increased cell surface level of EGFR in response to chronic arsenic exposure.

2634 Increased Protein O-GlcNAcylation Is a Driver of Arsenic-Promoted Diabetes

M. Dodson, P. Liu, and D. D. Zhang. *University of Arizona, Tucson, AZ.*

Inorganic arsenic (iAs) is a metalloid found ubiquitously throughout the environment. Chronic exposure to unsafe levels of iAs, greater than the World Health Organization recommended limit of 10 μg/L, is linked to an increased risk of numerous diseases, including type II diabetes. Exposure to pathogenic levels of iAs typically occurs through ingestion of contaminated food or drinking water, and affects populations globally, including the United States, Mexico, Chile, Taiwan, India, and Bangladesh, among others. A key component of metabolic diseases such as type II diabetes, is a shift from normal homeostatic metabolism to a new metabolic program that is pro-pathogenic. As such, generating a better understanding of the metabolic changes that occur during the progression of these diseases, particularly upon exposure to environmental toxins, is vital to enhancing current and future patient therapies. One key metabolic pathway linked to the progression of metabolic diseases is the hexosamine biosynthesis pathway (HBP), which utilizes ~2-5% of the cell's glucose to produce UDP-GlcNAc, a key metabolite used in the O-GlcNAcylation of target proteins. Importantly, altered HBP activity and protein O-GlcNAcylation have both been shown to contribute to the pathogenesis of type II diabetes. Here, we show that chronic exposure to iAs (up to 20 weeks) enhances global protein O-GlcNAcylation in differentiated 3T3-L1 adipocytes and C2C12 myoblasts. Mechanistically, iAs increases UDP-GlcNAc levels, presumably via increased expression of Glutamine-Fructose-6-Phosphate Transaminase 1 (GFPT1), the rate limiting enzyme of the HBP. Further investigation of O-GlcNAcylated targets revealed proteins involved in glucose metabolism, mitochondrial function, vesicle trafficking, and proteostasis, among others. Accordingly, knockdown of OGT, the enzyme responsible for the addition of UDP-GlcNAc to target proteins, partially ameliorated iAs-induced deficits in Glut4 translocation, glucose uptake, and insulin signaling, inferring that iAs-induced changes in HBP activity and protein O-GlcNAcylation could be key mediators of iAs-promoted diabetes. Due to the well-established link between iAs exposure and an increased prevalence of diabetes, clarifying the effects of iAs on the pathophysiological alterations that contribute to key diabetic phenotypes will prove extremely valuable in the generation of novel therapeutic strategies for exposed populations.

2635 Participation of the Nrf2-Keap1 Pathway in the Protective Effect of Curcumin in a Lymphoblast Cell Line (NL-49) Exposed to Inorganic Arsenic

A. Hernandez-Zavala. *Instituto Politécnico Nacional, Mexico City, Mexico.*

Inorganic arsenic (iAs) is a metalloid that is found naturally in water tables by polluting drinking water. iAs causes various adverse effects both carcinogenic and non-carcinogenic, mainly through the generation of reactive oxygen species (ROS). The transcription factor Nrf 2 is a master regulator in response to oxidative stress, by promoting the expression of antioxidant and detoxifying enzymes. The objective of this work was to evaluate the protective role of curcumin in lymphoblasts (NL-49) exposed to iAs through the Nrf2 -Keap1 pathway Lymphoblasts were treated with curcumin (5, 10 and 15 μM) at different times (12, 18 and 24 hours) and subsequently with sodium arsenite (5,10 and 20 μM) for 15 hours, assessing cell viability, Nrf-2 target genes and cell cycle. The results obtained allowed us to identify that the concentration of 5 μM curcumin was the least toxic and 10 μM arsenic as the concentration capable of inducing cell death below of 50%. Treatment with 5μM of curcumin for 9 hours, prior to exposure with 10 μM of arsenic, showed a loss of cell viability induced by arsenic, as well as cytostatic effects in the G1 phase of the cell cycle. In addition, it was observed that most of the genes analyzed are expressed after 9 hours of treatment and begin to decrease at 18 hours. Then it can be concluded that curcumin sensitizes the cell by increasing the damage generated by arsenic, decreasing cell viability and increasing apoptosis, despite inducing the expression of Nrf2 regulated genes.

2636 Using the Zebrafish Model System to Determine the Toxicity Interaction of Arsenic and Lead

K. G. Kiper, and J. L. Freeman. *Purdue University, West Lafayette, IN.*

Metals such as arsenic (As) and lead (Pb) are environmental pollutants, often found in common sites due to their ubiquitous nature and production of virgin Pb. Both As and Pb are heavy metals linked to adverse health effects; more specifically, As and Pb lead to cardiovascular toxicity and neurotoxicity, among various other effects including cancer and nephrotoxicity. A variety of studies have determined the individual toxicity, developmental toxicity, and biomarkers for the detection of toxicity induced by low dose exposures. Unfortunately, a majority of these studies have been on a single component or in mixture compositions that exceed a binary mixture of just Pb and As. This specific mixture of As and Pb may produce additive / synergistic effects due to their common pathways for neurotoxicity. This study aims to evaluate the interaction between As and Pb to determine what type of toxicity interaction may be present at such concentrations. The concentration addition (CA) model was applied to test the hypothesis that the type of toxicity interaction between Pb and As is additive, due to shared neurotoxicity and vascular toxicity pathways of Pb and As. To determine the toxicity interaction of As and Pb, the zebrafish (*Danio rerio*) biological model was used. The individual chemical studies and the mixture experiments began at 1 hour post fertilization (hpf). Every 24 hrs, survival was recorded. The treatments used for As were 0, 0.1, 0.5, 1, 5, and 10 mM and the treatments for Pb were 0, 0.05, 0.1, 0.15, 0.2, 0.25, 0.34, 0.39, 0.43, and 0.48 mM. The LC_{50} values for As and Pb at 120 hpf were 1.74 mM and 0.43mM, respectively. The LC_{50} from these two studies at 120 hpf was used to determine the mixture concentrations. The mixture assessment involved three separate exposure paradigms: experiment 1: [As LC_{25} + Pb LC_{75}, As LC_{50} + Pb LC_{75}, As LC_{75} + Pb LC_{75}, Pb LC_{75}, As LC_{25}, As LC_{50}, As LC_{75}]; experiment 2: [As LC_{25} + Pb LC_{50} , As LC_{50} + Pb LC_{50}, As LC_{75} + Pb LC_{50}, Pb LC_{50}, As LC_{25}, AsLC_{50}, As LC_{75}]; and experiment 3: [As LC_{25} + Pb LC_{25} , As LC_{50} + Pb LC_{25}, As LC_{75} + Pb LC_{25}, Pb LC_{25}, As LC_{25}, As LC_{50}, As LC_{75}]. The pH for all treatments was adjusted to 6.5 in order to avoid precipitation of Pb in solution and to maintain an optimal pH for zebrafish development. The mixture experiments indicate an additive toxicity interaction for As and Pb. Overall, this study serves as a foundation for future studies at lower mixture concentrations to determine if additive toxicity is also observed for specific neurotoxicity and vascular endpoints.

2637 Exposures to Trivalent Arsenicals Alter Metabolomics Profiles in β-Cells and Isolated Pancreatic Islets

Y. Li[1], C. Douillet[1], M. Huang[2], R. Beck[1], S. Jenkins Sumner[1], and M. Styblo[1]. *[1]University of North Carolina at Chapel Hill, Chapel Hill, NC; and [2]NIEHS/NTP, Research Triangle Park, NC.*

Inorganic arsenic (iAs) is a diabetogen, but mechanisms underlying its diabetogenic effects are poorly understood. Exposure to arsenite (iAs^{III}) and its metabolites, methylarsonite (MAs^{III}) and dimethylarsinite ($DMAs^{III}$), have been shown to inhibit glucose stimulated insulin secretion (GSIS) in β-cells and isolated pancreatic islets. GSIS is regulated by complex mechanisms that depend on metabolism of glucose and other energy producing pathways. The present study used UHPLC High Resolution Orbitrap MS Metabolomics to characterize metabolic fingerprints of β-cells (INS-1 832/13 insulinoma cells) treated with 2 μM iAs^{III}, 0.2 μM MAs^{III} and 2 μM $DMAs^{III}$, and murine islets treated with 2 μM iAs^{III}, 0.25 μM MAs^{III} and 0.5 μM $DMAs^{III}$. Treatment with iAs^{III} and $DMAs^{III}$ degreased GSIS in β-cells, but only the effect of $DMAs^{III}$ was statistically significant. GSIS in islets was significantly inhibited by all three arsenicals. Supervised orthogonal partial least squares discriminant analysis revealed that $DMAs^{III}$ treatment resulted in major metabolic perturbations in β-cells affecting 37 metabolites, as compared to 9 and 5 metabolites perturbed by iAs^{III} and MAs^{III}, respectively. Two metabolites, acetylcarnitine and succinic acid, were decreased following exposure to each of the three arsenicals. Pathway analysis revealed 25 metabolic pathways enriched by treatment with $DMAs^{III}$, including multiple pathways of amino acid transport and metabolism. Six and 17 pathways were enriched by exposure to iAs^{III} and MAs^{III}, respectively. The D-glucuronic acid pathway was the only pathway altered by all three arsenicals. In spite of their significant effects on GSIS, the overall impact of arsenical exposures on the metabolome of islets was less than that in β-cells. Several metabolites were altered by exposure to one or more arsenicals in both β-cells and islets, including acetylcarnitine, glutamate, suberic acid, glutathione and ornithine. The pathways of carbohydrate and amino acid metabolism were among the pathways most affected in both β-cells and the islets. Results of this study will inform future research of mechanisms by which iAs exposure impairs GSIS in β-cells.

2638 Arsenic (3) Methyltransferase (As3MT) Auto-Methylation Primes Arsenic Methyl-Transferase Activity?

S. Y. Mersaoui, C. Guilbert, H. Chou, S. Richard, and K. K. Mann. *Lady Davis Institute, Montreal, QC, Canada.*

Arsenic toxicity is a global concern to human health and is related to increased incidence of cancer, bronchopulmonary and cardiovascular diseases in exposed populations. In human and mouse, inorganic arsenic (iAs) is metabolized in a series of methylation steps catalyzed by arsenic (3) methyltransferase (As3MT), forming methylarsenite [MAs(III)], dimethylarsenite [DMAs(III)] and the volatile trimethylarsine [TMAs(III)]. Methylated intermediates may be more toxic than inorganic arsenite, and we have previously shown that As3MT is required for arsenic-enhanced atherosclerosis in mice. The methylation of arsenic is coordinated by three conserved cysteine residues proposed to participate in catalysis, namely Cys62, Cys157, and Cys207 in mouse As3MT. The current model of iAs methylation requires a series of intramolecular disulfide bonds formed before the enzymatic methylation of arsenite (iAs3+). In presence of GSH, these disulfide bonds are reduced, leading to the methylation of the iAs in presence of the cofactor S-adenosyl methionine (SAM). Using *in vitro* methylation assays in the absence of arsenic, we find that As3MT undergoes an initial automethylation step before iAs binding. This methylation is enhanced by GSH or DTT, suggesting that reducing cysteine bonds prepares As3MT for automethylation. Following the addition of iAs, the automethylated As3MT is decreased, as transfer of this methyl group completes the first round iAs methylation. Furthermore, using a Flag-As3MT immunoprecipitation coupled to MS/MS, we identify both Cys33 and Cys62 as an acceptor of the methyl group *in vivo*. Site-directed mutagenesis (Cys to Ala) reveals that three of the previously described cysteines are required for the automethylation step. Altogether, our results suggest a new mechanism of arsenic methylation that requires an additional step of As3MT automethylation. Additional *in vitro* and *in vivo* biochemical analyses will be necessary to define the role of the As3MT automethylation in arsenic species formation and/or putative target of As3MT.

2639 Cardiac-Specific SERCA Knockout Mice Replicate Adverse Cardiac Effects of Bromine and Demonstrate Enhanced Myocardial Injury

J. X. Masjoan Juncos[1], S. Shakil[1], W. E. Bradley[1], I. Zafar[1], N. Mariappan[1], W. E. Louch[2], L. J. Dell'Italia[1], G. Halade[1], A. Ahmad[1], and S. Ahmad[1]. *[1]University of Alabama at Birmingham, Birmingham, AL; and [2]Universitetet i Oslo, Oslo, Norway.*

Toxic halogens such as bromine are finding increased industrial applications and their storage and transport in large quantities poses risk of accidental or deliberate spills. Our studies have demonstrated that acute inhalation of high concentrations of bromine causes death by cardiopulmonary failure. The toxicity of halogens is mediated by halogenation and inactivation of important cardiac calcium pumps such as the sarcoendoplasmic calcium ATPase, SERCA2. SERCA inactivation causes increased calcium overload and activation of cytosolic calcium specific proteases such as calpains that damage the myocardium. The myocardial damage causes biventricular dysfunction and hypertrophy. To delineate mechanisms, we utilized cardiac specific SERCA knockout mice and exposed them to bromine. Decreased cardiac SERCA itself manifested in increasing the cardiac injury markers, such as troponin I and cardiac calpains. Cardiac specific knockout also demonstrated abnormal contractility. Moreover, exposure of these mice enhanced toxicity to bromine and caused increased damage to cardiac tissue leading to cardiac dysfunction and death. Further impairment in myocardial relaxation in SERCA knockout mice was evident after bromine exposure as demonstrated by hemodynamic analysis. Since loss of cardiac SERCA function and calcium overload have been implicated in the pathogenesis of several cardiac diseases, these studies predict susceptibility of individuals with preexisting cardiac disease to bromine/halogens.

2640 *In Vitro* Prediction of Cardiotoxicity by Simultaneous Evaluation of Multiple Endpoints

R. A. Moyer, E. E. Lemmon, J. D. Bartz, E. H. Moore, L. F. Hendey, and N. A. Young. *Battelle Memorial Institute, Columbus, OH.*

Human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) have shown promise for evaluating the electrophysiological effects of drugs. While perturbation of the heart's electrophysiological rhythm is a common

mechanism of drug-induced cardiotoxicity, many cardiotoxic compounds act through other mechanisms that might not be detected by solely measuring electrophysiological endpoints. Analysis of electrophysiology with microelectrode array (MEA) is a nondestructive, label-free technique that permits the evaluation of additional endpoints in the same experiment. We evaluated the effects of test compounds on cellular electrophysiology (MEA), viability (lactate dehydrogenase [LDH] release), and secretion of cardiac damage or inflammation biomarkers (MILLIPLEX® magnetic beads). Test compounds included well-characterized cardiac ion channel modulators (e.g., E-4031 and nifedipine) and mitochondrial toxicants (i.e., potassium cyanide [KCN], phosphine [PH_3], and hydrogen sulfide [H_2S]). Doxorubicin was included as a positive cytotoxic control. Exposure to H_2S or PH_3 was achieved by adding sodium hydrosulfide (NaHS) or zinc phosphide (Zn_3P_2) to the cell culture medium. MEA recordings were taken before and after compound addition; each ion channel modulator induced effects on electrophysiological parameters (i.e. beat period, beat amplitude, and field potential duration) that were consistent with previously reported results. Cyanide induced a robust decrease in beat period and beat amplitude. KCN, Zn_3P_2, and NaHS each triggered elevated levels of IL-8 at 24 hr, with a subsequent reduction at 48 hr. Robust increases in levels of some secreted biomarkers of cardiotoxicity (i.e., CKMB, FABP3, and troponin I) were observed at 24 hr and 48 hr with the highest concentrations of KCN, Zn_3P_2, and NaHS. With the exception of elevated levels of troponin I induced by E-4031 and nifedipine, no robust changes in biomarkers were observed in the cells treated with ion channel modulators. The highest concentrations tested of doxorubicin, KCN, Zn_3P_2, and NaHS each induced significant cytotoxicity that increased from 24 hr to 48 hr for all except Zn_3P_2. Collectively, these results demonstrate the utility of multiplex cardiotoxicity assays that can detect diverse mechanisms of toxicity. Further study is warranted to optimize the assay conditions and endpoints for optimal prediction of chemical-induced cardiotoxicity.

2641 Enhancing Aged Acetylcholinesterase Turnover by Targeting Members of the Enzyme Complex

J. W. Chambers. *Florida International University, Miami, FL.*

Organophosphate (OP) compounds are used as chemical weapons and pesticides. OP species are very potent inhibitors of cholinesterases (ChE), wherein OPs phosphylate the primary active site serine. The phosphate moieties from agricultural chemicals, like parathion, and nerve agents, such as sarin, become fixed in acetylcholinesterases (AChE) in minutes preventing reactivation by available oxime countermeasures. These "aged cholinesterases" contribute to glutaminergic hyperstimulation resulting in muscle contractions, respiratory depression, seizures, and possibly death. Current drug development strategies include generating compounds that can realkylate the phosphate moiety on ChE followed by administration of oximes or introducing increased ChE to combat the elevated levels of acetylcholine. However, no studies to date have tried to exploit endogenous cellular mechanisms to eliminate the impaired ChE. We have developed an on-cell western (OCW) for AChE that permits relative quantitation of protein levels on the surface of cells expressing AChE. When paired with an AChE biochemical assays, we can determine the relative amounts of the active enzyme on the cell surface. Using C2C12 mouse myoblast-like cells, we used the AChE OCW to screen chemicals that could remove diisopropylphosphofluoridate (DFP) aged AChE from the surface of cells. Candidate compounds for further study would be those that reduced aged AChE levels without impacting cellular viability and, after washing the compound from cells, would permit the emergence of active AChE from within cells. Our screen revealed that compounds targeting members of the AChE protein complex were successful at eliminating aged AChE. Furthermore, targeting members of the AChE complex with transient selective protein degradation approaches were also useful in removing aged enzyme. Our presentation will describe some of the targets, evidence, and potential complications of targeting the AChE complex. Nonetheless, our results demonstrate that exploiting the protein biochemistry of AChE and taking advantage of endogenous cellular proteostatic machinery could be a useful approach to solve the problem of aged cholinesterases.

2642 Effects of Hydrogen Sulfide on Brain-Lung-Heart Axis

D. Kim[1], C. Santana[1], R. Raineri[1], B. S. Purnell[2], R. Li[2], G. F. Buchanan[2], A. L. Mora[1], and W. K. Rumbeiha[1]. *[1]Iowa State University, Ames, IA; and [2]University of Iowa, Iowa City, IA.*

Hydrogen sulfide (H_2S) is a toxic gas with a rotten egg smell. Acute exposure to high concentration of H_2S can lead to severe injuries including neurological disorders and acute death. The exact mechanisms underlying H_2S-induced acute death have not been clearly elucidated. Hydrogen sulfide targets multiple organs including brain, lung, and heart. However, there is still a debate about the most critical organ responsible for acute death. In this study the effect of H_2S on the brain-lung-heart axis was evaluated. C57BL/6J mice exposed to 1000 ppm of H_2S by whole body inhalation developed clinical signs such as dyspnea, ataxia, and seizures. Pulmonary edema developed during H_2S exposure and was evident up to 24 h post-exposure. Serum cardiac troponin-I was elevated at 2 h and 24 h post-H_2S exposure, indicating cardiac injury, which was also observed on H&E stained sections. Plethysmography, electroencephalogram (EEG) and electrocardiography were simultaneously collected during H_2S exposure to identify the sequence of the pathophysiology to identify the critical organ responsible to acute death. Respiratory distress and apnea were observed during exposure to H_2S. Respiratory rate and minute ventilation decreased instantly, whereas the tidal volume decreased overtime. EEG results showed that brain activity was significantly and gradually suppressed over time during the H_2S exposure. During seizure episodes, H_2S exposed mice exhibited altered breathing pattern and arrhythmias. Interestingly, during knockdown mice exhibited significantly reduced EEG activity and apnea. Most significant finding was that the breathing pattern was first to be affected. Then brain activity ceased and closely followed by breathing cessation. Consistently, the heart continued to beat after brain activity and breathing had ceased in that order. Pre-treatment with midazolam prevented seizure and knock-down activity, allowing the H_2S exposed mice to avoid sudden loss of consciousness and apnea. An unexpected finding was that midazolam pretreatment significantly reduced pulmonary edema in H_2S-exposed mice. Taken together, these results indicate that brain death precedes breathing cessation and cardiac failure. Therefore, the brain and lung are the most critical organs responsible H_2S-induced acute death. Midazolam was shown to be beneficial both by reducing pulmonary edema and preventing seizure and knock-down activity. These results strongly suggest that countermeasures to increase survival should be directed at mitigating H_2S-induced neurotoxicity and improving respiratory function.

2643 *In Vitro* Degradation and *In Vivo* Biotransformation of Cyanide Antidote Candidate Dimethyl Trisulfide

M. M. Gomonit[1], I. K. Warnakula[1], C. T. Rios[1], A. C. Whiteman[1], R. D. Gaspe-Ralalage[1], D. E. Thompson[1], M. Kiss[1], G. A. Rockwood[2], and I. Petrikovics[1]. *[1]Sam Houston State University, Huntsville, TX; and [2]US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.*

Cyanide (CN) is a potent Cytochrome c Oxidase inhibitor resulting in lactic acidosis. Dimethyl trisulfide (DMTS) is a highlighted sulfur donor type cyanide antidote which can react with CN to form the less toxic thiocyanate. Literature data shows that dialkyl polysulfides can go through disproportionation, reduction, and oxidation reactions *in vitro*. The respective products are dialkyl polysulfides, thiols/hydrogen sulfide, and thiosulfonates/thiosulfinates. From the disproportionation reaction of DMTS, we identified dimethyl disulfide (DMDS) and dimethyl tetrasulfide (DM4S). The product of the oxidation reaction of DMDS was identified as S-methyl methanethiosulfonate. The further disproportionation of DM4S resulted in DMTS and dimethyl pentasulfide (DM5S). For these degradation species to be observed, longer time (months) at temperatures of at least 37°C were required. Products were analyzed by GC-MS-SPME and when the reference molecule was available, HPLC-UV was utilized. *In vivo* behavior of DMTS: It is known, based on our prior studies, that DMTS is concentrated in red blood cells and almost freely crosses the blood brain barrier to reach the brain. Our earlier studies indicated that in blood DMTS oxidizes hemoglobin to methemoglobin. During our blood absorption studies, DMDS was identified as one of the metabolites. Ongoing studies are focusing on identifying other metabolites in blood and other organs (brain, heart, and liver). Future studies will extend to other organs including pancreas, kidneys, and lungs. *This research was supported by the Counter ACT Program, NIH Office of the Director, and the NIAID, NIH/Department of Defense Interagency Agreement [AOD16026–001–00000/A120-B.P2016–01] and by the Robert A. Welch Foundation [X-0011] at the Sam Houston State University.*

2644 Inhibition of the Serine Hydrolase Fatty Acid Amide Hydrolase by a Sarin Surrogate

C. Price, M. Dail, and J. Chambers. *Mississippi State University, Mississippi State, MS.*

Organophosphates, such as nerve agents, inhibit acetylcholinesterase (AChE) and other serine hydrolases. Inhibition of AChE alone may not explain all of the neurotoxicity observed from acute exposure to nerve agents. Preliminary studies identified the serine hydrolase fatty acid amide hydrolase (FAAH) as being a possible target for the sarin surrogate nitrophenyl isopropyl methylphosphonate, NIMP. FAAH inhibition and resultant anandamide accumula-

tion has been implicated in delayed neurotoxicity and neuronal degeneration. Oximes play an integral role in the treatment of acute nerve agent exposure by reactivating inhibited AChE. Our laboratory developed a series of substituted phenoxyalkyl pyridinium oximes (US patent 9,227,937) that have been shown to provide central neuroprotection through reactivation of AChE in the brain and preservation of neuronal and glial structures from damage in a rat model. Reactivation of AChE alone may not be the only mechanism of neuroprotection provided by the novel oximes. Reactivation of other inhibited serine hydrolases, such as FAAH, during acute nerve agent exposure could provide a secondary neuroprotective mechanism provided by these novel oximes. Rat forebrain homogenates showed up to an 85% decrease in FAAH enzymatic activity in the presence of 1.0 μM NIMP, confirming that FAAH is a target of the sarin surrogate. Using rat forebrain microsomal preparations, an *in vitro* study inhibited FAAH with NIMP and assessed reactivation of FAAH by our lead oxime, Oxime 20. Initial results using western blot techniques suggested that Oxime 20 provided some reactivation as indicated by binding of the probe, FP-biotin. FAAH activity was monitored by HPLC-MS using an exogenous substrate anandamide (50 μM), but reactivation by Oxime 20 was not observed, suggesting that if the active site was restored by the oxime, it might not be functional. *Support NIH U01 NS083430.*

2645 Monitoring Persistent Neurological Damage in a Rat Model of Acute OP Intoxication Using Micro-CT Imaging

E. A. Gonzalez, A. C. Rindy, M. Guignet, D. A. Bruun, D. J. Rowland, and P. J. Lein. *University of California Davis, Davis, CA.*

Acute intoxication with organophosphate (OPs) pesticides and chemical weapons can trigger seizures that rapidly transition to *status epilepticus*, which is associated with long-term neuropathology and cognitive dysfunction. Medical countermeasures for OP-induced seizures can prevent lethality and attenuate seizures but do not sufficiently protect against long-term neurological consequences. Therefore, there is a need for non-invasive tools to longitudinally monitor the neurological health of OP-exposed individuals. The goal of this study was to evaluate the utility of *in vivo* micro-computed tomography (CT) imaging for monitoring brain injury in a rat model of acute intoxication with the OP threat agent diisopropylfluorophosphate (DFP). Adult male Sprague-Dawley rats were administered DFP (4 mg/kg, s.c.) followed 1 min later by treatment with atropine sulfate (2 mg/kg, i.m.) and pralidoxime (25 mg/kg, i.m.) to increase survival. At 40 min post-DFP, animals were injected with either diazepam (DZP) or midazolam (MDZ) to attenuate seizure activity. Micro-CT scans were obtained from all subjects at 3 and 6 mo post-intoxication to evaluate mineralization in the brain, a pathology associated with persistent neurodegeneration and cognitive deficits. A subset of DFP animals displayed resistance to seizure activity. This population, referred to as DFP low responders, was not treated with benzodiazepines, but were scanned using micro-CT at 2 mo post-intoxication. In animals that experienced DFP-induced seizures, micro-CT detected significant mineralization in the hippocampus and thalamus of animals at both time points, and indicated that neither DZP nor MDZ protected against this neuropathologic outcome. Interestingly, DFP low responders also presented with significant levels of mineralization in the brain. These findings highlight the feasibility of using micro-CT imaging to detect persistent neurological damage following acute OP intoxication, and suggest that current medical countermeasures do not protect against mineralization in the brain. They also suggest that mineralization in the brain caused by acute OP intoxication is mediated by seizure-independent mechanisms. *This work was supported by the NIH CounterACT program (U54 NS079202) and a NINDS National Research Service Award Fellowship to EAG (F31 NS110522).*

2646 The Role of Nicotinic Receptors in Seizure Activity and Death Triggered by Acute Organophosphate Intoxication in a Mouse Model

J. J. Calsbeek, E. A. González, B. Pressly, M. A. Guignet, D. A. Bruun, I. N. Pessah, and P. J. Lein. *University of California Davis, Davis, CA.*

Organophosphate (OP) nerve agents and pesticides can cause *status epilepticus* (SE) and death by inhibiting acetylcholinesterase (AChE). Excessive accumulation of acetylcholine (ACh) at central and peripheral synapses induces a cholinergic crisis as a consequence of overstimulation of nicotinic and muscarinic receptors. The current standard of care for OP intoxication includes atropine to block muscarinic receptors, pralidoxime to regenerate active AChE, and benzodiazepine to terminate seizures. While this medical countermeasure can prevent mortality, survivors often exhibit persistent neuropathology and electrographic abnormalities. It has been posited that the limited efficacy in preventing long-term effects is due to the fact that the current therapeutic approaches do not target nicotinic receptors. To test this hypothesis, we assessed the efficacy of the non-selective nicotinic receptor antagonist, mecamylamine (MEC), as a potential anticonvulsant in a mouse model of acute intoxication with diisopropylfluorophosphate (DFP). Adult male C56BL6/J mice were pre-treated with MEC (0.5-9.5 mg/kg, s.c.) or an equal volume (80-100 μl) of saline vehicle (VEH, s.c.) 10 min prior to administration of DFP (12.7 mg/kg, s.c.). Their seizure behavior was monitored for 4 h and seizure severity was scored using a modified Racine scale. MEC pretreatment dose-dependently reduced or prevented DFP-induced seizure behavior relative to vehicle controls. Post-exposure administration of MEC (9.5 mg/kg, s.c.) 10 min after DFP injection also significantly reduced DFP-induced seizure behavior within minutes. These findings suggest a necessary role for nicotinic receptors in DFP-induced seizure activity. These observations identify nicotinic receptors as potential therapeutic targets, and support further investigation to identify which receptor subtypes are important in this phenomenon. *This work was supported by the NINDS CounterACT Program (grant # U54 NS079202), the Department of Veterans Affairs VR&E Program, and a predoctoral fellowship from the UC Davis School of Veterinary Medicine 2019-2020 Graduate Student Support Program (GSSP).*

2647 DFP Influences Spontaneous EPSP in Hippocampus ca1, Revealing an Essential Role of nAChRs in DFP-Triggered Neural Network Hyperexcitability

W. W. Feng, and I. N. Pessah. *University of California Davis, Davis, CA.*

Our previous report indicated that cortical neuronal/glial co-cultures isolated from embryonic or PND 0 rats or mice express AChE and manifest strong muscarinic cholinergic neurotransmission (mAChR) that negatively modulate glutamatergic-mediated excitability. However, these cultures lack detectable changes in patterns of synchronous spontaneous Ca^{2+} oscillations and electrical spike activity in the presence of DFP or other surrogate nerve agents at concentrations well beyond those that fully inhibit AChE. We thus developed an *ex vivo* adult rat hippocampal slice preparation to measure patterns of spontaneous electrical spikes (SES) activity and assess their responses to DFP. Our results demonstrate that nAChR neurotransmission is essential for DFP-triggered hyper-excitability secondary to acute inhibition of AChE localized within cholinergic synapses. Our goal is to Identify ionotropic nAChR antagonists and partial agonists with differing spectra of subtype selectivity that show efficacy towards normalizing acute DFP-triggered cellular and network hyper-excitability, and ameliorate subsequent biomarkers of neuropathology shown to with following DFP-triggered status epilepticus. Perfusion of slices with DFP (3μM) in aCSF increased both the frequency and amplitude of SES after a short delay and these changes were resistant to washout up to 4 hours with aCSF alone. Perfusion of the dihydro-β-erythroidine hydrobromide (DHβE, 15μM), a selective α4-nAChR antagonist or methyllycaconitine (MLA, 5μM), a selective α7-nAChR antagonist) largely restored both SES frequency and amplitude of DFP-modified slices to those measured before introduction of DFP, and the effects were readily reversible. These results suggest functional nAChRs synapses are necessary and sufficient to acutely trigger seizure-like electrical hyperactivity within mature brain circuits secondary to AChE irreversible inhibition. Importantly, subunit selective nAChR antagonist of either α4-nAChR or α 7-nAChR may represent a new druggable target for combination therapy with standard of care GABA receptor antagonist midazolam. Moreover, the multi-well electrode-array slice preparation represents a valuable tool that permits detailed quantitative analysis of electrical spike patterns for threat agents with differing mechanisms of action as well *ex vivo* assessment of brain slices isolated from nerve agent exposed animals. *1U54 NS079202-06.*

2648 Positron Emission Tomography (PET) Analysis of Synaptic Density in the Rat Brain Acutely Intoxicated with Diisopropylfluorophosphate (DFP)

J. W. Loxterkamp, B. A. Hobson, C. R. Klocke, and P. J. Lein. *University of California Davis, Davis, CA.*

Acute intoxication with organophosphate (OP) cholinesterase inhibitors can trigger life-threatening *status epilepticus* (SE). Current medical countermeasures can prevent death from OP-induced SE, but do not effectively protect against chronic morbidity. The pathogenic mechanisms of these chronic effects remain unknown but are thought to involve altered synaptic connectivity. Testing this hypothesis involves quantifying synaptic density over time. Histologic techniques are considered the gold standard for quantifying synaptic density in brain sections; however, these techniques are time-consuming and do not allow for longitudinal assessments of synaptic density over time in the same animal. *In vivo* PET imaging overcomes such limitations. The molecule [^{18}F]UCB-H specifically binds synaptic vesicle glycoprotein 2A (SV2A), a

transmembrane protein expressed in synaptic vesicles, and has recently been developed as a PET probe for imaging synapses. The goal of this study was to determine whether synaptic density measured by PET correlates with *ex vivo* Golgi staining and immunohistochemical (IHC) synaptic metrics. Specifically, we assessed changes in presynaptic SV2A and postsynaptic drebrin and gephyrin. Adult male Sprague-Dawley rats (200-250 g) were administered a single dose of DFP (4 mg/kg s.c.) or vehicle (saline) followed by atropine sulfate (2 mg/kg i.m.) and 2-pralidoxime (25 mg/kg i.m.) 1 min later. Animals underwent *in vivo* PET and MRI (for anatomic registration) imaging at 10 and 28 days post-intoxication with a subset of animals euthanized after each time point to collect brain tissue. Hemisected brains were processed for Golgi staining and IHC. Our results indicate a significant decrease in [^{18}F]UCB-H uptake in the hippocampus following acute DFP intoxication, which appears dependent on the severity of DFP-induced seizures. Initial histological assessments indicate similar outcomes. Collectively, these observations demonstrate that acute OP intoxication causes a loss of SV2A binding sites consistent with an overall reduction in synapse density within the hippocampus and further suggest SV2A PET as a viable approach for assessing synaptic density in preclinical models. *Funding provided by NIH CounterACT (U54 NS079202).*

2649 Delayed Treatment with Midazolam, Allopregnanolone, and Perampanel Is Superior to Midazolam Alone in Reducing Spontaneous Recurrent Seizures and Neuroinflammation but Does Not Improve Long-Term Behavioral Deficits in the Rat Model of Acute DFP Intoxication

D. A. Bruun, A. Valenzuela, M. Guignet, Y. Tsai, E. González, J. Calsbeek, J. Vu, D. Tancredi, D. Harvey, A. Dhir, M. Rogawski, and P. Lein. *University of California Davis, Davis, CA.*

Organophosphate (OP) nerve agents are potent neurotoxicants. OPs can trigger seizures that rapidly progress to *status epilepticus* (SE). If not terminated within minutes, OP-induced SE leads to extensive neuropathology and neurological deficits. We have previously shown in a rat model of acute intoxication with the OP diisopropylfluorophosphate (DFP), that treatment with the standard-of-care anti-seizure drug midazolam in combination with allopregnanolone (a neurosteroid that acts as a positive allosteric modulator of the $GABA_A$ receptor) and perampanel (a selective non-competitive AMPA receptor antagonist) more effectively terminated acute electrographic seizures than midazolam alone. To determine whether improved seizure control mitigated chronic morbidity, adult male Sprague Dawley rats were dosed with DFP (4 mg/kg sc) immediately followed by atropine sulfate (2 mg/kg im) and 2-PAM (25 mg/kg im). At 40 min post-DFP, rats received midazolam (1.8 mg/kg im), allopregnanolone (6 mg/kg im) and perampanel (2 mg/kg im). Neuropathology was assessed by immunohistochemistry (IHC) at 1, 3, 7 and 28 d post-exposure; behavioral testing was performed at 1 and 2 mo post-exposure. The combined treatment was superior to midazolam alone in reducing spontaneous recurrent seizures (SRS) and neuroinflammation (GFAP and IBA-1 IHC). In contrast, the combined treatment was no better than midazolam in protecting against neurodegeneration (FluoroJade C staining) or in mitigating reactivity (Irwin reactivity test) or cognitive deficits (novel object recognition and contextual fear conditioning). In summary, the combined treatment was effective in improving some but not all long-term outcomes, and suggests that neuroinflammatory responses may contribute to OP-induced SRS, but not cognitive deficits. *Supported by NIH CounterACT Program (NS079202).*

2650 Pharmacological Inhibition of mTOR Activation by Rapamycin Attenuates Neuroinflammation and Spontaneous Recurrent Seizures in a Rat Model of Acute Organophosphate (OP) Intoxication

P. Andrew, M. Guignet, D. Bruun, and P. Lein. *University of California Davis, Davis, CA.*

Acute intoxication with OP cholinesterase inhibitors can cause seizures that rapidly progress to status epilepticus. If not treated within minutes of onset, this acute response can result in chronic neurological impairment, including spontaneous recurrent seizures (SRS), via unknown mechanisms. Studies from other labs have implicated enhanced mammalian target of rapamycin (mTOR) activity in neuroinflammatory and epileptogenic processes, suggesting the possibility that mTOR signaling is involved in OP-induced SRS. Therefore, we used a rat model of acute intoxication with the OP, diisopropylfluorophosphate (DFP), to establish the temporal profile of mTOR activation in the brain, and to determine whether pharmacological inhibition of mTORC1 with rapamycin (RAPA) attenuated neuroinflammation and SRS. Adult male Sprague-Dawley rats (200-250g) were administered a single dose of DFP (4 mg/kg sc) followed by atropine sulfate (2 mg/kg im) and 2-pralidoxime (25 mg/kg im) 1 min later. At 40 min post DFP, a subset of animals were administered midazolam (MDZ, 1.8mg/kg im), RAPA (6 mg/kg ip), or both MDZ and RAPA. Animals were euthanized at varying times post-exposure and brains were collected for biochemical analysis of mTOR activation (phosphorylation of ribosomal protein S6) and histological analyses of neuroinflammation (IBA1 and CD68). Western blot analysis revealed upregulated mTOR activity within 1 h post-exposure (HPE) that returned to baseline levels by 3 d post-exposure (DPE) in DFP animals not treated with MDZ/RAPA. Administration of MDZ/RAPA significantly inhibited mTOR activity at 24 HPE and 7 DPE. An additional cohort of animals were administered RAPA (6 mg/kg ip) once daily for 7 d following acute DFP intoxication and MDZ treatment. Daily RAPA treatment suppressed microglial activation at 7 DPE, and initial data from animals instrumented for cortical electroencephalographic (EEG) recording suggest that daily RAPA treatment attenuated SRS development in DFP animals. These studies characterize mTOR activation following OP intoxication and identify mTOR as a potential therapeutic target for mitigating OP-induced SRS. *Funding: NIH CounterACT program (NS079202).*

2651 Phosphylated Oximes Transiently Impair Cellular Respiration and Activate Stress Responsive Signaling

V. Godieva, and J. W. Chambers. *Florida International University, Miami, FL.*

Organophosphorus compounds (OPs) are a diverse class of compounds used as insecticides and chemical weapons. OPs are potent inhibitors of acetylcholinesterase (AChE) that can trigger a cholinergic crisis in humans resulting in muscle contractions, respiratory depression, seizures, and even death. The current countermeasure consists of atropine and oxime, which reactivates AChE by removing an alkylated phosphate group from the active site. Recent studies suggest that potential noncholinergic targets of OPs can lead to the persistence of symptoms and neurological sequelae long after recovery of AChE activity. To better understand pathology following OP exposures, we assessed the collective impact of OP and oxime on the physiology of cells with and without AChE. We subjected human SH-SY5Y neuroblastoma cells ($AChE^+$)cells, mouse C2C12 myoblast cells ($AChE^+$), and human IMR90 lung fibroblasts (AChE-null) to acute OPs exposures followed by AChE reactivation by oximes. $AChE^+$ cells administered increasing concentrations (up to 50μM) of diisopropylfluorophosphate (DFP) followed by stoichiometric equivalent amounts of pralidoxime (2-PAM) resulted in a transient inhibition (20-30%) of respiration. The inhibition of basal respiration was not observed in cells treated with DFP or oxime alone and was absent in AChE-null IMR90 cells. The transient respiratory impairment occurred with other OPs (i.e. paraoxon-methyl) and oxime (i.e. obidoxime) co-treatments. The magnitude of DFP and 2-PAM respiratory inhibition was increased nearly three-fold by adding a membrane permeabilization agent. Because phosphylated oximes are generated during AChE reactivation and are more lipophilic than unmodified oximes, we synthesized a phosphylated oxime (POX) of DFP and 2-PAM and treated AChE+ and AChE-null cells with increasing concentrations of POX. POX induced a transient inhibition of respiration slightly higher (25-35%) than the co-treatment of DFP and 2-PAM in $AChE^+$ cells, and POX treatment triggered a transient inhibition of respiration (18% on average) in AChE-null cells as well. Digitonin gradients and subcellular fractionation revealed that phosphylated forms of 2-PAM and POX species were present within cells, including inside mitochondria. The respiratory impairment coincided with increased MitoSOX-Red fluorescence and increased levels of phospho-JNK and phospho-p38. These results indicate that phoshphylated oximes can enter cells and affect cellular physiology and activate stress responses.

2652 Using a Novel Humanized KIKO Mouse Model to Investigate *In Vivo* Reactivation of Nerve Agent-Inhibited Acetylcholinesterase

C. Acon Chen, T. Loughery, K. Meads, A. Collazo Martinez, J. Moreno, U. Sarwadnya, M. Ballacchino, H. Belski, K. Hundertmark, C. Cadieux, J. McDonough, and T. Shih. *US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD.* Sponsor: J. Dillman

Organophosphorus nerve agents (NA) are potent acetylcholinesterase (AChE) inhibitors that cause numerous toxic effects, including hypersecretion, bronchoconstriction, convulsive seizures, and death. The ability to reactivate NA-inhibited AChE is critical to protect brain function and improve survival. The US military currently employs the oxime reactivator pralidoxime (2-PAM) as a countermeasure for NA poisoning. While 2-PAM restores AChE activity in the periphery, it cannot cross the blood-brain barrier (BBB) to reactivate NA-

inhibited AChE in the CNS. Here we employ a newly established mouse strain (KIKO) that lacks serum carboxylesterase, an endogenous bioscavenger for NA, and expresses human AChE in lieu of mouse AChE. This model can potentially provide results that are more comparable to the human response to NA countermeasures. In this study, we tested oximes obtained from Southwest Research Institute, SWRI-80 or SWRI-144, at 25, 45, or 63 mg/kg, fifteen min following exposure to sarin (GB), cyclosarin (GF), or VX. Brain regions (B) and peripheral tissues (P) were collected 45 min after oxime administration, and AChE activity was determined using an Ellman assay. AChE activity, expressed as a percentage of the saline/saline control activity, was significantly reduced after exposure to GB (4.5% - 6.4% B; 8.3%- 9.9% P), GF (22.8% - 36.9% B; 14.7%- 48.7% P), and VX (6.8% - 20.9% B; 6.3%- 10.9% P). Both SWRI-80 and SWRI-144 significantly reactivated AChE activity in brain and peripheral tissues. In animals exposed to GB, GF, and VX, the highest dose of SWRI-80 restored AChE activity up to 24.8% B and 51.9% P, 92.8% B and 82.2% P, and 60.3% B and 49.9% P, respectively. Similarly, the highest dose of SWRI-144 reactivated AChE activity to 22.9% B and 34.9% P, 50.8% B and 61.8% P, and 44.6% B and 41.2% P in animals intoxicated with GB, GF, and VX, respectively. Overall our results showed that the KIKO mouse model may be used to test AChE reactivation after NA exposure; moreover, both SWRI-80 and SWRI-144 displayed promise as countermeasures for NA, exhibiting the ability to reactivate NA-inhibited AChE in peripheral tissues and the CNS.

2653 A Comparison of *In Vitro* Reactivation Efficacy of Novel Substituted Phenoxyalkyl Pyridinium Oximes for Organophosphate-Inhibited Human and Rat Acetylcholinesterase

D. Stanford, E. Meek, and J. Chambers. *Mississippi State University, Mississippi State, MS.*

In vitro tests were conducted to compare the efficacy of 4 novel oximes and pralidoxime (2-PAM) for human and rat acetylcholinesterase (AChE). The novel oximes were from a platform of substituted phenoxyalkyl pyridinium oximes (US Patent 9,227,937). The organophosphates (OPs) tested were a sarin surrogate nitrophenyl isopropyl methylphosphonate (NIMP) and the active metabolite of the insecticide parathion, paraoxon (PXN). The source of AChE was erythrocyte "ghost" preparations from both species; these are composed of washed cell membranes and can be used as a model of AChE in the nervous system since the AChE is the same gene product in both tissues. The human blood samples were purchased from a commercial vendor. Rat blood samples were collected from Sprague Dawley rats. Preparation involved centrifugal separation of the erythrocytes, lysis of the cells and three washes to remove hemoglobin. The reactivation potential of the approved antidote 2-PAM and novel oximes 1, 15, 20, and 55 against NIMP and PXN was determined. Concentrations of NIMP (3.16 μM) and PXN (10 μM) were selected to yield about 80% AChE inhibition during a 15-minute incubation period, followed by oxime (100 μM) for a 30-minute incubation of reactivation. AChE activity was assessed by a modified Ellman method, 1 mM acetylthiocholine as a substrate and DTNB as the chromogen, with three replications to calculate the inhibition and reactivation compared to solvent controls. For NIMP, novel oxime reactivation was similar or higher for all 5 oximes for the human (82-92%) than the rat (80-89%). Additionally, reactivation was higher for all novel oximes than for 2-PAM with NIMP in rat and human samples. For PXN also, novel oxime reactivation was similar or higher for all 5 oximes for the human (20-64%) than the rat (13-64%). With PXN, reactivation with 2-PAM was higher than with the novel oximes. These data indicate that the novel oximes show reactivation efficacy toward OP-inhibited AChE from humans at least as good or higher than for rats, and that the efficacy results that are currently being obtained in rat experiments should be representative of reactivation efficacy that would occur in humans. *Supported by NIH U01:NS107127.*

2654 Novel Pyridinium Oximes in Combination with 2-PAM or Another Novel Oxime Potentiate Survival following Organophosphate (OP) Exposure in Rats

E. C. Meek, and J. E. Chambers. *Mississippi State University, Mississippi State, MS.*

Acetylcholinesterase (AChE) inhibition by OPs, including nerve agents and some insecticides, results in overstimulation of the nervous system and may lead to death. Traditional therapies for OP exposures include atropine, and an oxime to reactivate inhibited AChE, 2-PAM in the US. Although 2-PAM is an effective AChE reactivator and can increase survival following OP intoxication, it has limited ability to cross the blood-brain barrier (BBB) and reactivate inhibited AChE in the central nervous system. Novel pyridinium oximes (US patent: 9,227,937) synthesized to increase lipophilicity and BBB penetration have been shown to reactivate OP inhibited AChE, attenuate seizure-like behavior, decrease neuropathology and increase survival in rats. The three most efficacious of these oximes were tested in binary mixtures with 2-PAM or one of the other novel oximes in rats administered lethal doses of a sarin surrogate or paraoxon. A sarin surrogate, nitrophenyl isopropyl methylphosphonate, NIMP (0.6 mg/kg) or paraoxon (PXN, 0.8 mg/kg) were administered SC in rats followed by atropine IM (0.65 mg/kg) and binary mixtures of 2-PAM and novel oximes IM (146 μmoles/kg each) at the onset of seizure-like behavior. Novel oximes in combination with 2-PAM yielded 53-87% and 67-93% survival, while combinations of novel oximes yielded 47-87% and 47-60% survival for NIMP and PXN, respectively, in male rats. Similarly in female rats matched for estrus cycle, novel oximes in combination with 2-PAM yielded 67-83% and 73-87% survival for NIMP, and PXN, respectively, while combinations of novel oximes yielded 47-67% survival for NIMP and 47-60% for PXN. Combinations of oximes yielded equivalent or greater survival than a single oxime and attenuated seizure-like behavior. In addition, 24-hour survival was determined for mixtures of 2-PAM and novel oximes in guinea pigs (MRIGlobal) challenged with a LD_{85} of sarin. Guinea pigs were monitored and scored for signs of toxicity. Survival for mixtures of novel oximes and 2-PAM ranged from 63-87%. Toxic signs scores were lower for animals receiving mixtures of oximes. Preliminary safety studies were conducted on the novel oximes in binary mixtures with 2-PAM. Male rats were administered oxime mixtures and observed for 14 days. No signs of overt toxicity were observed. Results suggest these oximes have therapeutic potential for OP exposures. *Support: NIHU01:NS107127.*

2655 Analysis of the Inhibitory Potency, Oxime-Mediated Reactivation Profile, and Binding Characteristics of Metabolites of Phorate

W. L. Acuff, E. C. Meek, S. R. Gwaltney, and J. E. Chambers. *Mississippi State University, Mississippi State, MS.*

Organophosphates (OPs), used as insecticides and nerve agents, pose a severe threat to military personnel and civilians because of their potency as inhibitors of acetylcholinesterase (AChE). The OP insecticide phorate (rat oral LD50 1.4-3.7 mg/kg) is particularly toxic and could be used as a chemical weapon. Unlike similar OPs, phorate exhibits an unusual delay in the appearance of toxic signs in laboratory rats. Phorate has a more complex metabolism than most OPs: activation to phorate-oxon (PHO), then sulfoxidation to PHO-sulfoxide (PHX) and then to PHO-sulfone (PHS), which are increasingly more potent anticholinesterases. Additionally, PHO exhibits a different oxime-mediated reactivation profile than the well-studied OP paraoxon (PXN) which is also a diethyl phosphate. Two hypotheses, that PHO is bioactivated to its more potent metabolites PHX and PHS in the brain, and that PHO utilizes an unorthodox ethoxy leaving group, could help explain these differences between PHO and PXN. Analysis of OP scavenger carboxylesterase inhibition in rat liver by phorate metabolites indicates poor inhibition efficacy by PHX (IC50: 420 nM) as compared to PHO and PHS (IC50: 20 or 32 nM, respectively); this could support the hypothesis of an alternative leaving group. Computational modeling (docking, molecular dynamics, quantum mechanics/molecular mechanics) is used to further determine the plausibility of the alternative leaving group hypothesis. Finally, oximes, like FDA-approved 2-PAM, can reactivate inhibited AChE, but 2-PAM is unable to penetrate the blood-brain barrier (BBB). MSU's novel substituted phenoxyalkyl pyridinium oximes (US patent 9,277,937) have been shown to reactivate inhibited AChE in the brain in animal tests. *In vitro* results showed levels of novel oxime AChE reactivation in rat brain preparations inhibited by PHO, PHX, or PHS that are comparable to those of 2-PAM. Initial *in vivo* results showed increased 24-hr survival compared to 2-PAM when novel oximes were administered following lethal doses of PHO in rats. MSU's novel oximes may lead to better protection from phorate poisoning. *Support: NIH R21 NS108954.*

2656 Immediate-Early Gene Expression May Help Explain Hippocampal Neuroprotection of a Novel Phenoxyalkyl Pyridinium Oxime Antidote to Organophosphates

M. B. Dail, M. L. Brino, and J. E. Chambers. *Mississippi State University, Mississippi State, MS.*

Past assassinations and terrorist attacks demonstrate the need for a more effective antidote against nerve agents and other organophosphates (OP) which cause brain damage through inhibition of acetylcholinesterase (AChE). Our lab has designed novel phenoxyalkyl pyridinium oximes (US patent 9,277,937) that demonstrate the ability to cross the blood-brain barrier and attenuate hippocampal damage in a rat model (Dail *et al.,* 2019 *Tox Sci* 169:465). This project examined whether expression changes in immediate-early genes might help explain this protection. Sprague Dawley-derived

rats were subcutaneously (SC) given either the vehicle (DMSO) or a high sublethal dosage (0.325mg/kg) of the sarin surrogate, nitrophenyl isopropyl methylphosphonate (NIMP). One hour later peak inhibition (about 80%) of brain AChE and signs of hypercholinergic toxicity, including seizure-like behavior, occur. At this point, rats were intramuscularly (IM) given 146 µmoles/kg of 2-PAM or novel Oxime 20 in Multisol (48.5% H_2O, 40% propylene glycol, 10% ethanol, 1.5% benzyl alcohol) or Multisol alone. The hippocampus was dissected, snap frozen in liquid nitrogen, and stored at -80°C. RNA was isolated with the Qiagen RNeasy Plus Mini Kit and examined by duplex qPCR on a Stratagene MX3005 qPCR system using IDT PrimeTime qPCR Assays and Gene Expression Master Mixes. Expression of genes involved in brain repair (*Bdnf*), astrocyte damage (*Gfap*), initiation of neuronal regeneration (*Fos)*, and apoptosis control *(Jdp2, Bcl2l1, Bcl2l11)* were normalized to the housekeeping gene RPLP1, then compared across the treatment groups; NIMP alone, oxime alone, NIMP followed by oxime, and vehicles. *Gfap*, *Jdp2*, and *Bcl2l11* showed no statistically significant changes in any treatment group. *Fos* and *Bdnf* expression were not significantly altered from vehicle levels by NIMP/Oxime 20 but were significantly decreased and increased, respectively, by NIMP/2-PAM treatment. *Bcl2l1* expression was significantly decreased by NIMP. Although this was reversed by both oximes, Oxime 20 stimulated expression more than 2-PAM and returned it to a level closer to that of the vehicle. Since *Bdnf, Fos* and *Bcl2l1* are all involved in aspects of neuronal survival, their Oxime 20 associated expression could partially explain the observed attenuation of NIMP-related hippocampal damage. *Support: NIH U01NS107127.*

PS 2657 Evaluation of Intramuscularly Administered A1 Adenosine (ADO) Receptor Agonists as a Delayed Countermeasure for Organophosphorus Nerve Agent-Induced Status Epilepticus (SE)

T. Loughery[1], K. Meads[1], A. Collazo[1], C. Acon-Chen[1], U. Sarwadnya[1], T. Thomas[1,2], and T. Shih[1]. *[1]US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD; and [2]US Army Research Laboratory, Aberdeen Proving Ground, MD.* Sponsor: J. Dillman

Organophosphorus nerve agents like sarin (GB) and soman (GD) inhibit acetylcholinesterase, resulting in a buildup of acetylcholine that can lead to sustained seizure activity, or status epilepticus (SE). Previous research showed that activation of A1 ADO receptors inhibited neuronal excitability, which could aid in SE termination. (±)5'Chloro-5'-deoxy-ENBA (ENBA) and 2-Chloro-N6-cyclopentyladenosine (CCPA), two A1 ADO receptor agonists, effectively terminated GD-induced SE in rats when administered via intraperitoneal (IP) injection. However, IP injections are not a clinically relevant route of administration, so the current study evaluated the efficacy of these agonists in terminating GB- or GD-induced SE in rats when administered via intramuscular (IM) injection. Telemetrized adult male Sprague Dawley rats were exposed to either GB (150 µg/kg [1.2 x LD_{50}], SC) or GD (90 µg/kg [0.8 x LD_{50}], SC) and were treated with either ENBA or CCPA at 15, 30, or 60 minutes after seizure onset or left untreated. Neuropathology scores were assessed up to 7 days post-exposure (maximum score of 16). With the GB model and 60-minute treatment delay, ENBA-treated rats experienced 78.6% seizure termination (*N=14*) and reduced neuropathology (6.2 ± 1.85, *N=5*). However, CCPA-treated rats experienced 85.7% seizure termination (*N*=14) but only slightly reduced neuropathology (10.9 ± 2.19, *N*=7) compared to untreated animals with no seizure termination (*N=13*) and severe neuropathology (14.25 ± 1.03, *N*=4). With the GD model and 60-minute treatment delay, ENBA-treated rats experienced 92.8% seizure termination (*N*=14), CCPA-treated rats experienced 78.6% seizure termination (*N*=14), and untreated rats experienced 15.4% seizure termination (*N*=13). Neuropathology results for GD-exposed animals are in progress. While ENBA and CCPA both demonstrated a clear ability to terminate SE when administered up to 60 minutes after seizure onset, ENBA provided more neuroprotection, making it a promising candidate as a delayed countermeasure for nerve agent-induced SE. Future studies examining the efficacy of ENBA in conjunction with current medical countermeasures will be conducted.

PS 2658 Glutathione, Cysteine, and N-acetyl-cysteine Conjugates as Biomarkers of Exposure to Sulphur Mustard for a Specific and Noninvasive Analytical Method

M. Roser, and T. Douki. *Université Grenoble Alpes, Grenoble, France.*

Sulphur mustard (SM) is a vesicant chemical warfare causing severe skin, respiratory tract and eye damage at very low concentration with long-term effects. Despite the Prohibition of Chemical Weapons Convention, exposure to SM remains relevant to armed conflicts, terrorist acts or casualties with old shells. Therefore, sensitive non-invasive analytical assays to detect specific biomarkers in urine or blood are necessary for many reasons: in forensic science as a proof of contamination, for diagnostic and for prognostic. In the present work, we developed an ultra-high-pressure liquid chromatography - tandem mass spectrometry approach (UHPLC-MS/MS) to quantify adducts between CEES, the monofunctional derivative of SM. We also performed biological experiments to validate their use as biomarkers. SM, a strong bifunctional electrophile agent, rapidly reacts on biomolecules such as DNA, proteins, and glutathione. The monofunctional 2-chloroethyl ethyl sulphide (CEES) is used for this study because it is not as highly regulated as sulphur mustard. In DNA, the major adduct is the N7-guanine derivative. It rapidly depurinates and reaches the extracellular medium. Glutathione is a major detoxifying tripeptide in cells and is converted into CEES conjugates, which are further metabolized in cysteine-CEES and N-acetylcysteine-CEES conjugates. The latter metabolites are eliminated in biological fluids. Emphasis was placed in the work on the optimization of the sample preparation based on Solid Phase Extraction. All analyses were carried out by UHPLC-MS/MS in the "Multiple Reaction Monitoring" scan mode. The overall recovery yield of the SPE was between 70 and 90 % while the limit of detection of the UHPLC-MS/MS method was in the femtomolar range. The quantitative aspect was improved by use of isotopic dilution. We are able to quantify the biomarker N7-guanine adduct in the DNA of HaCaT cells (keratinocyte cell line) exposed 30 minutes to CEES. The same molecule was also detected in the culture medium 6h after the treatment, together with the glutathione and the cysteine S-conjugates. We could thus validate that the treated cells excreted these specific biomarkers. Similar experiments were performed in "fresh" human skin explants exposed to CEES with quantification of the biomarkers 1h, 6h and 24h after the treatment. In each case, the amounts of adduct and conjugates were dose-dependent. Interesting temporal effects were observed. Altogether, it can be concluded that the chosen biomarkers are biologically relevant. They will now be quantified in urine or blood and the assay will be extended to sulphur mustard.

PS 2659 Gaming All-Hazards Routing Theory (GARTH) Determines Probabilistic Risk of Toxic Industrial Chemicals and Materials in Urban Environments

E. A. Woolard, and L. D. Burgoon. *US Army Engineer Research and Development Center, Vicksburg, MS.*

The evolving landscape of chemical hazards demands that both military and civilian personnel navigate their environment with not only an awareness of current threats, but with the ability to forecast new ones. Toxic Industrial Chemicals (TICs) and Toxic Industrial Materials (TIMs) are of increasing risk to soldiers and civilian first responders, as there is growing concern that these may be exploited by enemy combatants as targets for creating weapons of opportunity. For instance, the common TICs ammonia, sulfur dioxide, and phosgene are stored in large quantities at predictable facilities, making them accessible targets for creating a chemical attack or explosion. These stored compounds could also be disrupted by natural disasters, creating situations requiring equally rapid chemical risk assessment. There is a need for tools that compute probabilistic risks and minimize them with respect to personnel readiness and safety due to these unpredictable hazards. We are developing Gaming All-Hazards Routing Theory (GARTH), a software system which quantitatively assesses environmental chemical threats for optimized navigation in complex environments, including areas of disaster relief, national emergency locations, and warzones. Risk analysis of routes is done by integrating exposure concentrations, routes of exposure, weather patterns, and other aspects of key environmental threats into a single quantification that describes the chance of encountering hazardous conditions in the area. In developing GARTH, we will also expand upon current systems to develop the Toxicological Operational Knowledgebase System (TOKS), which will contain relevant biochemical and toxicological data for better characterizing the biological effects of TICs and TIMs specific to urban environments. With an established route forecasting model and chemical database, our next step is to create an interactive graphics user interface, allowing soldiers and first responders to use GARTH for mission planning and disaster recovery purposes. Users will be able to enter real-time exposure information to update risk assessments and determine probability of risk associated with putative chemical exposures. This initial product will serve as a proof of concept that our algorithm effectively evaluates environmental threats for toxicity risk and makes accurate routing decisions based upon these assessments.

2660 Approaches for Probabilistic Health Risk Estimates during Emergency and Battlefield Situations

L. Burgoon. *US Army Engineer Research and Development Center, Apex, NC.*

Warfighters and first responders find themselves in rapidly deteriorating situations, where they may be exposed to chemical mixtures rarely seen by the general public. Typically these exposures will include toxic industrial chemicals (TICs) and toxic industrial materials (TIMs). In emergency situations, acute exposure is inevitable and toxicity reference values developed for the general public are generally not applicable. In order to perform better mission planning (e.g., ensuring access to the proper medical countermeasures), commanders need to know the probability of exposed warfighters and first responders to develop a critical acute toxicity that impairs mission readiness. To calculate this probabilistic risk, the commander needs to know 1) the probability the possible exposure levels and 2) the probability that any given exposure will yield a hazard. In this presentation I will demonstrate how I use Bayesian statistical approaches and curve-fitting techniques to calculate the probabilistic risk of developing acute toxicity that will impact the ability to complete the mission using data for the gases phosgene and chlorine. Bayesian approaches work by integrating data from multiple studies together into probability distributions. Curve fitting approaches are used to identify mathematical relationships between acute toxicity and exposure parameters such as concentration and time. By combining these approaches, I have calculated the probability of acute toxicity as a function of concentration and time using data from several studies. Using information about actual or predicted chemical exposure levels at the scene of a chemical release, my software estimates the probability that a warfighters or first responders will develop an acute toxicity of interest. *The opinions expressed are those of the author and do not necessarily reflect the views of the US Army.*

2661 Granulocyte Colony-Stimulating Factor (Neupogen; Filgrastim) Accelerates Neutrophil Recovery after Sulfur Mustard Exposure

P. H. Beske[1], J. A. Harvilchuck[1], C. E. Green[2], L. Iyer[2], K. O'Loughlin[2], G. E. Platoff Jr.[3], and D. T. Yeung[3]. *[1]Battelle Memorial Institute, West Jefferson, OH; [2]SRI International, Menlo Park, CA; and [3]NIH/NIAID, Bethesda, MD.*

While exposure to sulfur mustard (SM) is commonly associated with the production of vesicating dermal, ocular, and respiratory injuries, systemic damage to bone marrow, spleen, and lymphatic tissue also occurs. These effects decrease critical immune cell populations leading to higher susceptibility to infection and life-threatening septicemia. There are currently no approved medical countermeasures for SM-induced myelosuppression. An intravenous (IV) SM challenge model was developed in adult Sprague Dawley rats to evaluate the efficacy of immunostimulants such as Neupogen® (filgrastim) to rescue SM-induced leukopenia. The IV SM challenge model was used to isolate the hematologic toxicity from potentially confounding effects arising from dermal, ocular, or respiratory injuries. Characterization of injury progression through 35 days after IV SM exposure found toxic signs concurrent with body weight loss and marked decreases in complete blood cell counts. Early-onset lymphopenia 1-day post-exposure was followed by delayed neutropenia and thrombocytopenia at 5-7 days post-exposure. Flow cytometry of circulating blood revealed changes in B- and T-cell populations, accompanied by loss of mesenchymal and hematopoietic bone marrow stem cells. Prior to efficacy testing, pharmacokinetic/pharmacodynamic (PK/PD) analyses were performed in naïve rats to select the apparent human equivalent dose of Neupogen®, administered as a single dose or daily for 8 days. The $t_{1/2}$ for Neupogen® was ~3 hr, and drug concentrations did not increase with repeat dosing, while PD analyses showed that 8 daily doses resulted in neutrophil counts as much as 32-fold higher than pre-dose values and 2-4 fold higher than a single dose. When administered at ~24 hours after SM-challenge, daily Neupogen® treatment did not prevent delayed-onset neutropenia. However, Neupogen®-treated animals recovered from SM-induced neutropenia and body weight loss faster than vehicle controls. Collectively, this work 1) Corroborates results of a previous pilot large animal study, 2) Validates the utility of a small rodent IV SM screening model, and 3) Provides compelling evidence for the potential clinical utility of Neupogen® as an adjunct treatment following SM exposure. *Disclaimer: The views expressed in this abstract are those of the authors and do not reflect the official policy of Battelle, SRI, NIH, or the US Government.*

2662 Rabbit Conjunctiva as a Target for Ocular Injury Induced by Sulfur Mustard

L. B. Joseph[1], G. Wahler[1], C. R. Croutch[2], J. Kang[1], M. K. Gordon[1], D. E. Heck[3], and J. D. Laskin[1]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; [2]MRIGlobal, Kansas City, MO; and [3]New York Medical College, Valhalla, NY.*

Sulfur mustard (SM; bis(2-chloroethyl) sulfide) is a bifunctional alkylating agent that has been used in chemical warfare. SM can induce ocular irritation, tearing, pain, photosensitivity, and short-term blindness depending on the dose and duration of exposure. In the present studies, we examined the effects of neat SM (0.4 microliters applied to the central cornea) on the conjunctiva of New Zealand white male rabbits. Twenty-eight days post-SM exposure rabbits were euthanized, eyelids removed and prepared for histology and immunohistochemistry. Following SM exposure, H&E staining revealed erosions in the epithelial surface of the conjunctiva, squamous metaplasia, engorged lymph nodes and an inflammatory cell infiltrate in the adjacent dermis, while Gomori's trichrome staining showed compacted dermal collagen. In control tissue, proliferating cell nuclear antigen (PCNA), a marker of cellular proliferation, was expressed in conjunctiva cell nuclei surrounding goblet cells; this was continuous throughout the basal layer. In SM-exposed rabbit eyelids PCNA was upregulated in the nuclei of cells in the hyperplastic conjunctiva, in cells surrounding goblet cells, and in cells in the basal epithelium. SM-induced PCNA expression was also expressed in the nuclei of cells in the dermal inflammatory cell infiltrate, and in nuclei of cells in the conjunctival-dermal associated appendages including lymph nodes and accessory lacrimal gland acini. pH2.AX, a marker of DNA double-strand breaks, was also expressed in PCNA expressing lymph nodes of SM-exposed rabbit eyelids. Keratin 17, a marker of epithelial cell wound repair, was constitutively expressed in basal cells of the conjunctiva in control eyelids while it was upregulated throughout the hyperplastic conjunctiva, in the accessory lacrimal glands, at the transition zone of the junction between the conjunctiva, and in the cornified epithelium. These data indicate that SM injury to the conjunctiva may in part modify epithelial cell function leading to impaired ocular barrier integrity. *Supported by NIH grants AR055073 and ES005022.*

2663 Epithelial Repair in the Rabbit Cornea following Exposure to Sulfur Mustard

M. K. Gordon[1], D. R. Gerecke[1], P. Zhou[1], R. A. Hahn[1], Y. Chang[1], C. R. Croutch[2], J. D. Laskin[1], D. E. Heck[3], and L. B. Joseph[1]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; [2]MRIGlobal, Kansas City, MO; and [3]New York Medical College, Valhalla, NY.*

Sulfur mustard (SM; bis (2-chloroethyl) sulfide) is a potent vesicating agent that has been used in chemical warfare. Exposure of the eyes to SM can cause corneal erosions, epithelial defects, neovascularization, microblistering, and/or dry eye disease, all injuries that can lead to corneal epithelium sloughing and ultimately blindness. In the present studies, the effects of ocular exposure to SM vapor (0.420 mg/L for 8 min) on the corneas of male New Zealand white rabbits was characterized at 1, 3, 7, 14, 21 and 28 days post-exposure. During this time, corneal thickness increased from 400 microns to 900 microns (14d), then decreased to 600 microns (28d). Unexposed control corneas were clear throughout the time course. However, after SM exposure, increased corneal thickness was associated with increased corneal opacity and neovascularization. Histologically, SM exposure induced epithelial-stromal separation at 3 days, by which time 16% of the epithelia had separated from the stroma, and by 28 days detachment had decreased to 9%. Also observed was post-SM epithelial thinning, increased stromal disorganization, and edema. Sporadic keratocytes were also evident in the edematous stroma by day 14. At 28 days post-SM, an inflammatory cell infiltrate was observed in the stroma. In control corneas, keratin 17, a marker of wound repair, was constitutively expressed in the limbus and bulbar conjunctiva. By 14 days post-SM, keratin 17 was expressed in the peripheral corneal epithelium, and by 28 days it was expressed in the central cornea. PCNA, a proliferation marker, was constitutively expressed in the nuclei of control corneal epithelial cells. Three days post-SM, PCNA expression was decreased along the damaged basal layer. Twenty eight days post-SM, PCNA was upregulated in the nuclei of hyperplastic cells of the central cornea and cells of the limbus, indicating wound repair. These data suggest that limbal and /or conjunctival epithelial cells play a role in the repair of SM-induced corneal injury. A better understanding of the mechanisms of SM-induced corneal damage will lead to the development of new therapeutics for the treatment of these debilitating ocular injuries. *Supported by NIH grant AR055073.*

2664 Effect of Supersaturated Oxygen Emulsion on Corneal Injury from Chemical Warfare Agent Chloropicrin Exposure

H. N. Wright[1], K. Pate[2], S. K. Singh[1], D. G. Goswami[3,4], L. N. Braucher[1], J. A. Klein[1], M. Godziela[1], I. A. Ali[1], M. Lake[2], S. Lake[5], and N. Tewari-Singh[1,4]. *[1]Michigan State University, East Lansing, MI; [2]Roccor Inc., Longmont, CO; [3]Texas Tech University Health Sciences Center, El Paso, TX; [4]University of Colorado, Aurora, CO; and [5]OE Co. LLC, Lafayette, LA.*

Ocular exposure to chemical warfare agents can lead to immediate pain, edema of eyelids, inflammation, massive corneal necrosis and blindness. Ocular chemical injuries have frequently been associated with poor prognoses, and the loss of viable corneal epithelial cells, leaving patients with few effective treatment options. It is evident that oxygen plays a vital role in ocular tissue preservation and is critical for tissue preservation and wound repair, especially in case of chemical injuries. This is important in avascular tissues like the cornea and delicate cell populations such as in the limbus. The oxygen therapy derives from a liquid *supersaturated oxygen emulsion* (SSOE) wound-healing technology originally funded by DARPA, and reformulated for ocular use. Oxygen levels in the emulsion and ocular tissues treated with the SSOE were evaluated using a micro-sensor. To test the efficacy of SSOE in treating corneal injury from chemical exposure, we used chloropicrin (CP). CP is a broad-spectrum pesticide that has been used in chemical warfare and causes severe ocular toxicity. Our team has previously shown that application of the SSOE (55%) to human corneal epithelial cells increased cell viability, wound (scratch) healing and reversed CP induced DNA damage, apoptotic cell death, and oxidative stress markers. In the present study, we have developed an *ex vivo* rabbit corneal injury model using CP. Corneas were exposed to CP (500 or 700 nmol) for 2 h, and then washed and cultured in media with or without supersaturated oxygen emulsion (SSOE; 55%) for 24 h or 96 h. Corneal sections were collected and hematoxylin and eosin (H&E) and immunohistochemical (IHC) stained as well as subjected to molecular analyses for apoptotic cell death, inflammatory markers like cytokines. SSOE treatment abrogated the CP-induced cell death and degradation at 24 h post exposure. At 96 h of corneal culture, SSOE treatment enhanced healing of the epithelial layer as well as reversed CP-induced keratocyte cell death. Ongoing molecular analysis will further help decipher the protective effects and mechanism of the SSOE in the *ex vivo* cornea culture injury model. Additional studies to examine the treatment efficacy of SSOE in reversing chemical injury or enhancing wound healing in *in vivo* corneal injury rabbit models are warranted.

2665 *In Vivo* Injury Models, Biomarkers, and Dexamethasone Treatment for Corneal Damage by Vesicating Agents

N. Tewari-Singh[1,2], D. G. Goswami[3,2], R. Kant[2], C. Agarwal[2], R. W. Enzenauer[2], J. Petrash[2], and R. Agarwal[2]. *[1]Michigan State University, East Lansing, MI; [2]University of Colorado Denver, Aurora, CO; and [3]Texas Tech University Health Sciences Center, El Paso, TX.*

Vesicating agents, Sulfur mustard (SM), Nitrogen mustard (NM) and Lewisite (LEW), are potent chemical warfare agents that primarily cause damage to the ocular, skin, and respiratory systems. Of these, ocular tissue is the most sensitive organ. Ocular vesicant exposure causes photophobia, corneal lesions, corneal edema, ulceration, and neovascularization, and may result in a complete loss of vision. The ocular injury upon exposure to SM, the most extensively used vesicant in warfare, has been well documented. NM is a bi-functional analogue of SM and has been shown to cause injuries similar to SM. However, there are very few reports on ocular injury by LEW. The injury symptoms upon LEW exposure appear instantly after exposure compared to SM. Despite extensive research efforts, effective therapies for vesicant-induced ocular injuries, mainly to the most affected corneal tissue, are not available. One of the major impediments to progress in the discovery and validation of ocular therapies against vesicating agents is the lack of established and accessible ocular injury models suitable for the studies on the pathogenesis of eye lesions and associated mechanisms. We have established useful ocular injury clinical, biological and molecular markers in *in vivo* rabbit corneal model to understand the mechanism of injuries from NM, SM, and LEW exposure. Using these markers as relevant end points, we have evaluated the efficacy of glucocortecosteroid dexamethasone formulation (DM) for treating vesicant-induced ocular injuries. DM exerts immunosuppressive and anti-inflammatory effects, and regulates proliferation and apoptosis in corneal epithelial cells. DM treatment resulted in a significant reversal in mustard and arsenical vesicants-induced ocular injury parameters. DM treatment reduced vesicants-induced clinical and biological markers including corneal opacity, corneal neovascularization and corneal thickness. DM treatment also reduced vesicants-induced COX-2, VEGF, and MMP-9 expression. Together, these studies warrant further *in vivo* optimization of DM treatment in mustard and arsenical vesicants-induced corneal injury and to understand the mechanism of efficacy.

2666 Nitrogen Mustard Targets Pathways for Tetrahydrobiopterin Biosynthesis in Human Keratinocytes

S. Yang[1], Y. Jan[1], V. Mishin[2], D. E. Heck[3], D. L. Laskin[2], and J. D. Laskin[1]. *[1]Rutgers School of Public Health, Piscataway, NJ; [2]Rutgers Ernest Mario School of Pharmacy, Piscataway, NJ; and [3]New York Medical College, Valhalla, NY.*

Nitrogen mustard, mechlorethamine (bis(2-chloroethyl)methylamine; HN2), and sulfur mustard are potent vesicants that can modify cellular macromolecules and disrupt metabolism. Important in many metabolic processes including endothelial function, cell growth regulation, neuropathic pain, oxidative stress, immunity and inflammation, is tetrahydrobiopterin (BH4, 6R-L-erythro-5,6,7,8-tetrahydrobiopterin) a key cofactor for nitric-oxide synthases as well as aromatic amino acid hydroxylases important in synthesizing catecholamines, neurotransmitters, and indoleamines. We have discovered that HN2 targets the BH4 biosynthetic pathway in HaCaT cells, a human keratinocyte cell line. BH4 is generated in HaCaT cells from dihydrobiopterin (BH2) via the enzyme NADPH sepiapterin reductase using sepiapterin as a substrate. Once formed from sepiapterin, BH2 is converted to BH4 by various intracellular reductases including dihydrofolic acid reductase. Treatment of HaCaT cells with HN2 for 1-4 hr was found to cause a concentration-dependent inhibition of intracellular biosynthesis of BH2 and BH4 (IC_{50} = 28.5 μM) without affecting cell viability. Inhibition of BH4 biosynthesis was not due to inhibition of the reduction of BH2. Thus, HaCaT cells pretreated with HN2 (10-160 μM) readily synthesized BH4 when incubated with BH2. In cell lysates, incubation with sepiapterin (200 μM) readily generated BH2. Treatment of cell lysates with HN2 caused a concentration-dependent inhibition of BH2 formation (IC_{50} = 31.6 μM) indicating that the vesicant was targeting NADPH sepiapterin reductase. Using human recombinant NADPH sepiapterin reductase, we found that HN2 caused a time- and concentration-dependent inhibition of enzyme activity (IC_{50} = 74.6 μM). Taken together, our data demonstrate that HN2 targets BH2/BH4 biosynthesis in human keratinocytes by targeting NADPH sepiapterin reductase. Overcoming inhibition of this enzyme by HN2 will be important in ameliorating toxicity of HN2 associated with enzymes that are dependent on BH4. *Supported by NIH grants AR055073 and ES005022.*

2667 Optimizing Nitrogen Mustard Administration to Obtain Reproducible Model Vesicant Skin Burns

T. Roldan[1,2], F. Al-Zubaydi[1,2], G. Wahler[2,1], D. Kakkar[1,2], L. Shike[1,2], D. Gao[1,2], N. D. Heindel[2,3], J. D. Laskin[2,1], and P. J. Sinko[1,2]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; [2]Rutgers CounterACT Center of Excellence, Piscataway, NJ; and [3]Lehigh University, Bethlehem, PA.*

Sulfur mustard (SM) is a chemical warfare vesicant that damages exposed skin, eye, and lung tissues requiring the advancement of countermeasures to develop effective therapies. Nitrogen mustard (NM) is a primary vesicating and bifunctional agent widely used as a model vesicant surrogate for SM owing to its comparable skin injuries and similar mechanisms of cytotoxicity. A consistent NM skin injury/burn animal model is required for wound healing efficacy studies. Researchers have established consistent NM burn efficacy models with mixed levels of success. Our currently used model entails shaving the dorsal skin of female CD-1 mice at the lumbar region and delivering a 20 μmol bolus of NM in acetone to the skin using 6mm glass fiber filter discs as a wound template. The NM induced skin inflammation was evaluated by punch biopsies (on day 3) of the treated area and compared to the control groups. Although this model resulted in comparable wound severity, we could not obtain highly reproducible NM skin burns. Therefore, we hypothesized the variation was related to hair shaft height, follicle density, sequence of acetone/NM administration and dose/volume delivered. The first hypothesis tested was that shaving hair resulted in variable contact between the skin surface and filter discs. To improve contact between the skin and filter discs, a chemical depilatory, Nair™, was employed to remove the hair from the epidermal surface. Results indicate that hair removal using the depilatory appreciably reduced burn incidence inconsistencies as compared to the shaving method. After shaving, the hair shaft was present above the entire epidermis and stratum corneum, while the application of the depilatory shortened the hair shaft to beneath the epidermal surface and preserved the follicle. Histological analysis revealed improved contact surface using Nair™ with no significant alterations of skin structure. In addition, it was found that by changing the sequence, volume and concentration of acetone/NM administration, model burns could be reliably and consistently produced yielding a model that allowed for countermeasure efficacy studies in rodents. *Supported by NIH grant #U54AR055073.*

2668 Treatment of Sulfur Mustard Burns: Silvadene, Silver Nylon, or Combined and Evaluation of Silver Ion Distribution in a Minipig Model

F. Reid[1], D. Barillo[2], C. R. Croutch[3], A. Barillo[2], W. Sosna[3], J. Roseman[3], J. Grotheer[3], and E. Peters[3]. *[1]Aggie Reid Tox Consulting, Kansas City, MO; [2]Disaster Response/Critical Care Consultants LLC, Mt. Pleasant, SC; and [3]MRIGlobal, Kansas City, MO.*

Sulfur mustard (SM) is a chemical weapon / terrorist weapon that is easily synthesized, concealed and deployed. SM skin exposure results in burns that are indolent, refractory and recurrent. We tested silver-nylon (Silverlon® BCD) dressings, silver sulfadiazine (SSD), and a combination of both in a porcine model of partial thickness SM injury as a GLP non-inferiority study. A total of 680 deep partial thickness burns were produced in 85 Gottingen minipigs by vapor cap exposure for 90 minutes. Wounds were then debrided with 7 days of saline wet/wet dressings. BCD dressings were applied and changed either daily, or every 4 or 7 days. Control SSD dressings were changed daily. A cohort of 5 animals were treated with SSD placed underneath Silverlon® and changed daily. Dressings were applied for 30 days followed by 7 days of no treatment. Animals were euthanized and wounds assessed for complete healing and re-epithelialization by three subject matter experts. Secondary endpoints included body weight, food intake, normal behavior, and silver levels in wound and blood. There was no morbidity or mortality, or wound infection seen. All animals demonstrated normal behavior, appetite and weight gain. All wounds healed well and there were no appreciable differences in healing between the SSD + Silverlon® group and the others. Blood levels of silver were at or below lower limit of detection (0.03 µg/gram) in virtually all cases. Silver ion was detected in all wounds. Mean silver levels for 1, 4, or 7 day BCD treatment were 3.61, 5.43 and 4.4 µg/g respectively. Mean silver levels for SSD were 3.74 µg/g. Mean wound sliver levels for BCD combined with SSD were 2.84 µg/g (range 1.0 -11.0 µg/g). All treatment methods produced good wound healing, negative blood silver assay and elevated wound silver levels. SSD applied under silver-nylon dressings showed no advantage compared to the other methods and the combination of SSD with BCD had no deleterious effects to the wound or the minipig.

2669 Silver-Nylon Treatment of Sulfur Mustard Burns: Bioengineering Assessment of Successful Wound Closure

C. R. Croutch[1], F. Reid[2], W. Sosna[1], J. Roseman[1], J. Grotheer[1], E. Peters[1], A. Barillo[3], A. Singer[4], and D. Barillo[3]. *[1]MRIGlobal, Kansas City, MO; [2]Aggie Reid Tox Consulting, Kansas City, MO; [3]Disaster Response/Critical Care Consultants LLC, Mt. Pleasant, SC; and [4]ToxPath Solutions, Ponte Vedra, FL.*

Sulfur mustard (SM) is a chemical weapon first used in 1917 Ypres with 11 subsequent regional conflicts to include ISIS use in 2016 Syria. We tested silver-nylon (Silverlon BCD) dressings in a porcine model of partial thickness SM injury in a GLP non-inferiority study. A total of 1320 superficial (SD) or deep partial (DD) thickness burns were produced in 165 Gottingen minipigs by vapor cap exposure. The wounds were then debrided with 7 days of saline wet/wet dressings. BCD dressings were applied and changed either daily, or every 4 or 7 days. Control silver sulfadiazine (SSD) dressings were changed daily. Dressings were applied for 30 days followed by 7 days of no treatment. Animals were euthanized and wounds assessed by histopathology. The non-inferiority margin for histopathology score was 1.5 (10% of maximum possible score) when comparing BCD dressings to SSD. Secondary endpoints included body weight, wound closure, planimetry, Modified Draize Score (MDS), clinical chemistry, hematology, silver ions in selected tissue, colorimetry, and transepidermal water loss (TEWL). BCD, when applied once every 7 days to superficial or deep wounds, was not inferior to the comparator treatment, SSD, as evaluated by histopathology. Blood silver levels were drawn pre-, mid-study, and at necropsy in addition to liver, spleen and kidney samples and were negative with BCD, while with SSD silver ions were detected. Silver ions were detected in virtually all wounds with either treatment. The overall mean net wound color change was not different in the DD or SD with BCD or SSD by the end of the study. Planimetry also showed that while the eschar came off earlier in the SSD group, all wounds were close to 100% re-epithelialization by the end of the study. MDS were also unremarkable in that there was very little edema with the SM wounds; erythema and necrosis developed during the wound/injury phase and during the wet/wet saline debridement with complete resolution by the end of the treatment period and study. There were no significant differences in TEWL when comparing any of the treatment groups. Silverlon BCD dressings provide effective treatment for SM burns. This study and program work resulted in the first FDA clearance of Silverlon BCD bandage for a vapor sulfur mustard indication.

2670 Inhibition of Matrix Metalloproteinase 9 (MMP9) Suppresses Inflammation and Enhances Wound Healing in Mouse Skin Treated with Sulfur Mustard

Y. Chang, S. Muhn, M. Wong, R. A. Hahn, M. K. Gordon, J. D. Laskin, and D. R. Gerecke. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Sulfur mustard (bis(2-chloroethyl) sulfide, SM) is a highly reactive bifunctional alkylating agent that can induce inflammation and blistering in the skin. Effective medical countermeasures against SM-induced cutaneous injury have yet to be established. Overexpression of MMP9 has been implicated in the pathogenesis of SM-induced skin injury. MMP9 is known to degrade basement membrane (BM) and play a role in regulating the migration of macrophages and neutrophils to sites of tissue injury; inhibition of MMP9 reduces inflammatory cell migration and suppresses inflammation in tumors and various wound models. In the present studies, we tested ([N-hydroxy-3-phenyl-2-(4-phenylbenzenesulfonamido) propanamide], BiPS), a specific MMP9 inhibitor, for its ability to suppress inflammation and enhance wound healing following SM exposure using the mouse ear vesicant model. Treatment of male CD1 mouse ear skin with SM (0.08 mg) caused a characteristic cutaneous injury including edema, inflammatory cell infiltration, and the formation of microvesicles at the dermal-epidermal junction (DEJ). Expression of MMP9 mRNA and protein in the skin progressively increased with time 24-168 h following SM exposure. Immunofluorescence studies showed disruption of the BM molecule collagen IV (ColIV), increased expression of COX2, and upregulation of the skin wound marker keratin 6 (K6) in SM induced skin wounds. SM also caused macrophage (F4/80) accumulation in the tissue which persisted up to 168 h post exposure. Pretreatment of ear skin with BiPS reduced SM-induced dermal edema by 60% and maintained the integrity of the DEJ as evidenced by contiguous expression of ColIV. At 168 h post SM exposure, mRNA and protein expression of MMP9 was significantly downregulated in BiPS treated mice. BiPS treatment also suppressed SM-induced inflammation, reducing the number of macrophages accumulating in the tissue; it also suppressed expression of COX2 and downregulated expression of K6. These data indicate that targeting MMP9 by BiPS effectively protected mouse ear skin from SM induced injury. MMP9 inhibitors may be useful as medical countermeasure against SM-induced cutaneous injury. *Supported by NIH grants ES005022 and AR055073.*

2671 Nitrogen Mustard Induces Mitochondria-Mediated Apoptosis Associated with Endoplasmic Reticulum Stress-Regulated MAPK Signaling in Human HaCaT Keratinocytes

Y. Jan[1], Y. An[1], D. E. Heck[2], and J. D. Laskin[1]. *[1]Rutgers, The State University of New Jersey, Piscataway, NJ; and [2]New York Medical College, Valhalla, NY.*

Vesicating agents, including sulfur mustard (SM, bis(2-chloroethyl) sulfide) and nitrogen mustard mechlorethamine (HN2, bis(2-chloroethyl)methylamine), are bifunctional alkylating agents that are highly reactive in the skin causing extensive tissue damage and blistering. Previously, we reported that treatment of HaCaT human keratinocytes with HN2 caused a block in the S phase of the cell cycle and cell cycle dependent DNA damage signaling, processes contributing to cytotoxicity. In the present studies, we evaluated molecular mechanisms underlying HN2 toxicity. Multi-color flow cytometric analysis revealed that HN2 treatment caused a time- and concentration-dependent induction of apoptosis. This was associated with selective activation of caspase 3, caspase 6, caspase 7 and caspase 9, but not caspase 8 or caspase 10, suggesting that HN2 triggers mitochondrial-mediated apoptosis. The is supported by findings that HN2 also caused increases in levels of Bax and p62, and decreases in Bcl-xL. In contrast, HN2 had little or no effect on expression of LC3B and Beclin-1, markers of autophagy. Expression of cleaved caspase 3 and cleaved PARP was found to be homogenous throughout the cell cycle, suggesting that HN2-induced apoptosis is cell cycle independent. HN2 also triggered endoplasmic reticulum (ER) stress and activation of mitogen-activated protein kinase (MAPK) signaling in HaCaT cells, which was identified by enhanced phosphorylation of several key molecules including eukaryotic initiation factor 2α (eIF2α), p38, ERK1/2 and c-Jun N-terminal kinases (JNKs) and up-regulation of ATF4 expression. GSK2606414, an ER stress inhibitor, reduced phosphorylation of these proteins. Conversely, MAPK inhibitors, including SB203580, PD98059 and SP600125, blocked phosphorylation of p38, ERK1/2 and JNKs, but not eIF2α. These data indicate that ER stress regulates MAPK signaling in HN2-treated HaCaT cells. A pan-caspase inhibitor, z-VAD-FMK, was also found to suppress HN2-induced ER stress and MAPK activation and to attenuate cytotoxicity and block apoptosis. Taken together, these data demonstrated that ER stress and MAPK signaling play an important role in HN2-induced apoptosis, contributing to vesicant-induced cytotoxicity and tissue injury. *Support: NIH grants AR055073, NS108956, and ES005022.*

2672 Characterization of Molecular Pattern in Sensory Pain Signaling and Its Neurotransmitters on Mouse Skin following Mustard Exposure

H. Kim[1], L. B. Joseph[2], G. M. Composto[2], M. Huang[2], J. D. Laskin[2], and D. E. Heck[1]. *[1]New York Medical College, Valhalla, NY; and [2]Rutgers, The State University of New Jersey, Piscataway, NJ.*

Sulfur mustard (Sulfur mustard (SM, bis(2-chloroethyl sulfide))) is a warfare chemical which causes inflammation, epidermal blistering, and the characteristic but the unique effect of delayed skin pain. However, the underlying mechanisms mediating sensory pain following mustard exposure remain unclear. We have previously demonstrated activation of cannabinoid signaling following exposure of skin to mustards. Therefore, we hypothesized that downstream signaling following activation of cannabinoid receptors by mustards may modulate the sensory pain following mustard exposure in the skin and mediate the 4-12 hour delay in pain often experienced. In the present study, we investigated reprogramming of dermal sensory pain receptors by chemokines following mustard exposure utilizing mouse skin models. In these studies, we investigated correlations between cell proliferation and cellular responses important in pain, we measured differences in cell proliferation and pro-inflammatory gene expression in keratinocytes following mustard exposure. Mustard exposure mediated a distinct pattern of cell proliferation (PCNA mRNA) that was altered in a time-sensitive manner; in contrast, mRNA levels for Keratinocyte marker protein (Krt10) following mustard exposure, exhibited distinct redox patterns. A four-fold induction NQO1 and NQO2 including GST-1beta expression in in the early phase was observed. Contrarily, the pattern of NOXs (NOX1, NOX4 and NOX5) expression in response to SM was upregulated by two or three-fold in the later phases (at 48hr) compared to early (24 hr) responses. Of note, the tropism of pain receptors in mouse skin was distinctly altered from kappa (OPRK) to delta opioid receptor (OPRD) in a time-dependent manner. In addition, we found that NGF mRNA may play a role in the early phase responses in contrast to other neurotransmitters including BDNF, GDNF, and PDYN. Interestingly, SM triggered transient receptors by up- /down- (to TRPV1 mRNA) or down-/up- (TRPV3 mRNA) in a time-dependent manner. In general, these results indicate that sensitivity to Cannabinoid receptors in mouse skin was diminished in later time periods when compared to early responses. We speculate that those opioid receptors may implement cannabinoid signaling by promoting TRPV1 signaling, a process effected by mustard exposure dependent manner in the dermal lesion.

2673 BRD4-Dependent Chromatin Remodeling by Vesicant Arsenicals in Murine Skin

R. Srivastava, J. Khan, S. Muzaffar, W. Liu, P. Guroji, M. Kashyap, Z. Weng, and M. Athar. *University of Alabama at Birmingham, Birmingham, AL.*

Warfare or industrial chemicals are highly toxic and pose significant threat to the environment and human health if exposed accidently or deliberately. Arsenicals are warfare chemical vesicants, developed for use in World War-I/II. Skin exposure to these chemicals cause painful inflammation, however, the underlying mechanisms remain undefined. In other systems, various inflammatory responses have been associated with the remodeling of nuclear chromatins. In this regard, a role of bromodomain and extra-terminal domain (BET) family proteins has recently been highlighted. Bromodomain 4 (BRD4) mediated epigenetic regulation can be important in acute inflammatory responses. Here, we demonstrate histone lysine hyper-acetylation of H3 and H4 target proteins H3K9ac, H3k18ac and H3k27ac and H4k5ac and H4k8ac respectively following topical exposure to various arsenicals including lewisite, diphenylchlorarsine, diphenylcyanoarsine and diethylchlorarsine *etc.* in murine model. We show that arsenicals augment protein lysine acetylation. This is accompanied by the enhanced expression of BRD4. BRD4 regulated inflammatory genes such as SAA3, LCN2, FPR-1, SLFN-1, IL-6, and IL-19 are significantly-induced in the skin of arsenicals treated animals. Interestingly, these pro-inflammatory gene profile is identical for structurally distinct arsenicals, although the magnitude of induction differed. Furthermore, employing human skin keratinocytes and murine peritoneal macrophage, we demonstrate a cell context-dependent responses of BRD4-regulated inflammation. In this regard, chemokines such as CXCL1 and CXCL2 were predominantly altered in macrophage but not in skin keratinocytes. Our findings suggest that BRD4 is an initial central regulator of arsenicals-mediated skin inflammatory responses and could be a potent druggable target for developing antidotes against these and similar chemicals.

2674 Toxicologic Pathology and Related Mechanism following Cutaneous Exposure of Phosgene Oxime

S. K. Singh[1], D. G. Goswami[2,3], C. R. Croutch[4], R. Agarwal[3], E. L. Noland[1], and N. Tewari-Singh[1]. *[1]Michigan State University, East Lansing, MI; [2]Texas Tech University Health Sciences Center, El Paso, TX; [3]University of Colorado Denver, Aurora, CO; and [4]MRIGlobal, Kansas City, MO.*

Phosgene Oxime (dichloroform oxime; CX), an urticant categorized as a vesicating agent, is a potential chemical warfare and terrorist agent. Its exposure causes rapid toxicity, severe pain with dermal symptoms including erythema (redness), urticaria, blanching, itching hives, necrosis and systemic effects. Due to its fast penetration, severe dermal injury, and instant lethal toxic effects resulting in high mortality, CX could be weaponized with other chemical warfare agents to enhance their deleterious effects. CX is one of the least studied vesicating agents with no effective treatment available. In the present study, we exposed the dorsal skin of SKH-1 hairless mice with neat CX for 0.5 and 1.0 min using two 12 mm vapor caps, and studied different parameters associated with its pathophysiology. Clinical data from our study showed that CX exposure leads to acute skin lesions (edema, erythema, necrosis, urticaria and blanching) as well as decreases in heart and respiratory rate, drop in body temperature, vasculature dilation and blood congestion in multiple organs indicating urticaria and anaphylaxis. Histopathological analysis showed a CX-induced increase of over 2-fold in the mouse skin epidermal thickness at 2 hr and 14 days following 0.5 min and 1.0 min exposures, respectively. Similarly, 1.5-2.0-fold increase in dermal plus hypodermal thickening was observed at all study time points following 0.5 and 1.0 min CX exposures. Dermal fibrosis, necrotic blood vessels, hyperkeratosis, cell death and an increase in inflammatory cells was also observed at day 1 and 14 following 0.5 min CX exposure. Edema, necrosis and dying fat cells were observed within 2 hr in the skin of both the CX exposure groups. CX induced an increase in mast cell degranulation within 30 min of its exposure which peaked to over 90% at 24 hr post exposure and was associated with increased histamine and tryptase levels. To further assess the observed CX-caused pathological changes, skin sections are currently being analyzed for macrophages (F4/80), apoptotic cell death (TUNEL staining) and myeloperoxidase activity (neutrophil infiltration). Molecular markers and cytokines associated with CX-induced mast cell degranulation and inflammatory responses are being evaluated to identify the signaling pathways and key molecular targets in toxicologic pathology from CX cutaneous exposure.

2676 Development of an Organophosphorus Skin Disclosure Kit for Whole Body Surface Sampling

T. Wille[1], J. Mikler[2], A. Wosar[1], M. Baumann[1], H. Thiermann[1], and F. Worek[1]. *[1]Bundeswehr Institute of Pharmacology and Toxicology, Munich, Germany; and [2]Defence Research and Development Canada, Suffield Research Centre, Medicine Hat, AB, Canada.*

The recent use of nerve agents with low vapor pressure and high percutaneous toxicity such as VX and Novichok for assassinations in Malaysia and the UK underline the constant threat by these compounds for both the military and civilian chemical defense. Early disclosure and detection are key issues in the management of chemical casualties. However, a major gap exists for nerve agents with low vapor pressure and high percutaneous toxicity such as VX and Novichok. To overcome this obstacle we recently developed a robust but sensitive, easy to use and generic organophosphate skin disclosure kit. A moistened cotton swab is used for skin sampling and put into a test tube pre-filled with test buffer. Lyophilized erythrocyte membranes as acetylcholinesterase (AChE) source dissolved in the buffer of the test tube allow incubation with the samples from the swab and AChE. Subsequently, lyophilized acetylthiocholine and 5,5'-dithio-bis-2-nitrobenzoic acid (DTNB) are added to facilitate Ellman reaction. Formation of a yellow end product advocates absence of AChE inhibitors including nerve agents, pesticides and carbamates while colorless or pale yellow indicates the presence of an AChE inhibitor. The whole procedure takes only about 5 min and can be performed easily in the field. It showed a lower limit of detection with V-type nerve agents on glass slides in the range of 100 ng and 10 µg with the OP pesticides paraoxon-ethyl and malaoxon being several orders of magnitude lower than estimated incapacitating or lethal doses of the respective compound. However, the skin area to be detected with the field test is very limited whereas already µL-amounts of nerve agent somewhere on the whole body surface of humans might pose a lethal dose. Thus, we developed a scaled up kit comprising a sponge fixed to a customized holding device and a small bucket including chemicals for Ellman reaction. The kit allows whole body sampling and identification of nerve agent-exposed people without or with unclear clinical signs in need of decontamination and medical countermeasures within 2 min. When 800 cm2 porcine belly skin were sampled 5 min after exposure to 2 µl VX with

the whole-body OP disclosure kit, the test results unambiguously advocated presence of an AChE inhibitor. The whole-body OP disclosure kit might be a helpful tool in disaster and military medicine for the identification of victims exposed to a broad range of AChE-inhibiting agents and rationally allocate limited medical countermeasures (e.g. decon, specific antidotes).

PS 2677 Biomarkers of Chlorine Gas Exposure in a Swine Model

S. Achanta[1], C. Albert[2], K. A. Schultz[2], D. Ford[2], R. Patel[3], and S. E. Jordt[1].

Chlorine (Cl_2) gas has been used as a chemical weapon since World War I and most recently in the Syrian conflict. In the United States, transportation and industrial accidents have caused multiple fatalities. Cl_2 exposures cause severe injuries to the respiratory, cardiovascular and nervous systems. However, biomarkers that specifically indicate Cl_2 exposure remain to be identified and validated. Previous studies in rodent models demonstrated that inhaled Cl_2 reacts with plasmalogens to form chlorinated aldehydes and fatty acids, detectable in plasma and lung tissue upon Cl_2 exposure. It is unknown whether these biomarkers are also formed in Cl_2-exposed large animals such as swine, a species used as a translational model for human exposures, and for FDA-enabling studies to identify Cl_2 injury countermeasures. Here, we examined whether chlorinated fatty acids can be detected in Cl_2-exposed pigs. Specific pathogen-free Yorkshire swine were exposed to Cl_2 gas (≤ 240 ppm for 1 h) or filtered air, under anesthesia. Plasma samples were collected at various time points and lung tissues were collected immediately after euthanasia. Total (free+esterified) 2-chlorofatty acids were measured by LC/MS after base hydrolysis, while free 2-chlorofatty acids were not subjected to base hydrolysis. Extractions were performed using plasma fortified with 2-chloro-[d4-7,7,8,8]-palmitic acid (2-[d4]-ClPA) as internal standard using Dole extraction. Lung tissue was pulverized and lipids extracted using the Bligh-Dyer method in the presence of 2-[d4]-ClPA. Half of the lung extract was subjected to LC/MS analyses of free 2-chlorofatty acids, and the other half subjected to alkaline hydrolysis followed by LC/MS for total 2-chlorofatty acids. Exposure to Cl_2 gas resulted in severe hypoxemia, increased airway resistance and peak inspiratory pressure, lung neutrophil infiltration and decreased dynamic lung compliance. Vascular leakage and edema were evident in Cl_2 exposed pigs, and increased levels of pro-inflammatory cytokines. Free- and esterified 2-chloropalmitic acid (2-Cl-PA) and 2-chlorostearic acid (2-Cl-SA) were detected in the lungs and plasma of Cl_2-exposed pigs, but not in clean air-breathing controls. Levels of Cl-lipids in plasma were highest immediately after Cl_2 exposure, and then declined with levels remaining 40- to 60-fold higher at 24h compared to baseline. Free- and esterified 2-Cl-PA and 2-Cl-SA were also significantly increased in the lungs of Cl_2 exposed-pigs. These observations in swine models validate chlorinated fatty acids as biomarkers of Cl_2 exposure across species, potentially serving as forensic biomarkers to validate human exposures.

PS 2678 Investigating the Role of Mast Cell Activation by Nitrogen Mustard in Lung Toxicity

A. A. Cruz-Hernandez[1], R. Mendoza[1], N. Tewari-Singh[2], and J. Brown[1].
[1]University of Colorado Anschutz Medical Campus, Denver, CO; and [2]Michigan State University, East Lansing, MI.

Chemical warfare agents (CWA) were widely used during the Gulf War (1990-1991) and as a result left ~30% of veterans suffering from Gulf War Illness (GWI). The vesicating agent, sulfur mustard (SM) is one of the most noteworthy CWA used during this time and exposure results in similar symptoms as those seen in GWI. Prior research has demonstrated that SM targets the bone marrow and has the potential to influence immune cells. Previous data in mice exposed to SM demonstrated a significant increase in pro-inflammatory cytokines followed by infiltration of neutrophils and macrophages in the lung. In the skin, exposure to SM was reported to induce mast cell degranulation. Therefore, the aim of this study was to determine if nitrogen mustard (NM) (a surrogate for SM) exposure promotes activation of mast cells. Using murine bone marrow derived mast cells (BMMCs) we assessed early, intermediate and late phase activation through degranulation, eicosanoid expression, and pro-inflammatory cytokine production respectively. While NM exposure (1 μM – 50 μM) did not result in mast cell degranulation, we observed an increase in intermediate phase activation demonstrated by a 30-fold increase of cyclooxygenase-2 (COX-2) mRNA production at 10μM at 6h. In addition, IL-6 production by BMMCs post 24h exposure to NM demonstrated a dose dependent increase from 10μM - 50μM, indicative of late phase activation. To further demonstrate a pivotal role for mast cells in NM exposure, we compared the effects of NM exposure on lung pathology between C57BL/6 and B6.Cg-KitW-sh/HNihrJaeBsmJ (mast cell deficient) mice. Significant lung injury was observed in C57BL/6J following NM exposure at 72 hrs as indicated by increase immune cell infiltration as well as red blood cell accumulation in the alveolar sacs. In contrast, significantly less injury was observed in mast cell deficient mice. Similarly, increases in total protein and IL-6 was observed in C57BL/6 mice but not mast cell deficient mice. These results suggest that mast cells play a prominent role in the injury induced by NM and may contribute to symptoms observed in GWI.

PS 2679 Differential Activation of Alveolar Type II Epithelial Cells and Alveolar Macrophages after Nitrogen Mustard Exposure in Rats

V. Sunil, K. Vayas, E. Abramova, R. Rancourt, R. Malaviya, J. Laskin, and D. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Nitrogen mustard (NM) is a cytotoxic vesicant known to target the lung, causing acute injury which progresses to fibrosis. In previous studies, we demonstrated that alveolar macrophages (AM) are activated following NM exposure and contribute to the pathogenic response. In the present studies, we assessed the effects of NM on alveolar Type II (TII) epithelial cells. Male Wistar rats (150-174 g; 8-10 weeks) were euthanized 3 days after intratracheal administration of NM (0.125 mg/kg) or PBS control. TII cells and AM were collected 3 d later. NM exposure resulted in increases in bronchoalveolar lavage (BAL) cells, protein, IgM, receptor for advanced glycation end products (RAGE), high-mobility group box (HMGB)-1 and surfactant protein (SP)-D; AM and TII cells also increased, indicating damage to the alveolar epithelium and inflammation. This was associated with increased numbers of microparticles in BAL, suggesting activation of inflammatory and cell death pathways. To assess this, we analyzed expression of proteins associated with these pathways in AM and TII cells by western blotting. Expression of inflammatory proteins SP-D, the C-type lectin Dectin-1 and RAGE increased in AM, but not in TII cells after NM exposure. The pro-inflammatory protein, matrix metalloproteinase-9 was also increased in AM, as well as TII cells after NM exposure, while HMGB-1 was decreased. The PI3K/Akt and suppressor of cytokine signaling (SOC)-2 pathways are known to regulate inflammation. NM exposure downregulated expression of PI3K, Akt and SOC-2 in TII cells, with no significant effects in AM. Expression of pro-apoptotic proteins caspase-3 and caspase-9 increased in AM and TII cells, respectively, after NM exposure. In contrast, NM down regulated expression of the pro-apoptotic protein, poly-ADP-ribose polymerase (PARP) in TII cells, with no major effects in AM. Significant increases in the anti-apoptotic protein, Mcl-1 were observed in AM after NM exposure, but decreases in the anti-apoptotic protein, β-catenin was noted in TII cells. These data demonstrate that TII cells, like AM, are highly responsive to NM, and that distinct inflammatory and cell death signaling pathways are activated in these two cell types in rat lung. These findings suggest that TII cells and AM play unique roles in the pathogenesis of pulmonary toxicity caused by mustards.

Sulfur mustard (SM, 2 (bis-chloroethyl) sulfide) is a cytotoxic vesicant used as a chemical warfare agent known to target the lung. Herein, we characterized the progression of SM-induced pulmonary injury in rats. Male Wistar rats were anesthetized, intratracheally intubated, and exposed to 0.4 mg/kg SM by vapor inhalation. Animals were euthanized 3, 7, 16 and 28 d later. SM inhalation resulted in necrosis of proximal bronchiole epithelium, peribronchial edema and increases in inflammatory cells 3 d post exposure. BAL levels of fibrinogen, matrix metalloproteinase (MMP)-9, receptor for advanced glycation end products (RAGE), and surfactant protein (SP)-D were also increased at 3 d, consistent with alveolar epithelial cell injury. This was correlated with increases in BAL cell number, protein content, and levels of high mobility group box (HMGB)-1. SM also induced oxidative and nitrosative stress in the lung, as measured by expression of heme oxygenase (HO)-1 and inducible nitric oxide synthase (iNOS). Lung levels of proliferating cell nuclear antigen (PCNA) and fibrinogen were also upregulated at 3 d post SM, along with tumor necrosis factor (TNF)α, cyclooxygenase (COX)-2, MMP-9, galectin (Gal)-3 and Ym1. These inflammatory changes persisted in the lung at relatively lower levels up to 16 d post SM exposure when epithelial damage and peribronchiolar inflammation were also evident in distal and respiratory bronchioles. At 28 d post SM, BAL cells and protein, as well as MMP-9, RAGE, SP-D and fibrinogen were increased to levels at or above those observed 3 d post SM. In addition, at 28 d post SM, PCNA, MMP-9, iNOS, COX-2, fibrinogen, Gal-3 and Ym1 were also upregulated. This correlated with the appearance of airway protein-

aceous exudate entrapping inflammatory cells, diffuse squamous metaplasia, aberrant bronchial epithelial repair and multifocal alveolar interstitial and peribronchial fibrosis. These data demonstrate that similar pulmonary pathologic events occur in rats and humans following SM exposure and suggest that this rodent model will be useful for mechanistic studies on SM and for the identification of efficacious therapeutics for mitigating acute injury and fibrosis. *Support: NIH U54AR055073, R01ES004738, P30ES005022; EUH 778051; MSHEP 3899/H2020/2018/2.*

2681 Microparticle Detection and Phospatidlyserine Exposure in Airway Surface Liquid in Response to Nitrogen Mustard Inhalation in Rats

R. C. Rancourt, R. Malaviya, J. Cervelli, A. Sowinski, J. D. Laskin, and D. L. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Inhalation of mustard alkylating agents injures the respiratory tract, resulting in airway inflammation and procoagulant effects. Evidence suggests that microparticles (MP) released following exposure to toxicants play a role initiating inflammation and coagulopathy. In these studies we determined if MPs are involved in the adverse effects of nitrogen mustard (NM). Sprague-Dawley rats were exposed by intratracheal instillation to vehicle (PBS) or NM (0.15 mg/kg). Twenty-four hours later, rats were euthanized and MPs were analyzed in bronchoalveolar lavage fluid (BALF). To identify MPs, BALF was fractionated into three distinct populations by serial centrifugation (Fraction 1: 1,200 *g*/10 min; F2: 10,000 *g*/30 min; F3: 108,000 *g*/60 min). Western blot analysis revealed high level mitochondrial aconitase expression in protein extracts recovered from the initial two fractions, whereas the vesicular sorting protein ALIX, an exosomal marker, was detected almost exclusively within the third fraction. Flow cytometric analysis revealed a three-fold increase in MPs (0.15-1.0 µm) in all three fractions following NM exposure. Use of a lactadherin-FITC probe to detect phosphatidylserine+ MPs also demonstrated increased percentages of positive events in initial and intermediate MP fractions from NM-exposed subjects. Despite increases in MPs and phosphatidylserine positivity, no change in the level of ALIX was observed between NM and control groups. Our findings indicate MPs are increased in BALF from rats exposed to NM. The increasing proportion of phosphatidylserine+ events in the absence of any change in ALIX suggests the rise in MPs originates from apoptotic events rather than increased exosome release by airway cells.

2682 Farnesoid X Receptor Regulates Macrophage Activation in Nitrogen Mustard-Induced Lung Injury in a Sex-Dependent Manner

A. Murray, T. Banota, E. Abramova, J. Andres, C. Smith, D. Rizzolo, B. Kong, G. L. Guo, A. J. Gow, J. D. Laskin, and D. L. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Nitrogen mustard (NM) is a cytotoxic vesicant known to cause acute lung injury which progresses to fibrosis. Following NM exposure, there is a sequential accumulation of pro-inflammatory/cytotoxic M1 and anti-inflammatory/wound repair M2 macrophages in the lung, which we have demonstrated contribute to lung toxicity. In these studies, we analyzed mechanisms regulating macrophage phenotypic activation, focusing on the dysregulation of lung lipids which we hypothesize promotes acute lung injury and fibrosis. Farnesoid X receptor (FXR) is a nuclear receptor involved in regulating lipid homeostasis and inflammation; FXR target genes have been shown to enhance anti-inflammatory M2 macrophage activity and metabolic programming. To analyze the role of FXR in macrophage activation, we used $FXR^{-/-}$ mice. Male and female WT and $FXR^{-/-}$ mice were treated with PBS (control) or NM (0.08 mg/kg, i.t.). Bronchoalveolar lavage (BAL) and lung tissue were collected 3, 14 and 28 days later. NM caused progressive histopathologic alterations in the lung including inflammatory cell infiltration, septal damage and epithelial thickening; increases in expression of heme-oxygenase-1 (HO-1), a marker of oxidative stress were also noted, along with elevations in BAL protein and cells, markers of alveolar epithelial injury. These changes were more prominent in $FXR^{-/-}$ mice at all times examined, especially in males. Additionally, in male, but not female $FXR^{-/-}$ mice, there was evidence of foamy macrophages and fibrosis, as assessed histologically and by Gömöri trichrome staining. NM-induced increases in pro- and anti-inflammatory lung macrophages as quantified by flow cytometry, were also more significant in male $FXR^{-/-}$ mice, when compared to female $FXR^{-/-}$ mice. These findings demonstrate that FXR modulates the response of macrophages to NM and is involved in regulating lung injury, oxidative stress and the development of fibrosis. Our observation that male mice lacking FXR are more sensitive to NM than female mice suggests a potential protective role of estrogen signaling in this model of lung injury. *Supported by NIH Grants AR055073, ES004738 and ES005022.*

2683 Evaluation of Multiple Dosing of Nucleic Acid Neutralizing Agent on Survival of Rats Exposed to an Analog of Sulfur Mustard

N. Mariappan, I. Zafar, C. Wei, S. Ahmad, and A. Ahmad. *University of Alabama at Birmingham, Birmingham, AL.*

Sulfur mustard (SM) is one of the major chemical warfare agents. Its acute/chronic exposure causes injury to the respiratory tract, eyes and skin leading to multi-organ damage. Among these, pulmonary toxicity appears to be the major cause of mortality. Our studies in rats exposed to 2-chloroethyl-ethyl sulfide (CEES, aka: half mustard), a SM analog, have implicated nucleic acid release as the underlying cause of CEES-induced activation of inflammatory and coagulation cascades, which lead to lung injury and death. Previously, we have shown that exposure of rats to aerosolized CEES caused around 60% mortality by 12 h. We also demonstrated efficacy of a single dose administration of hexadimethrine bromide (HDMBr), a nucleic acid neutralizing agent, in mitigating CEES-induced injury and survival (100% survival) in rats over a 12 h period after which they started to die. Here, we examine whether re-dosing of HDMBr can prolong survival of rats exposed to aerosolized CEES. Male Sprague Dawley rats were exposed to 10% CEES for 15 minutes via nose-only aerosol inhalation. HDMBr was administered 2 hours post CEES exposure and then every 10 hours thereafter. Re-dosing improved oxygen saturations as assessed by pulse oximetry. Re-dosing also improved arterial blood oxygenation. There was increase in PaO2 and a decrease in the PaCO2 in the HDMBr treated group. In the HDMBr treated group there was also decrease in protein leak in the lung as assessed by total protein and IgM levels in the bronchoalveolar lavage fluid. More importantly, re-dosing with HDMBr improved survival over a 48 h period. There was 78% survival in the HDMBr re-dosed animals compared to untreated group where there were no survivors. In the animals that received a single dose the survival was 20% in 48 h. Overall these results provide evidence for the improved efficacy of HDMBr upon repeat dosing and prolonged protection, highlighting the importance of nucleic acid neutralizing agents for treating CEES/SM induced lung injury.

2684 The Use of Molecular Imaging Methodology to Develop a Feed Forward Model to Assess Lung Function in Mustard-Induced Lung Injury

J. Andres, A. Murray, L. Chao, P. Georgopoulos, J. D. Laskin, A. J. Gow, and D. L. Laskin. *Rutgers, The State University of New Jersey, Piscataway, NJ.*

Nitrogen mustard (NM; Tris[2-chloroethyl] amine) is a cytotoxic vesicant known to cause pulmonary damage which progresses to chronic fibrosis. Using computed tomography (CT) and magnetic resonance imaging (MRI) we can monitor NM-induced alterations in the lungs non-invasively as pathology develops. The goal of this study was to use structural changes identified by MRI and CT scanning to predict functional alterations, so as to conduct *in vivo* toxicological assessment. Male Wistar rats were exposed to PBS (control) or NM (0.125 mg/kg) via i.t. instillation. CT and MRI scans were performed prior to exposure and 3, 7, 14 and 28 d post exposure. To correlate pulmonary structure and function rats imaged at 3 and 28 d post NM exposure were assessed for lung function using a SCIREQ flexiVent. Baseline pulmonary mechanics were collected at a positive end expiratory pressure (PEEP) of 3 cm H_2O. Total lung volume was calculated from MRI (W) as it provides an accurate and artifact free assessment of lung tissue volume. The relative volumes of the lung using CT were used to summarize hyperinflation (I), normal lung, and consolidated lung tissue (B) using voxel density as a marker. CT is capable of differentiating between areas of the lung as air and water which are separated by over 1000 Hounsfield units; allowing voxel density to be used as a direct measure of fluid density within the tissue. Using these elements, we constructed a feed forward model to predict respiratory impedance (Z), a measure of airflow through a system, with the equation: $Z = ((H(\eta\text{-}j))/(\omega\text{^}\alpha))$ where $H = (B/(I+W))$. Calculated H revealed lung alterations following NM exposure (1.38 ± 0.08 n=4 in controls vs 0.99 ± 0.16 n=3) as a result of hyperinflation in NM-treated rats. The predicted Z spectra Z spectra generated using the flexiVent at PEEP 3. A strong correlation was observed between predicted and measured Z spectra at 28 d post NM ($R^2=0.98 \pm 0.01$, n=7). Both the predicted and the measured Z spectra were consistent with prior data showing loss of function at higher frequencies. Data was also analyzed at 3, 7, and 14 d to provide longitudinal analysis of the functional pathological changes over time. End expiratory pressure can be used to further assess lung function. These findings indicate that structural imaging data can be used to predict lung function as a toxicological endpoint following exposure to pulmonary toxicants. *Supported by NIH U54AR055073, R01ES004738, P30ES005022.*

2685 PADI2 Promotes Peribronchial Fibrosis in Phenyl Arsine Oxide-Exposed Mice

R. Surolia, F. Li, M. P. Kashyap, R. Srivastava, A. Agarwal, a. ahmad, M. Athar, and V. Antony. *University of Alabama at Birmingham, Birmingham, AL.*

The class of chemical warfare agents known as vesicants includes among others, arsenicals and mustard agents. Lewisite, the most common arsenical developed as a chemical weapon for use in World War II. Unfortunately, the stockpiles of Lewisite still exist. Lewisite causes deleterious inflammatory effects in the skin, and also manifest systemic damage including acute lung injury. However, survivors from arsenical exposure may develop chronic lung injury. The mechanisms underlying these effects are not known. Here, employing phenyl arsine oxide (PAO), an analog of Lewisite, we provide a novel mechanism that contributes to chronic lung injury following its cutaneous exposure. The mice were exposed topically to PAO and sacrificed 10 weeks later. The histological analysis demonstrated increased inflammation and the presence of peribronchial bronchitis. We observed an increased expression of PADI2 in the alveolar macrophages in PAO exposed mice. Our *in vitro* studies also demonstrate increased expression of PADI2 and ER stress-related proteins CHOP and ATF4 in macrophages treated with PAO. Additionally, these macrophages show increased production of pro-fibrotic mediators PDGF and TGF-b1. We used 'pulmospheres', an *ex vivo* 3D model of the human lung for this study. The incubation PAO activated macrophages with 'pulmospheres' results in increased invasiveness and myofibroblasts differentiation. The pharmacological and genetic inhibition of PADI2 results in decreased ER stress as well as secretion of pro-fibrotic mediators. Overall, these data demonstrate that PADI2 contributes to peribronchial bronchitis in PAO exposed mice. *This work was supported by NIH grant U54ES030246.*

2686 Cutaneous Lewisite Exposure Causes Acute Lung Injury in Mice

S. Manzoor, N. Mariappan, I. Zaffar, C. Wei, S. Ahmad, M. Athar, and A. Ahmad. *University of Alabama at Birmingham, Birmingham, AL.*

Lewisite, an organo-arsenic compound first produced in 1918 is a strong vesicating and lethal warfare agent. Owing to its lipophilic nature, Lewisite can be readily absorbed through skin; thus, cutaneous exposure to Lewisite can make it immediately available to multiple organs via circulation. Previously, cutaneous exposure to Lewisite has been shown to cause skin lesions, multi-organ damage and death. A previous report showed decreased lung function in workers of a Lewisite factory. However, studies to characterize or address effects of cutaneous exposure to Lewisite on lungs are non-existent. To investigate whether cutaneous exposure to Lewisite would be injurious to lungs, we applied Lewisite at different doses (2.5, 5.0 and 7.5 mg/kg) to dorsal skin of age matched Ptch1$^{+/-}$/SKH-1mice. Twenty-four hours later, lung injury was assessed by measuring arterial blood gas parameters, neutrophils, cytokines and HMGB1 in bronchoalveolar lavage fluid (BALF). Moreover, lung tissues were assessed for histological scoring, cytokines and myeloperoxidase staining. A single topical application of each dose of Lewisite significantly increased partial pressure of CO_2 ($PaCO_2$) and decreased pH and partial pressure of O_2 (PaO_2) in arterial blood, implying impaired gas exchange. Histological evaluation and subsequent quantification showed an increase in lung injury score in Lewisite exposed mice. There was also a significant increase in neutrophils and other markers of lung inflammation like HMGB1, CXCL1 and CXCL5 in BALF 24 h post exposure. Similar increases in protein levels of CXCL1, CXCL5 and myeloperoxidases were also observed in the lung tissue of Lewisite exposed animals. These data collectively demonstrated that cutaneous Lewisite exposure causes acute lung injury in mice by increasing proinflammatory molecules and neutrophil infiltration.

2687 Utility of High-Throughput *In Vitro* Genotoxicity Methods for Hazard Identification and Categorization of "Data-Poor" Compounds

S. Bryce[1], J. C. Bemis[1], S. L. Smith-Roe[2], K. L. Witt[2], and S. Dertinger[1]. *[1]Litron Laboratories, Rochester, NY; and [2]NIEHS/NTP, Research Triangle Park, NC.*

The Toxicology Testing in the 21st Century (Tox21) consortium has used ~100 quantitative high throughput screening (qHTS) assays to acquire information on thousands of data poor compounds of environmental concern. Five of the Tox21 assays aimed to detect genotoxic potential of compounds. The MultiFlow DNA Damage assay is a multiplexed, high content, flow cytometry assay that classifies compounds as clastogenic, aneugenic, or non-genotoxic. As an orthogonal approach, we investigated whether MultiFlow could be remodeled as an HTS assay by using one time point (4 h) and a single, high concentration of test article. To evaluate this approach, we tested TK6 cells with a set of 49 reference compounds and generated unsupervised and supervised models for classification of compounds as active or inactive for genotoxicity. Compared to *a priori* calls, the new screen correctly classified 33/33 compounds as active and 13/16 as inactive. In a set of 84 NTP compounds previously evaluated using MultiFlow, we identified 46 compounds with sufficient data from conventional genotoxicity assays to be identified as clearly active or inactive. The new screen correctly identified 31/36 actives and 6/10 inactives. Of the 38 NTP compounds with insufficient genotoxicty data, 28 were active in both the new MultiFlow screen and the five Tox21 DNA damage qHTS assays. Retrospective analysis of standard MultiFlow data revealed that 17 of the 28 compounds were classified as genotoxic (clastogenic or aneugenic). Two additional analytical schemes were then applied to these data. First, benchmark dose was calculated for specific endpoints to enable potency ranking of the individual compounds. Second, the area under the curve was calculated to conduct unsupervised clustering to reveal relationships between the unknown compounds and the training set of well-understood genotoxicants. This comprehensive information collected across multiple assays contributes to more-informed characterization of data poor compounds and enhances decision-making around experimental design for additional testing requirements. The outcome of these experiments is the development of a combined-assay data generation and analytics strategy that can be scaled to much larger compound libraries and efficiently provide opportunities for read across-driven hazard identification and risk assessment.

2688 Effect of Age and Sex on Human Blood *PIG-A* Mutant and Micronucleated Reticulocyte Frequencies

S. L. Avlasevich[1], D. K. Torous[1], M. G. Khattab[2], A. Baig[3], L. J. Saubermann[3], D. P. Lovell[4], V. E. Walker[5], J. T. Macgregor[6], J. C. Bemis[1], and S. D. Dertinger[1]. *[1]Litron Laboratories, Rochester, NY; [2]Baylor College of Medicine, Houston, TX; [3]University of Rochester Medical Center, Rochester, NY; [4]St. George's, University of London, London, United Kingdom; [5]University of Vermont, Burlington, VT; and [6]Toxicology Consulting Services, Bonita Springs, FL.*

We previously described immunomagnetic separation/flow cytometry-based methods for enumerating two human blood biomarkers of DNA damage: micronucleated reticulocytes (MN-RET) and *PIG-A* mutant reticulocytes (mutant RET). Early work indicated that intra-subject variation of these endpoints is low and inter-subject variation is relatively high. We have now analyzed blood samples from 362 volunteers, the majority of which were self-reported healthy adults. Pediatric samples were obtained from several sources: cord blood from healthy full-term deliveries, babies prior to a diagnostic CT scan related to congenital abnormalities, and children being seen at a gastroenterology clinic. We found that mutant RET frequencies were influenced by age, sex, and age x sex interaction. For females, ANOVA showed each of the other 6 age groups exhibited significantly higher mutant RET than the youngest cohort (i.e., < 11 yr). Regression analysis indicated that the data were well described by a quadratic polynomial with an initial rise and a plateau (R^2 = 0.218; $p < 0.0001$). For males, ANOVA showed each of the other 6 age groups exhibited significantly higher mutant RET than the youngest cohort, as well as elevated frequencies for the 51-60 and 65+ yr groups compared to the 11-20 yr group. Regression analyses suggested the data were well described by a cubic polynomial that exhibited an initial rise, a leveling off, and finally an upturn (R^2 = 0.342; $p < 0.0001$). Statistical analyses showed no evidence for an age or sex effect on MN-RET values. These results suggest that while mutant cells accumulate with age, MN-RET do not. Further investigation into the factors that influence "spontaneous" mutant RET and MN-RET frequencies will be important for designing appropriately powered human biomonitoring studies.

2689 Weight of Evidence Assessment of the Genotoxicity of an Extract of Chinese Skullcap—A Traditional Chinese Herbal Medicine

B. Sun[1], A. Allemang[2], C. Mahony[3], and S. Pfuhler[2]. *[1]New Chapter Inc./Procter & Gamble, Brattleboro, VT; [2]Procter & Gamble, Mason, OH; and [3]Procter & Gamble, Egham, United Kingdom.*

Chinese Skullcap (*Scutellaria baicalensis*) root has a long history of use in traditional Chinese medicine. It is widely used in dietary supplements marketed in U.S and one of the commercially available preparations is Chinese Skullcap powdered extract (CSPE). This specific extract contains a high level (~30 %)

of flavonoids, the most abundant of which are Baicalin and Wogonoside. To assess the genotoxic potential of CSPE, OECD guideline-compliant Ames and *in vitro* whole blood human lymphocyte micronucleus (HLM) assays were performed and found that CSPE was negative in the HLM, but weakly positive in the Ames test. As a follow-up to this finding, an OECD guideline-compliant HPRT study found CSPE negative for induction of gene mutation in mouse lymphoma L5178Y cells, suggesting that CSPE is unlikely to cause gene mutation in mammalian cells. It was hypothesized that CSPE flavonoids, like many other well-known botanical flavonoids, might cause genotoxicity through a secondary, threshold-like mode of action (MoA) like oxidative stress. In line with this hypothesis, CSPE tested negative in HLM in whole blood cultures, which can buffer oxidative stress, but increased micronucleus frequency in the human lymphoblastoid cancer TK6 cells. When TK6 cells were also tested in the presence of the antioxidant N-acetyl-cysteine, the effect shifted to higher doses at which intrinsic defense mechanisms were likely overwhelmed, further supporting the oxidative stress hypothesis. Likewise, in the Toxtracker® reporter assay, CSPE strongly activated gene expression markers for oxidative stress at doses lower than those inducing a weak increase in DNA damage markers, adding additional support for this hypothesis. In summary, the weight of evidence of the dataset for CSPE indicates that its weak mutagenicity observed in the Ames test was not reproduced in mammalian cells. Additionally, its *in vitro* clastogenicity observed in the TK6 cells is likely due to secondary effect via oxidative stress, which was further supported by its distinct dose-response profiles in Toxtracker® assays. Therefore, CSPE is unlikely to represent a genotoxic hazard, however, this assessment is specific to the particular preparation investigated.

PS 2690 Trifluoroiodomethane—*In Vivo* Transgenic Rodent Gene Mutation Assay

C. Beevers[1], S. Mukhi[2], M. Singal[2], D. Nuber[2], and M. Boelens[2]. [1]*Exponent, Harrogate, United Kingdom; and* [2]*Honeywell International Inc., Morris Plains, NJ.*

Trifluoroiodomethane (CF_3I: CAS: 2314-97-8) is a non-flammable gas with several industrial uses, e.g., as a fire suppressant and a key component in refrigerants. CF_3I is positive for mutation in the Ames test (OECD TG471) and, at high inhalation exposures (>2%), it induces micronuclei in the bone marrow of exposed rats and mice. Due to its genotoxic profile, the EU classified CF_3I in 1997 as Cat. 2 Mutagen (i.e. substances which cause concern for humans owing to the possibility that they may induce heritable mutations in the germ cells of humans). To evaluate the *in vivo* mutagenicity of CF_3I, a transgenic rodent *in vivo* gene mutation assay (OECD TG488) in Big Blue® TgF344 rats was performed. This test provides a definitive measure of mutations *in vivo*. Male rats were exposed to CF_3I at 0, 0.125, 0.25 and 0.5% (0, 1250, 2500 and 5000 ppm) for 6 hrs/day (nose-only, inhalation), 7 days/week for 28 days. In addition to clinical observations, body weight, food consumption, and body temperature (measured hourly during exposure) were recorded. On Day 31, 3 days after the last exposure, lung (site of first contact), bone marrow (a high turnover tissue and the target for micronucleus induction), and liver (a slow turnover, control tissue) were analysed for *cII* transgene mutant frequency (MF). Inhalation exposure to CF_3I did not produce an increase in MF in either lung, bone marrow or liver. However, reduced body temperatures were observed in animals exposed to 0.25 and 0.5% CF_3I. More marked reductions in body temperature were observed in the preliminary phases of the study conducted at 1, 2 or 4% CF_3I. This is the first reported observation of body temperature effects following CF_3I exposure and provides a potential mechanism for formulation of micronuclei observed previously in rodents. Chemically induced hypothermia is known to induce bone marrow micronuclei via mechanisms that do not involve direct DNA reactivity (Tweats *et al*., 2007. Mut Res 627: 78-91). The data reported here confirm that the mutagenicity of CF_3I observed *in vitro* in the Ames test is not expressed *in vivo* in Big Blue TgF344 rats. Furthermore, the observation that CF_3I causes significant loss of body temperature in Big Blue TgF344 rats suggests the positive micronucleus findings seen in previous studies may have been caused by an indirect, non-genotoxic mechanism (i.e. hypothermia) rather than via direct DNA reactivity. Further work is being conducted to examine this hypothesis in more detail.

PS 2691 Investigation of Genotoxic Potential of Pharmaceutical Agents in the Alternative Chicken Egg Model (CEM)

T. Kobets[1], J. D. Duan[1], K. D. Brunnemann[1], E. Vock[2], U. Deschl[2], and G. M. Williams[1]. [1]*New York Medical College, Valhalla, NY; and* [2]*Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany.*

Genotoxic potential of a set of pharmaceutical agents with different pharmacological effects was assessed in the Chicken Egg Model (CEM) using comet and ^{32}P-nucleotide postlabeling (NPL) assays to detect DNA strand breaks and adducts, respectively. Among investigated compounds were a nonsteroidal anti-inflammatory drug (ibuprofen), antipyretic analgesics (phenacetin and its metabolite acetaminophen), local anesthetics (lidocaine and prilocaine), chemotherapy agents (cyclophosphamide and mitomycin C), antibiotic (ciprofloxacin) and antihypertensive vasodilator (hydralazine). Potential DNA damage was evaluated in the livers of chicken embryo-fetuses, which on days 9 through 11 of incubation received 3 daily injections of test substances at various dose levels and were terminated 3 hours after the last dose on day 11. Ibuprofen, phenacetin, acetaminophen and ciprofloxacin at the tested doses yielded negative results in the model, as expected based on the lack of their genotoxicity in other systems *in vitro* and *in vivo*. However, low solubility of these compounds limited the dose range tested in CEM. In contrast, several tested pharmaceutical agents yielded strongly or weakly positive outcomes in at least in one of the assays. For example, local anesthetics lidocaine and prilocaine produced DNA adducts which were chromatologically similar to those previously detected in rats by NPL technique. Additionally, lidocaine was positive in the comet assay, although the dose that induced DNA strand breaks was fetotoxic. Chemotherapeutic agents, cyclophosphamide and mitomycin C, which act as cross-linkers with established genotoxic potentials, also produced DNA damage in the model. Hydralazine which also previously showed evidence of genotoxic potential, produced DNA strand break, however, it was not dose dependent, and thus, this agent was considered to be equivocal in the CEM. In conclusion, DNA damage produced by several therapeutic agents requires additional investigation *in vivo* due to potential genotoxic properties.

PS 2692 Establishment of a Mutation Assay Using Whole Genome Sequencing of *Salmonella typhimurium* Cells

T. Chen[1], H. Du[2], B. Pan[1], A. Alund[1], J. Yan[1], Y. Chen[1], T. Robison[3], and R. Heflich[1]. [1]*US FDA/NCTR, Jefferson, AR;* [2]*University of California Riverside, Riverside, CA; and* [3]*US FDA/CDER, Silver Spring, MD.*

Although next generation sequencing (NGS) provides a promising tool for mutagenicity studies on the detection and quantification of somatic mutations in the genomes of multiple cells, the technology is currently limited by the inability of NGS to distinguish somatic mutations from sequencing errors. Several approaches to sequence the whole genome of cells from single clones have been developed to address this problem. In this study, we evaluated the mutagenicity of several agents in *Salmonella* typhimurium TA100 cells using whole genome sequencing of single clones. *S. typhimurium* TA100, a commonly used Ames test strain, was treated with mutagens via two methods, continuous exposure in solid agar and short-term exposure in a liquid medium. Genomic DNA isolated from cells expanded from single clones in different treatment groups was sequenced and the data were analyzed using an established in-house bioinformatics pipeline to identify mutation frequency and mutation types. Our results showed that the mutation frequency was increased by the mutagens in a dose dependent manner. The major type of spontaneous mutations were G:C>A:T transitions, whereas the predominant types of mutagen-induc*ed mutations* reflected the "signature" mutations known for these mutagens. Moreover, the liquid medium exposure procedure increased the sensitivity for the test and minimized the sequencing coverage required for reliable mutation determination compared with the continuous exposure in solid agar. Taken together, our results suggest that the approach of using single-clone sequencing of the bacterial genome can be a practical, reliable, and cost-effective test method for detecting genome-wide somatic mutations.

PS 2693 Probiotic *Escherichia coli* Strain Nissle 1917—Preclinical Evaluation of Genotoxicity

S. Stiller[1], C. Freitag[2], P. Allingham[1], K. Weber[3], S. P. Müller[4], and M. Schimiczek[5]. [1]*BSL Bioservice Scientific Laboratories GmbH, Planegg, Germany;* [2]*Eurofins BioPharma Product Testing Munich GmbH, Planegg, Germany;* [3]*Anapath Services GmbH, Liestal, Switzerland;* [4]*MPC Müller Pharma Consult, Mannheim, Germany; and* [5]*Pharma Zentrale GmbH, Herdecke, Germany.* Sponsor: S. Müller, Safety Pharmacology Society

Escherichia coli strain Nissle 1917 (EcN) has been used as probiotic agent for more than a century. Among others, its probiotic effects were reported on diarrhea and inflammatory bowel diseases, with an efficacy similar to 5-aminosalicylic acid for the maintenance of remission in ulcerative colitis. EcN is well tolerated; however, *in vitro* DNA double-strand breaks were published suggesting genotoxic activity of EcN, related to colibactin. In order to evaluate the genotoxicity of EcN upon therapeutic treatment *in vivo* we initially estimated the MTD in male rats at 10^{11} CFU EcN/animal. This exceeds the daily maximum dose applied in human by a factor of 6×10^4. A study with oral administrations for 2 days was performed in 3 dose groups (10^{11}; 10^{10} and

10^9CFU EcN/animal). No clinical findings were observed. The genotoxicity was assessed by Alkaline Comet Assay. Cells from the small intestine, the upper and lower colon were isolated, embedded in agarose, lysed and DNA migration in electrophoresis was determined and expressed as tail intensity. Very interestingly, obtained tail intensities showed no biologically relevant differences in the dosing groups vs control. Next, the animals were treated daily p.o. with the same dose for 28 days. All animals survived with common back ground clinical findings. A histopathological evaluation of cecum, duodenum, colon, jejunum ileum, Peyer's Patches and rectum was performed. The EcN administration induced slight hyperplastic changes in Peyer's Patches and a minimal increased lymphocytes apoptosis at different doses in some EcN treated animals, which are related to the known immune properties of EcN. Most notably in the Alkaline Comet Assay no biologically relevant increase of tail intensity was found after treatment with the test item in cells from the small intestine as well as the upper and lower colon at any of the dose groups. The exposition with EcN was verified by assessment of feces samples taken from the animals before first application, on day 14 and on day 27 of the study. In summary these results suggest that in pre-clinical situation any EcN related genotoxicity is excluded and available *in vitro* data does not reflected this particular *in vivo* experimental setting.

2694 Risk Management of Topical Drug Development Candidates with *In Vitro* Aneuploidy Findings

M. Schuler, J. Cheung, S. Coffing, J. Cook, M. Engel, M. Engel, K. Hales, B. Hollingshead, M. Homiski, Z. Radi, A. Robertson, E. Rubitski, G. Seitis, L. Tomlinson, J. Travers, and Y. Zhan. *Pfizer Inc., Groton, CT.*

Aneuploidy risk management for oral drug candidates is well established. However, for topically applied compounds the approach is less defined because of a lack of readily available methodology to accurately measure unbound drug concentrations in proliferating skin keratinocytes of the stratum basale layer of the epidermis. In order to address this gap and develop tools to characterize aneugenic risk in skin, we explored several experimental approaches with previously reported aneugens. First, we evaluated the use of the 72-hour Epiderm™ 3D *in vitro* micronucleus assay for the detection and quantitative dose-response analysis for aneugenic agents with known mechanisms like tubulin binding and aurora B kinase inhibition administered both apically and in basal medium conditions. Second, we integrated mechanistic biomarkers that typically change with aneugenic response (phospho-H3, Ki67, polyploidy), which could be detected and quantified by immunohistochemistry in skin sections. Third, we compared the biomarker dose-response with the micronucleus dose-response using a benchmark-dose analysis (BMD) approach. The results from these initial studies show that the Epiderm™ micronucleus assay is sensitive for the detection of compounds that induce aneuploidy by either tubulin binding or the inhibition of aurora B kinase. The data further demonstrate that tubulin binders induce increases in mitotic cells as measured by Ki67 or phospho histone H3 at or below the concentrations where micronucleus induction is observed. By comparison, aurora B inhibitors induce decreases of mitotic cells and increases in polyploid cells at doses that are equivalent to the concentration were micronucleus induction is observed. The results indicate that the Epiderm™ 3D *in vitro* micronucleus assay could be used to risk manage early topical drug candidates. We conclude from the quantitative analysis that Ki67 changes (i.e. increase with tubulin binders and decrease with aurora inhibitors) might be applied as a surrogate marker in skin from dermal toxicity studies to evaluate aneuploidy risk following the topical application of compounds with *in vitro* aneugenic properties. Thus far our data support that histopathology biomarkers may be able to be used as surrogates for aneugenicity risk assessment in nonclinical dermal minipig studies, and future *in vivo* studies could be conducted to build confidence in this approach.

2695 Drug-Induced Replication Stress Drives Genome Instability in Mammalian Genomes

S. Minocherhomji[1], Y. Liu[2], Y. He[2], and M. Fielden[1,3]. *[1]Amgen Inc., Thousand Oaks, CA; [2]Amgen Inc., South San Francisco, CA; and [3]Expansion Therapeutics, San Diego, CA.*

Genome instability is a hallmark of most human cancers and is exacerbated following cellular exposure to drugs/xenobiotics that promote replication stress and low-fidelity DNA repair. However, the effects drugs/xenobiotics have in promoting genome instability in normal cells remains unexplored. Here, we studied the genomic consequences of drug-induced mutagenic DNA damage response (DDR) following treatment of Sprague Dawley rats with 10 mg/kg of cyclophosphamide for two, three or fourteen days followed by PCR-free whole genome sequencing (WGS) at a sequencing depth of approximately 30X of isolated bone marrow and duodenum cells. Drug-induced somatic variants/rearrangements were called using the Sentieon TNScope pipeline that was previously vetted by the Precision FDA truth challenge. Cyclophosphamide-induced chromosomal structural rearrangements including inter-/intra-chromosomal translocations, were evident in all treatment groups irrespective of the study duration. Cyclophosphamide induced somatic structural rearrangements at 99, 90, 82 genes in the bone marrow and 90, 89, 84 genes in the duodenum following 2-days, 3-days or 14-days of treatment, respectively. Inter- and intra-chromosomal translocations were evident in treated bone marrow and duodenum samples and impacted an average of 36 genes in each sample. Comparatively, somatic structural rearrangements were largely absent in all vehicle treated controls. Pathway level analyses revealed a subset of cancer-associated genes, including some tumor suppressors genes, to be mutated more frequently than expected by chance alone. In summary, assessing genomic endpoints has the potential to identify drug-induced genome instability (DiGI) in mammalian genomes, which is not adequately addressed by current testing standards.

2696 Unraveling the Role of UVA Exposure and Melanin in Melanomagenesis

M. Weng. *NYU School of Medicine, New York, NY.*

Cutaneous malignant melanoma (CMM) occurs mainly in sunlight-exposed skin. More than 70% of CMM cases have mutations in the oncogenic B-RAF gene, codon 600, all of which, intriguingly, lack the UV-induced pyrimidine-dimer signature. This study raises the possibility that DNA damage other than dipyrimidine photoproducts plays a crucial role in melanomogenesis and that B-RAF codon 600 is a preferential target. To test this possibility, we determined UVA-induced oxidative DNA damage (ODD) in melanocytes (MC) versus normal human skin fibroblasts (NHSF), and we mapped the ODD distribution at the nucleotide level in the B-RAF gene. We found that UVA induces higher levels of H_2O_2 and 8-oxo-deoxyguanosine in darkly pigmented African American MC (AAMC) than in lightly pigmented European American MC (EUMC), but induces neither H_2O_2 nor 8-oxo-deoxyguanosine in NHSF. Besides, UVA does not induce dipyrimidine photoproducts in MC or in NHSF in this study. UVA induces mutations, mainly thymine to adenine base substitutions, in MC, but does not induce mutations in NHSF. *In vitro*, UVA induces higher levels of H_2O_2 and 8-oxo-deoxyguanosine in a eumelanin solution than in a pheomelanin solution. Significantly, we found that the frequency of ODD formed at the purines in B-RAF codon 600 is 2-fold higher than at other sequences examined in MC. No such differences were found in H_2O_2-treated NHSF. We conclude that UVA sensitizes melanin to generate H_2O_2, which induces ODD and that the B-RAF codon 600 in MC is a preferential target. These results indicate that UVA plays a major role in initiating melanomagenesis.

2697 SPRTN Knock-Down Elevated the Level of Formaldehyde-Induced DNA-Protein Crosslinks and Impaired the BPDE-DNA Adducts Repair in the K562 Cell Line

Y. Yang, L. Chi, J. Leng, C. Liu, T. Xu, H. Ru, and K. Lu. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

DNA-protein crosslinks (DPCs) are bulky DNA lesions formed with the covalently linked DNA-binding proteins and DNA, which can interrupt DNA replication and cause genome instability. Formaldehyde is a typical crosslinking agent causing DPC formation, but the repair mechanism of formaldehyde-induced DPCs is not well understood. SPRTN was recently proposed to be a key player in DPC repair. Whether SPRTN plays a role in the repair of formaldehyde-induced DPCs is unknown. As bulky lesions, DPCs can disturb the DNA replication, however, whether formaldehyde-induced DPCs affect the repair of other DNA adducts are still unclear. Here, we knocked down the expression of *sprtn* gene in K562 cells and investigated the formaldehyde-induced DPC formation. We first treated wild-type and *sprtn* knock-down cells with [$^{13}CD_2$]-formaldehyde for 2 hours, and quantified the formaldehyde-induced DPCs by ultra-performance liquid chromatography and high-resolution mass spectrometry (UPLC-MS). We found that *sprtn* knock-down cells had a higher level of formaldehyde-induced DPCs, which indicated that *sprtn* gene had an important role in the repair of formaldehyde-induced DPCs. In addition, we investigated whether DPCs affected the repair efficiency of bulky DNA adducts. First, we treated wild-type and *sprtn* knock-down cells with benzo(a)pyrene diol epoxide (BPDE) for 20min, and transferred cells to clean medium for adduct repair. Cells were harvested after 0-hour, 3-hour, 8-hour, and 20-hour repair. We measured the BPDE-DNA adducts by UPLC-MS and we didn't find that the amount of BPDE-DNA adducts had significant difference between wild-type and *sprtn* knock-down cells in each time point. Then, we treated cells [$^{13}CD_2$]-formaldehyde for 2 hours, following with 20 min BPDE treatment. Likewise, cells were transferred to clean medium and harvested after 3-hour, 8-hour, and 20-hour repair. The data indicated that, in presence of formalde-
